Conductivity detection (CD) is particularly promising for detecting small inorganic and organic ions in microfluidic systems. Conductimetry measures the conductance of a solution in a microchannel, and the response is proportional to the concentration of the analyte ions. CD can be classified into contact and contactless modes. Contact CD is carried out by galvanic contact between the measurement electrodes and the solution, while contactless CD is

carried out with external electrodes that are coupled capacitatively to the electrolyte. Comparatively, contact CD is more sensitive. However, the galvanic contact with the solution is a potential source of problems for microchip CE. The generation of bubbles by electrolysis, and electrode fouling may disturb the analysis. Furthermore, special protection of the detector circuit and electronics is required to prevent damage resulting from the high electric field. Contactless CD for microchip CE avoids the problems associated with direct solution contact by insulating the measurement electrodes electrically from the electrolyte.

Potentiometric detection in microfluidic systems is based on a detection electrode bearing sensing membranes, which allow the buildup of a measurable potential, which follows the Nernst equation. Such electrodes are known as ion-selective electrodes. For useful detection in electroseparation methods, the selectivity should extend to a range of ions so that universal potential sensors can be formed.

Key Research Findings

As the most commonly used ECD mode, AD has been employed in conventional CE, microchip CE, and other microfluidic analysis systems. The alignment between the channel outlet and the detection electrode is of high importance because it affects not only the sensitivity but also the separation efficiency. The distance between the channel outlet and the working electrode affects the post-capillary band broadening. Two approaches have been employed in the capillary/working-electrode arrangements for AD. One is to fabricate the working electrode in or just outside the exit of a microchannel. Woolley et al. were the first to report a CE chip with an integrated amperometric detector [3]. They fabricated a band-shaped platinum detection electrode just outside the exit of the separation channel using a photolithographic process. In this flow-by design, the surface of the platinum electrode was parallel to the flow direction. In view of the easy contamination of amperometric detectors, another approach has been developed, where the detection electrode is aligned with the channel outlet with the aid of a self-positioning electrode system. The separation channel and the detector are divided, because such placement of the working electrode results in self-isolation from the high separation potential because of the dramatic drop in potential across the capillary. Such a detector allows fast replacement of passivated electrodes, comparison and use of different electrode materials, and convenient surface modification. Wang et al. described a planar screen-printed carbon line electrode for a microchip CE system [4]. The electrode was mounted permanently, perpendicular to the channel outlet, allowing

easy and fast replacement. Unfortunately, neither design allows 3D adjustment. If the carbon line electrodes are not printed in the middle of the support, or the position of the guiding tube moves after the epoxy has cured, the alignment between the channel outlet and the detection electrode will deteriorate. For end-column AD in microchip CE, it is still highly desirable to develop a simple and convenient device to simplify the microchannel–electrode alignment procedures.

Recently, Chen et al. have fabricated a novel 3D AD setup for microchip CE [5]. This facilitates precise 3D alignment between the channel outlet and the detection electrode without a complicated 3D manipulator. The performance of this unique system was demonstrated by separating five aromatic amines. Details of the microchip CE-AD system are illustrated in Fig. 2. Plexiglas holders (g) were fabricated for housing the separation chip (a) and the detection reservoir (k), allowing their convenient replacement and reproducible positioning, with silicone grease providing sealing. A three-electrode AD system fabricated in the detection reservoir consisted of a platinum wire auxiliary electrode (o), an Ag/AgCl wire reference electrode (p), and a 320 μm-diameter carbon disk detection electrode (m). The detection electrode was placed opposite the channel outlet (t) through a stainless-steel guide

tube (1500 μm I.D. × 800 μm O.D.). Short pipette tips (d–f) were inserted into each of the three holes in the glass chip for solution contact between the channel on the chip and the corresponding reservoir (h–j) on the left chip holder in Fig. 2. Platinum wires (q), inserted into the individual reservoirs (h–k), served as contacts to the high-voltage power supply. The end of the guide tube (l) outside the detection solution reservoirs on chips (k) was sealed by a small silicone rubber holder (n, 3 mm diameter, 2.5 mm thick), with the capillary-based detection electrode (m) inserted inside. The silicone rubber holder could not only prevent the solution in the detection reservoir from leaking out, but could also hold the detection electrode while allowing that electrode to move back and forth to define a desired gap distance from the channel outlet (t). The distance (20 mm) between the two bolts (r) on the right Plexiglas holder in Fig. 2 was wider than the width of the microchip (a, 6 mm), allowing the microchip to move right and left slightly to accomplish good alignment with the detection electrode. A piece of 2.5 mm-thick high-elasticity silicon-rubber sheet (s) was attached to the bottom of the microchip and subsequently sandwiched between a Plexiglas cover plate (u) and the Plexiglas holder (g) with the aid of the bolts (r) and nuts (v), allowing the microchip to be adjusted up and down within a range of approximately 1 mm to align the channel outlet with the detection electrode. With the aid of the 2D adjustable CE microchip (a) and the 1D adjustable disk detection electrode (m), the microchip CE-AD system shown in Fig. 2 facilitates 3D alignment between the channel outlet and the detection electrode without the need for a complicated 3D manipulator. This novel AD device has also been employed in conventional CE [6].

In addition, we have fabricated a novel self-positioning detection electrode system that facilitates the alignment of the working electrode with the capillary outlet [7]. The details of the device are illustrated in Fig. 3. Figure 3a shows an elevation of the novel self-positioning carbon disk detection electrode. A rectangular hole (10 mm × 5 mm) was machined through the center of a Plexiglas block (20 mm × 20 mm × 50 mm). The hole not only allows the diffusion of solution away from the detection point, but also makes polishing the surface of the working electrode more convenient. Two 400 μm-diameter holes were drilled carefully through the block in a line to locate the working electrode and the capillary. A disk-type carbon working electrode was used in this experiment. To fabricate the disk electrode, a piece of carbon rod (300 μm diameter, 9 mm length) with one end linked conductively to a piece of copper magnet wire (100 μm diameter, 10 cm length) and with the sides covered by an insulating coating was inserted into one hole in the block. A poly(methylmethacrylate) solution in chloroform (5%, w/w) was then applied to both ends of the hole to secure and seal the carbon rod in place and isolate the connection between the carbon rod and the copper lead. The carbon rod (ca.1 mm long) protruding from the hole was coated with epoxy. After the epoxy had cured, the sealed end of the carbon rod in the hole was filed to form a disk electrode. Another hole in the block guided the outlet of the capillary to the surface of the carbon disk electrode. The self-positioning working electrode makes it possible to align the detection electrode with the capillary outlet without a 3D micro-manipulator. A rubber chip with a self-sealing bore was glued to the top of the block to immobilize the capillary. In addition, a Plexiglas cell with inner dimensions of 2.2 cm width, 2.4 cm length, and 5 cm height was fabricated to accommodate a platinum ground electrode for CE, a platinum wire auxiliary electrode, a saturated calomel electrode, and the self-positioning working electrode, which were all immersed in the electrolyte solution contained in the cell. Figure 3c shows an elevation of the configuration in the electrochemical cell. It has been demonstrated that our self-positioning detection electrode facilitates the alignment of the working electrode with the capillary outlet without the need for a micromanipulator. The primary advantage of the capillary-electrode holder

is its simple design and construction, which makes the present setup very attractive for the routine analysis of electroactive species by CE with ED. A self-positioning carbon electrode has been successfully coupled with CE to determine bases in real DNA samples. This design has also been employed in AD for microchip CE [8].

In principle, conductivity detection is a universal detection method for most modes of capillary electrophoresis because all ions give a measurable response. It is carried out by applying an AC voltage to a pair of detection electrodes to eliminate faradic reactions. In an early arrangement, a pair of 25 μm Pt wires was inserted into a capillary through laser-drilled holes. In addition, a simpler wall–jet arrangement has been used in a commercial instrument for capillary zone electrophoresis. Conductivity detection is increasingly being used in chip-based CE microsystems. Such a detection scheme monitors differences between the conductivity of analyte zones and the background electrolyte and, hence, can sense all ionic species. Conductivity detection can be accomplished either by direct contact of the run buffer with the sensing electrodes or by a contactless mode in which the electrodes do not contact the solution. The contactless detection mode offers several distinct advantages, such as the elimination of surface fouling and bubble formation, simplified construction and alignment of the detector, and effective isolation from high separation voltages. We have developed a novel, movable contactless conductivity detection system for microchip CE [9]. A schematic diagram of a microchip electrophoretic system with a movable contactless conductivity detector is shown in Fig. 4. The movable detector is based on changing the detector position along the separation channel by *sliding* the sensing electrodes along the length of the microchip (Fig. 4). This mobile detector system consists of aluminum-film sensing electrodes (Fig. 4c, k) mounted on a thin polymer plate that is clipped onto both sides of a polymethylmethacrylate (PMMA) separation chip (Fig. 4e). Movement of the conductivity detector to different locations along the separation channel has been shown to offer several important advantages over fixed-detector formats. These include convenient visualization of the progress of separation, improved optimization of the separation process, a shorter analysis time (higher sample throughput), convenient switching between *total* and *individual* (fingerprint) assay modes in the same channel, and faster detection of late-eluting compounds (in connection with repositioning the detector during the run). We have given [9] a detailed characterization and reported the attractive analytical performance of the new moving CCD microchip detection system in connection with the detection of low-ionic explosives and nerve-agent degradation products.

Compared with separation-based techniques, potentiometry is a difficult technique to use to detect multiple analytes because of the selectivity of the ion-selective electrode. Because of the influence of the separation voltage, it is difficult to measure the response of the electrode potential, which is correlated logarithmically to the concentration of analyte; it has not yet been employed with microchip CE. Potentiometric detection has found application in conventional CE. Kappes and Hauser have fabricated a universal potentiometric sensor for CE by coating wire electrodes with a solid PVC membrane [10]. The sensor was of approximately the same diameter as the outside of the capillary and located at a distance of about 50 μm from the capillary outlet. A reference electrode was located beside the detection electrode. These coated-wire electrodes with PVC membranes have been employed to determine alkali and alkaline earth metals, small inorganic anions, and lipophilic organic ions such

as quaternary amines, aliphatic sulfonates, and carboxylates.

Future Directions for Research

Electrochemical techniques play a key role in conventional CE, microchip CE, and other microfluidic systems. Future directions in these techniques will focus on minimizing the size of the ECD device and integrating the electronic circuit and the detection electrodes on microfluidic chips. With the rapid development of microfluidic chips, it is highly desirable to develop new theoretical models, experimental methods, and new experimental devices for ECD in microfluidic analysis systems.

Definition

ECL is a type of chemiluminescence (CL) in which the light-emitting reaction is triggered by an electrochemical reaction. The electrochemically generated reactants undergo electron transfer from the excited state to generate excited molecules which emit light.

Overview

ECL involves the production of reactive intermediates from stable precursors at the surface of an electrode, which converts electrical energy into radiative energy. These intermediates then react under a variety of conditions to form excited states that emit light. Besides the advantages of CL such as extraordinary sensitivity, a wide dynamic range and inexpensive instrumentation, electrochemical reaction allows the time and position of the light emission to be controlled. The phenomenon of luminescence upon electrolysis has been known for a long time. Reports can be found as far back as 1927 for the light emission of Grignard compounds in anhydrous ether and 1928 for the ECL of luminol. However, this phenomenon was not studied in detail until the 1960s. Over 1000 papers have been published on ECL since the 1960s, ranging from mechanism investigations to analytical applications. Several comprehensive reviews and book chapters covering various aspects of ECL have been published [1–5].

ECL, which can be coupled with various separation techniques such as HPLC and capillary electrophoresis (CE), has been proved to be a powerful tool for analytical applications and investigations with high sensitivity ($< 10^{-11}$ M), high selectivity and wide linear range. Excellent chemical and ECL properties make $Ru(bpy)_3^{2+}$ (bpy = bipyridine) and its derivatives the most important

ECL systems for analytical applications. Interest in ECL immunoassay is rapidly growing. By employing ECL-active species as labels on biological molecules, ECL has found applications in immunoassays, enzymatic biosensors and DNA analysis [1, 4, 5]. Commercial ECL systems are also available for clinical diagnostics, environmental assays and food safety tests (examples can be found at http://www.igen.com/). Recently, ECL has shown great promise in the rapidly developing micro total analysis systems (also called Lab-on-a-Chip or μTAS), with the aim of realizing the whole analytical process of sampling, reaction, separation and detection on a several square centimeter-sized chip [6].

Basic Methodology

ECL Luminophores

ECL luminophores are the compounds that undergo electron transfer reactions to generate excited states which emit light. ECL luminophores involve a large number of compounds which can be generally divided into inorganic systems and organic systems.

Inorganic Systems

Many inorganic compounds and complexes have been observed to be electrochemiluminescent. The mostly investigated metals include Ru, Os, Cr, Cd, Pd, Re, Pt, Mo, Tb, Ir, Eu and Cu, but much attention has been paid to $Ru(bpy)_3^{2+}$ and its derivatives. $Ru(bpy)_3^{2+}$ can undergo ECL both in aqueous solutions and non-aqueous solutions, with or without co-reactants at room temperature, which make $Ru(bpy)_3^{2+}$ the most valuable luminophore for analytical applications. Other advantages of $Ru(bpy)_3^{2+}$ include easily attainable potentials with reversible one-electron transfer reactions and high quantum efficiency.

ECL from $Ru(bpy)_3^{2+}$ in acetonitrile using tetrabutylammonium tetrafluoroborate as the electrolyte is a classic example. ECL is generated by alternate pulsing of a potential on an electrode to form oxidized $Ru(bpy)_3^{3+}$ and reduced $Ru(bpy)_3^{+}$:

$$Ru(bpy)_3^{3+} - e^- \rightarrow Ru(bpy)_3^{3+} \quad (1)$$

$$Ru(bpy)_3^{3+} + e^- \rightarrow Ru(bpy)_3^{+} \quad (2)$$

$$Ru(bpy)_3^{3+} + Ru(bpy)_3^{+} \rightarrow Ru(bpy)_3^{3+} + Ru(bpy)_3^{3+} \quad (3)$$

$$Ru(bpy)_3^{3+} \rightarrow Ru(bpy)_3^{3+} + h\nu(610\,\text{nm}) \quad (4)$$

$Ru(bpy)_3^{2+}$ is the excited-state molecule that emits light (the emission maximum is ∼610 nm). The formation of an excited state as a result of electron transfer involves a kinetic manifestation of the Franck–Condon principle. The reactions are very energetic (typically 2–4 eV) and very fast. Since it is difficult for the molecular structure to absorb such a large amount of released energy in a mechanical form on such a short time scale, there is a significant probability that an excited product will be produced (Eq. (3)), with consequent light emission to return to the ground state (Eq. (4)).

By attaching suitable chemical groups to the bipyridine moieties, $Ru(bpy)_3^{2+}$ can be linked to biological molecules such as antibodies, where it serves as a label for analysis in a manner similar to that of radiative or fluorescent labels. This property results in a wide range of ECL applications in clinical diagnostic assays. It was reported that heterogeneous ECL immunoassays for carcinoembryonic antigen and α-fetoprotein as well as competitive ECL immunoassays for digoxin and thyrotropin could be realized by using $Ru(bpy)_3^{2+}$ NHS ester. Also, $Ru(bpy)_3^{2+}$ ECL was demonstrated to be applicable for the determination of the HIV-1 gag gene by detecting polymerase chain reaction (PCR) products.

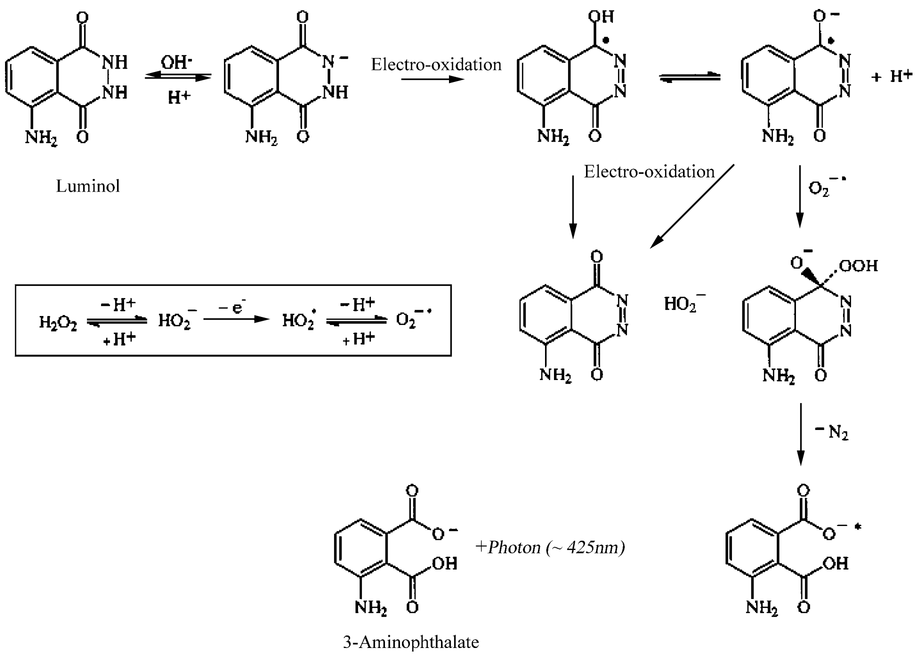
Researches on the surfactant effect of $Ru(bpy)_3^{2+}$ ECL have attracted extensive interest. Soluble $Ru(bpy)_3^{2+}$ in aqueous nonionic surfactant solutions leads to significant and potentially useful changes in the ECL properties. For example, up to 8-fold increases in ECL efficiency were observed in surfactant media upon oxidation of $Ru(bpy)_3^{2+}$ and TPrA (TPrA = tri-*n*-propylamine). The precise mechanism of the surfactant effect is still under study, but it appears that the adsorption of surfactant on the electrode surface should be responsible for these surfactant effects. The dramatic increases in ECL intensity, coupled with work on more efficient ECL labels and co-reactants, may have profound impacts on the sensitivity of ECL for a variety of applications.

The properties of electrode surfaces greatly affect the ECL efficiency. For example, significant increases in TPrA oxidation rate and in $Ru(bpy)_3^{2+}$/TPrA ECL intensity were observed at alkanethiol-modified electrodes, whereas the influence of the thiol layer with a hydrophobic terminal group on both TPrA oxidation and ECL was much less.

Organic Systems

Organic ECL luminophores includes luminol (2,3-aminophthalhydrazide), ABEI (*N*-(4-aminobutyl)-*N*-ethylisoluminol), lucigenin (*N,N′*-dimethyl-9,9-bisacridinium), 9,10-diphenylanthracene (DPA), RUB (rubrene), diimides and various other organic compounds.

Luminol is a classic organic species that continues to generate interest. Light emission from luminol at electrodes

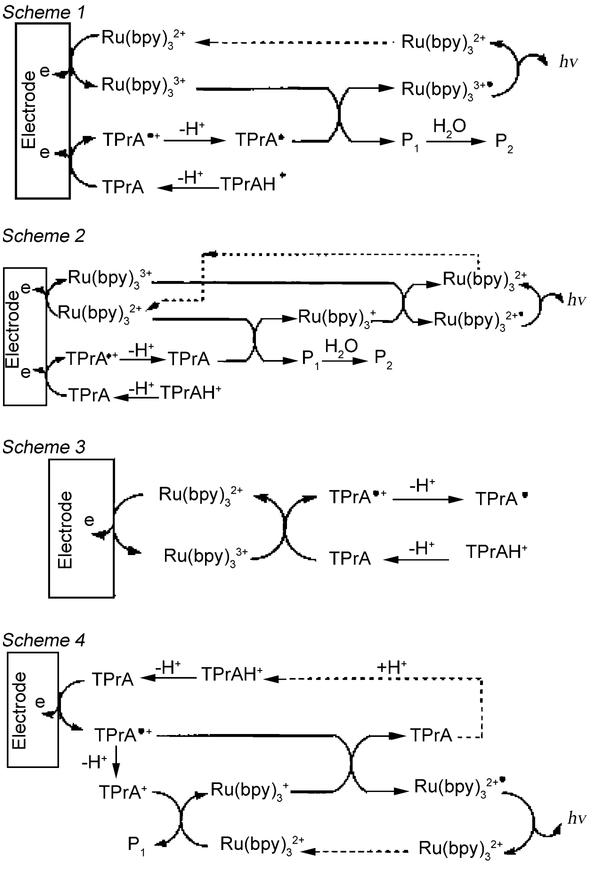


Electro Chemo Luminescence (ECL), Figure 1 Proposed mechanism for ECL reactions of luminol with hydrogen peroxide

was first reported in 1929 upon application of +2.8 V in aqueous alkaline solution. The proposed ECL mechanism for luminol is shown in Fig. 1. The ECL reaction of luminol with hydrogen peroxide in alkaline medium is similar to the chemiluminescence (CL) that is generated upon chemical oxidation. Luminol deprotonates in basic solution to form an anion that can undergo electrochemical oxidation. This intermediate species undergoes further electro-oxidation in the presence of hydrogen peroxide to produce 3-aminophthalate in an excited state. 3-Aminophthalate then produces the characteristic luminol emission at 425 nm. Different mechanistic pathways have been proposed depending on the applied potential. However, all result in the irreversible oxidation of luminol to non-recyclable species. The high nonspecific background ECL possibly due to the formation of oxygen at the anode in aqueous solution, followed by chemiluminescent reactions involving oxygen and the extremely basic conditions ($pH > 11$) that are needed to generate sufficient light emission have resulted in fewer practical applications for the luminol/H_2O_2 system compared to $Ru(bpy)_3^{2+}$.

An interesting area of luminol ECL is the study of electrogenerated catalysts that promote both the conventional CL reaction and the luminol/H_2O_2 ECL reaction. This allows the detection of analytes directly or by the enhancement of luminol ECL for the detection of analytes. A recent example is the enhancing effect of hydrazine on luminol ECL based on hydrazine's in situ electrochemical modification at a preanodized Pt electrode. A method for the determination of phloroglucinol was also reported with a detection limit of 1.2×10^{-4} g/l. The proposed mechanism involves the sensitization of the weak luminol anodic ECL signal in basic (0.1 M $NaHCO_3$) medium. Hydrogen peroxide is an integral part of most luminol studies. Its role in the ECL mechanism appears to involve the peroxide anion, HO_2^-, and the electrochemically formed superoxide radical, $O_2^{\bullet-}$. Because many enzymes produce hydrogen peroxide during their substrate-specific enzymatic activity, sensitive and selective detection in the presence of luminol may be possible. However, in order to fully exploit this chemistry, a compromise has to be found between the basic conditions required for luminol/H_2O_2 ECL and the destruction of enzymes in alkaline solution.

ABEI produces ECL when oxidized at ~1.0 V vs. Ag/AgCl in alkaline aqueous solution. In contrast to luminol, ABEI labels do not markedly lose their CL efficiency when conjugated with proteins. ECL immunoassays with a flow injection analysis (FIA) system using ABEI-isothiocyanate as a label were proposed, which have a better performance than either single-radial immunodiffusion or nephelometric immunoassays. ABEI can also be used as an oligonucleotide marker to label a DNA probe. The intensity of the ABEI ECL was linearly related to the concentration of the complementary sequence in the range 96 pM to 96 nM, and the detection limit was down to 30 pM.



Electro Chemo Luminescence (ECL), Figure 2 Proposed ECL mechanisms for the $Ru(bpy)_3^{2+}$/TPrA system

General Mechanisms of ECL

Annihilation ECL

Annihilation ECL involves electron transfer reactions between an oxidized and a reduced species, both of which are generated at an electrode by alternate pulsing of the electrode potential. This approach is typically called annihilation. Radical ions are produced by anodic oxidation and cathodic reduction:

$$R_1 - e^- \rightarrow R_1^{\bullet+} \tag{5}$$

$$R_2 + e^- \rightarrow R_2^{\bullet-} \tag{6}$$

The excited singlet state $^1R_1^*$ is formed in an ion annihilation reaction involving the ion radicals $R_1^{\bullet+}$ and $R_2^{\bullet-}$, where R_1 and R_2 can be either the same or two different precursors. In energy sufficient systems the formation of the excited state is energetically accessible to the redox process and the ion annihilation occurs via the S-route:

$$R_1^{\bullet+} + R_2^{\bullet-} \rightarrow {}^1R_1^* + R_2 \tag{7}$$

$$^1R_1^* \rightarrow R_1 + h\nu \tag{8}$$

An energy sufficient system is one in which ΔH^0 of the electron-transfer reaction in Eq. (7) is larger than the energy required to produce the excited singlet state from the ground state (Eq. (8)). In contrast, in energy deficient systems, where the excited singlet state $^1R_1^*$ is inaccessible to the redox process, the emitting species are formed via a triplet–triplet annihilation (T-route) involving triplet intermediates:

$$R_1^{\bullet+} + R_2^{\bullet-} \rightarrow {}^3R_1^* + R_2 \tag{9}$$

$$^3R_1^* + {}^3R_1^* \rightarrow {}^1R_1^* + R_1 \tag{10}$$

$$^1R_1^* \rightarrow R_1 + h\nu \tag{11}$$

In both cases, S-route and T-route, the excited species can be either $^1R_1^*$ or $^1R_2^*$, depending on their relative energies. In energy sufficient systems light might be produced by both routes, but the S-route will usually dominate.

ECL of rubrene (RUB) is a classical example of an energy sufficient system. ECL is generated when a double-potential step is applied to an electrode to produce the radical cation ($RUB^{\bullet+}$) via anodic oxidation and the radical anion ($RUB^{\bullet-}$) via cathodic reduction. The resulting electrogenerated products can then react and undergo annihilation (Eq. (14)) to produce an excited state ($RUB^{\bullet}$) that is then able to emit light.

$$RUB - e^- \rightarrow RUB^{\bullet+} \tag{12}$$

$$RUB + e^- \rightarrow RUB^{\bullet-} \tag{13}$$

$$RUB^{\bullet+} + RUB^{\bullet-} \rightarrow RUB + RUB^{\bullet} \tag{14}$$

$$RUB^{\bullet} \rightarrow RUB + h \tag{15}$$

In RUB, one of the products of the reaction is therefore produced with excess energy that can be emitted as light. The ΔH^0 in Eq. (17) is 2.32 eV and the energy required in Eq. (18) is 2.30 eV ($\lambda_{max} \approx 540$ nm).

An example of an energy deficient system is the 9,10-diphenylanthracene (DPA) and N,N,N',N'-tetramethyl-p-phenylenediamine (TMPD) ECL system:

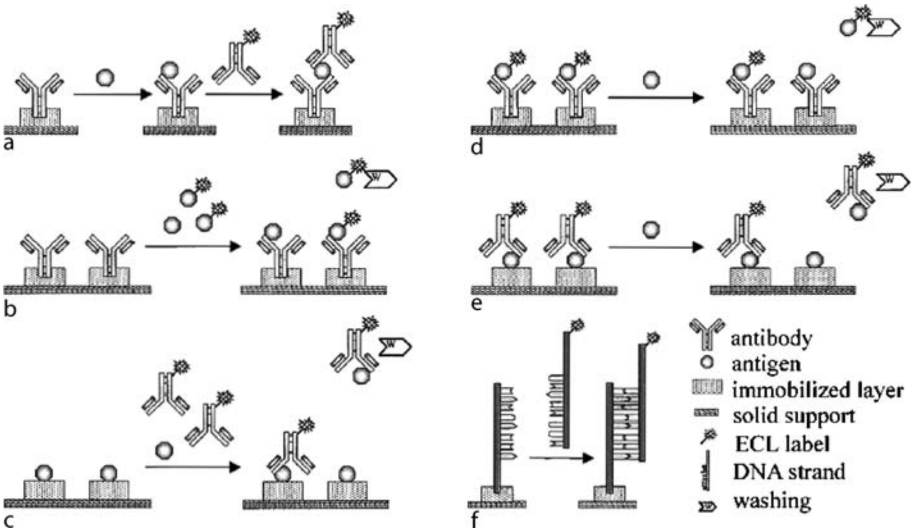
$$TMPD - e^- \rightarrow TMPD^{\bullet+} \tag{16}$$

$$DPA + e^- \rightarrow DPA^{\bullet-} \tag{17}$$

$$TMPD^{\bullet+} + DPA^{\bullet-} \rightarrow TMPD + DPA^{\bullet} \tag{18}$$

$$DPA^{\bullet} \rightarrow DPA + h\nu \tag{19}$$

$DPA^{\bullet}$ is the excited molecular radical that emits light. In theory, light may be emitted from either $DPA^{\bullet}$ or $TMPD^{\bullet}$.



Electro Chemo Luminescence (ECL), Figure 3 Systems for ECL bioassays: (**a**) sandwich assay; (**b**) competition assay with immobilized antibody; (**c**) competition assay with immobilized antigen; (**d**) displacement assay with immobilized antibody; (**e**) displacement assay with immobilized antigen; (**f**) DNA-probe assay

However, the emitted light generated via ECL is identical to DPA photoluminescence, indicating that $DPA^{\bullet}$ is the ultimate product of charge transfer. However, the enthalpy for the electron-transfer reaction is 2.03 eV, much less than that required to reach the emitting singlet excited state for DPA of 3.00 eV. The proposed mechanism involves triplet intermediates, the so-called triplet or T-route:

$$TMPD^{\bullet+} + DPA^{\bullet-} \rightarrow TMPD + {}^{3}DPA^{\bullet} \quad (20)$$

$$^{3}DPA^{\bullet} + {}^{3}DPA^{\bullet} \rightarrow DPA + {}^{1}DPA^{\bullet} \quad (21)$$

Reaction (21) is generally called triplet–triplet annihilation, where the energy from two electron transfer reactions is pooled to provide sufficient energy to form the singlet excited state. Many ECL reactions with different precursors follow this route, and the T-route may also operate in energy sufficient systems.

The ECL quantum efficiency, Φ_{ecl}, is the ratio of the emitted photon number ($N_{h\nu}$) to the molecular number (N_r) of reactant which generates excited states. For example, for the RUB ECL system, this would involve annihilations between $RUB^{\bullet+}$ and $RUB^{\bullet-}$ (Eq. (14)) and the photons emitted (Eq. (15)). Values of Φ_{ecl} can be expressed by the following formula:

$$\Phi_{ecl} = \frac{N_{h\nu}}{N_r} = \frac{\int_t^0 Idt}{Q} \quad (22)$$

where I represents the total ECL intensity integrated over a period of time t, and Q represents the total charge transferred during the same time period. Relative ECL efficiency, which is often found in the literature, can be defined as the Φ_{ecl} ratio of an ECL system to a reference ECL system. For example, with $Ru(bpy)_3^{2+}$ as a reference system, the relative Φ_{ecl} of $Ru(dp-bpy)_3^{2+}$ and $Ru(dp-phen)_3^{2+}$ (dp-bpy = 4,4′-diphenyl-2, 2′-bipyridine; dp-phen = 4,7-diphenyl-1,10-phenanthroline) system is calculated to be 0.05 or 5%.

Experiments on ECL are often carried out in fairly conventional electrochemical apparatus. In annihilation ECL, however, ECL cells, electrodes and experimental procedures must be modified to allow electrogeneration of two reactants, rather than one, with considerations given to constraints imposed by optical measurement equipment and the need for light exclusion. Much attention should be paid to the purity of the solvent/supporting electrolyte system, especially with organic systems. Water and oxygen have been proved to be particularly harmful to annihilation ECL because they can quench this kind of ECL. Therefore, many apparatus are constructed to allow the distillation of solvents directly to the cell and de-gassing on a high-vacuum line, or the apparatus incorporates a nitrogen purging system.

Co-Reactant ECL

A co-reactant is a compound that can produce an intermediate via oxidation or reduction to react with an ECL luminophore to produce excited states. The

$Ru(bpy)_3^{2+}$/TPrA ECL system, a good example of an oxidative–reductive system, has been extensively studied [7]. The general ECL mechanism (Fig. 2) of this system indicates that oxidation of TPrA generates a strongly reducing species. This oxidation can be via a catalytic route where electrogenerated $Ru(bpy)_3^{3+}$ reacts with TPrA as well as by direct reaction of TPrA at the electrode described by both Scheme 1 and Scheme 2. The catalytic route involving homogeneous oxidation of TPrA with $Ru(bpy)_3^{3+}$ is shown in Scheme 3. The contribution of this process to the overall ECL intensity depends on the $Ru(bpy)_3^{2+}$ concentration and is small with relatively low concentrations of $Ru(bpy)_3^{2+}$. Scheme 4 summarizes an additional route for the generation of ECL within the potential range before direct oxidation of $Ru(bpy)_3^{2+}$ at the electrode, involving formation of excited state on reaction of $TPrA^{\bullet +}$ with $Ru(bpy)_3^{+}$ (formed by reaction of $Ru(bpy)_3^{2+}$ with $TPrA^{\bullet}$). If the maximum distance at which light is observed, $\sim 6\,\mu m$, represents the distance that $TPrA^{\bullet +}$ can diffuse before deprotonation, the half-life of the cation radical would be $\sim$ 0.2 ms.

Most of the ECL reactions of $Ru(bpy)_3^{2+}$/co-reactant are of oxidative–reductive type. It can undergo the reductive–oxidative pathway to generate ECL, with a strong oxidant as co-reactant. For example, the reduction of peroxysulfate ($S_2O_8^{2-}$) generates a strong oxidant sulfate radical ($SO_4^{\bullet -}$) to oxidize the ECL luminophore to generate light:

$$Ru(bpy)_3^{3+} + e^- \rightarrow Ru(bpy)_3^{+} \quad (23)$$

$$S_2O_8^{2-} + e^- \rightarrow SO_4^{\bullet -} + SO_4^{2-} \quad (24)$$

$$SO_4^{\bullet -} + Ru(bpy)_3^{+} \rightarrow Ru(bpy)_3^{3+} + SO_4^{2-} \quad (25)$$

$$Ru(bpy)_3^{3+} \rightarrow Ru(bpy)_3^{3+} + h\nu(610\,nm) \quad (26)$$

The electrochemical instruments for co-reactant ECL and annihilation ECL are usually the same. In co-reactant ECL the electrode typically only oxidizes or reduces the reagents in a single potential step, while in annihilation ECL a double-potential step is required to generate the highly energetic precursors. Also, co-reactant ECL can be generated in both nonaqueous and aqueous solutions. In contrast, annihilation ECL requires water and oxygen to be excluded. Co-reactant ECL is widely used in analytical applications, such as ECL immunoassays, flow injections, HPLC and CE.

Cathodic Luminescence

A different type of ECL can be observed at certain oxide-covered metal electrodes such as aluminum, tantalum, magnesium, gallium or indium, during the reduction of persulfate, oxygen or hydrogen peroxide. However, the mechanism is distinctly different from the other types of ECL reactions. Analytical applications of cathodic ECL for species such as copper, thallium and terbium chelates and salicylic acid and their use as labels in immunoassays have been reviewed, and the mechanism has been discussed in detail [5].

Key Research Findings

The use of ECL immunoassay is rapidly growing. ECL immunoassay with ECL detection has several advantages over existing immunoassay techniques. No radiative isotopes are used, thus reducing the problems of sample storage, handling and disposal. The ECL labels are extremely stable, having shelf lives in excess of 1 year at room temperature. The detection levels are extremely low at sub-picomole levels, since each label can emit several photons per measurement cycle, and the linear dynamic range extends over 6 or more orders of magnitude. Also their small size allows multiple labeling of the same molecule without affecting the immunoreactivity or hybridization of the probes. Assays have been developed for a wide range of applications, such as the diagnosis of thyroid diseases, pregnancy and sex function, tumors, anemia, cardiological function and infectious diseases. The scheme of ECL immunoassay methods is summarized in Fig. 3.

In immunoassays, the antigen or antibody can be modified with biotin and bound to streptavidin-modified magnetic beads. The immunoassay is then carried out with either a Ru complex-labeled antibody or antigen, depending on the chosen immunoassay format (sandwich, competition or displacement). Commercial instrumentation, available for the detection of DNA or messenger RNA by reverse transcription PCR based on $Ru(bpy)_3^{2+}$ ECL, includes the QPCR System 5000® from Perkin-Elmer and the Origen® Analyzer from Igen. The PCR product is immobilized on a solid support (magnetic beads) using biotin–streptavidin chemistry. The DNA (RNA) is then detected with a $Ru(bpy)_3^{2+}$ label down to attomolar levels. The systems use biotin labeled primers and labeled probes. In a recent publication, both instruments were used and mRNA isolated from 10 melanoma cells in a background of 107 cells could be detected.

IGEN International Inc. holds many patents related to $Ru(bpy)_3^{2+}$-based luminophores for diagnostic testing in markets such as immunoassay clinical diagnostics, life sciences and biodefense. Roche Diagnostics offer ECL instruments and commercial ECL kits based on IGEN's technology. In both commercially available models, Elec-

sys 1010 and 2010, the whole ECLIA procedure is fully automated. Various immunoassays have been developed for Elecsys 2010 since 1999, and lots of comparisons between different assay formats have been made. Generally, ECLIA has always had at least an equal analytical performance in these comparisons to other competing technologies.

ECL has been coupled with separation techniques such as HPLC and capillary electrophoresis to offer outstanding sensitivity and selectivity. And ECL has been reported with precolumn, on-column or postcolumn detection mode. The scheme of a typical instrument of ECL with postcolumn detection is shown in Fig. 4. The detection limit can be as low as that of LIF, but with simpler and much less costly instrumentation. The linear range is wide and the reactions typically have fast kinetics, making ECL well suitable to low-volume on-line detection. With the increasing interest in microfabricated devices, microchip-based CE has become popular recently. A wireless ECL detector for electrophoresis on a microfabricated glass device was reported [8]. The results show that a micellar electrokinetic separation and direct ECL detection of 10^{-16} mol of $Ru(phen)_3^{2+}$ and 4.5×10^{-16} mol of $Ru(bpy)_3^{2+}$ and the indirect detec-

tion of three amino acids were achieved. A solid-state ECL detector coupled with microchip-based CE was fabricated by immobilizing $Ru(bpy)_3^{2+}$ into an Eastman AQ55D-silica-carbon nanotube composite thin film on an indium tin oxide (ITO) electrode [9]. The results show that the solid-state ECL detector displays good durability and stability in the microchip CE–ECL system. Proline was selected to test the microchip device with a limit of detection of 2 μM (S/N = 3) and a linear range from 25 to 1000 μM. Compared with the CE–ECL of $Ru(bpy)_3^{2+}$ in aqueous solution, the microchip-based CE with solid-state ECL detector system gave the same sensitivity of analysis, a much lower $Ru(bpy)_3^{2+}$ consumption and a high integration of the whole system.

Spatially resolved ECL on an array of electrode tips has been reported [10]. An array of electrode tips with 6 μm center-to-center spacing, fabricated through chemical etching of an optical fiber bundle, and coated with gold (Fig. 5), was used for initiating ECL in an aqueous solution of $Ru(bpy)_3^{2+}$ and TPrA. ECL generated at the tips of the electrodes in the array was detected with a CCD camera and exhibited both high sensitivity and high resolution. In the case in which the ECL signal could not be distinguished from the background, ECL signals could be obtained by pulsing the array and summing multiple CCD images. Gold nanopariticle-enhanced ECL detection has been reported recently [11]. 4-(Dimethylamino)butyric acid (DMBA) labeling combined with gold nanoparticle amplification for ECL determination of bovine serum albumin (BSA) and immunoglobulin G (IgG) was demonstrated. ECL signals were generated from the electrodes immobilized with BSA or IgG. With gold nanoparticle amplification, the ECL peak intensity was proportional to the concentration over the range 1 – 80 and 5 – 100 μg/mL for BSA and IgG consuming 50 μL of sample, respectively. A 10- and 6-fold sensitivity enhancement was obtained for BSA and IgG over their direct immobilization on an electrode using DMBA labeling.

Future Directions for Research

Having been an important analytical technique since the first detailed studies in the mid-1960s, ECL will continue to have a promising future in analytical and bioanalytical science. The ECL of $Ru(bpy)_3^{2+}$ and its derivatives will be further investigated to expand the range of its applications, especially in the area of diagnostic testing and immunoassay. ECL coupled with separation techniques should still be attractive for analysts. The need for low-cost, portable analytical instruments in the areas of environmental analysis and food safety will be a great opportunity for ECL, which does not require a light source and results in simple instrumentation. There are also favorable prospects for ECL to be used in micro total analysis systems. ECL detectors have been used in micro total analysis systems successfully. And further miniaturization and integration and solid-state ECL techniques will mean a promising future for ECL on chips.

Definition

Electrokinetic dispensing is a method using electroosmotic pumping to inject a small quantity of samples, the size and concentration of which can be controlled by manipulating applied electrical potential fields, modifying channel surfaces and changing channel dimensions. A simple cross-linked microchannel is commonly employed for electrokinetic dispensing.

Overview

There has been tremendous interest in developing Lab-on-a-Chip (LOC) devices, which have a wide range of applications in life sciences, biotechnology, and biomedical engineering fields. A typical LOC device includes a microfluidic chip platform with a network of microchannels, electrodes, electrical circuits and detectors integrated on it to perform a series of sample processes such as cell separation, cell lysis, biomolecular separation, polymerase chain reaction and final detection. Although LOC devices hold great promise to revolutionize the current level of biomedical and chemical analysis and treatment, the development of LOC devices has been largely hindered due to the lack of the capability for precise on-chip sample manipulations, among which dispensing a sample volume on the order of nanoliter to picoliter is key. To this end, many researches have been done in developing miniaturized dispensing systems using different pumping mechanisms such as piezoelectric pumping, pneumatic (thermal and pressure) pumping, electrowetting pumping, surface acoustic wave pumping, ultrasonically driven pumping, and electroosmotic (EOF) pumping. We will focus on the introduction of electrokinetic dispensing using EOF pumping in this entry. Interested readers are referred to a thorough review of micropumps [1].

EOF is generated when an external electrical field is applied to the liquid in a microchannel tangentially, due to the presence of net charges within a thin layer near the solid-liquid interface. This thin layer is called the electrical double layer (EDL) and the net charges in the EDL are the result of charge separation in the bulk liquid induced by the surface charge, which originates from several mechanisms, such as ionization of surface groups and electrolyte ion adsorption to solid surfaces. The EDL generally consists of two layers: one is the inner compact layer where ions are strongly attracted to the charged surface and the other is the diffuse layer where ions are free to move. The

electrical potential in the liquid generally decays dramatically from the surface and almost reaches zero at some distance slightly beyond the EDL region. The potential at the shear plane, which separates the compact layer and the diffuse layer, is referred to as the zeta potential, ζ. The zeta potential is a function of both solid-liquid interface and liquid properties and is located at the fluid flow boundary, where zero velocity (no slip boundary) is assumed for an electroosmotic flow. The velocity then increases as a result of the force balance between the electrostatic force exerted on the net charges in the EDL and the viscous force in the liquid, and reaches a maximum value at the edge of the EDL. Because no forces exist in the bulk liquid, the velocity then keeps constant across the bulk liquid region. Considering a 10 mM electrolyte solution, which is the concentration commonly used in chemical and biomedical analysis, in a 100 μm-i.d. cylindrical capillary with a uniform surface property, the EDL is around 10 nm (0.01% of the channel diameter). The velocity variation over such a thin EDL is negligible and thus the liquid appears to slip on the surface exhibiting a plug-like velocity profile. This allows the assumption of a slip velocity boundary condition, which has been applied in many numerical and analytical studies of EOF flow.

EOF pumping is preferred in developing LOC devices because of its plug-like velocity profile eliminating sample dispersion due to cross-stream velocity gradients, the rate of flow rate control it allows, no moving parts involved eliminating maintenance working loads and its potential for integration. Therefore, it has also been used for dispensing applications, which is often referred to as electrokinetic dispensing. Early studies about on-chip sample dispensing using EOF were driven by capillary electrophoresis (CE) applications where sample separation requires a clear-cut initial sample plug to be generated. Harrison et al. [2] first integrated CE and sample handling (loading and dispensing) on a planar glass chip. Since then, many experimental and numerical studies involving on-chip sample dispensing have followed [3–5]. Although several channel layouts have been proposed for electrokinetic dispensing such as single cross, double-T and triple-T configurations, a straight cross-linked microchannel was mostly employed as shown in Fig. 1. In this layout, the separation channel (i. e., the channel between the intersection and the buffer waste reservoir) is normally designed much longer than the other three channels allowing sufficient time for samples to be separated. Generally, electrokinetic dispensing in such a configuration includes two steps which are the loading and dispensing step.

During the loading step, a small amount of sample is loaded from the sample reservoir to the intersection by applying potentials to the four reservoirs connected by microchannels. Once the loading process reaches steady state, the applied potentials are switched so that the sample in the intersection can be dispensed into the separation channel which is in the perpendicular direction to the loading direction as shown in Fig. 2. In order to dispense a desired sample size and volume, both the loading and dispensing processes must be understood and well controlled, which requires a better understanding of fluid flow and mass transport in microchannels. In this entry, we focus on the introduction to the numerical simulation of fluid flow and mass transport in a cross-linked microchannel for electrokinetic dispensing applications. A brief description of the experimental procedures for electrokinetic loading and dispensing is also provided.

Electrokinetic Dispensing, Figure 2 A typical loading and dispensing of a sample

Basic Methodology

Governing Equations

In order to understand the physics of sample dispensing in a microfluidic chip and develop analysis tools for the design and control of microfluidic dispensers, a numerical model consisting of a set of governing equations must be developed. First, for precisely dispensing a small amount of sample, the sample concentration distributions for both the loading and dispensing step must be known. This requires the solution of the flow field, which influences the concentration through the convection effects, and the solutions of the EDL potential field and applied potential field which affect the flow field through the electrical driving force. The governing equations for the loading and dispensing should be the same, the boundary conditions, however, are different. Considering a simple cross-linked microchannel shown in Fig. 1, the equations describing the loading and dispensing processes and the boundary conditions are discussed below.

The Concentration Field

The concentration equations for a buffer solution which is electrically neutral in its bulk region and the ith sample species in the buffer solution are:

$$\frac{\partial C_\mathrm{b}}{\partial t} + \boldsymbol{u} \cdot \nabla C_\mathrm{b} = D_\mathrm{b} \nabla^2 C_\mathrm{b} + R_\mathrm{b} \quad (1)$$

$$\frac{\partial C_i}{\partial t} + \boldsymbol{u} \cdot \nabla C_i = D_i \nabla^2 C_i + \frac{D_i z_i e}{k_\mathrm{b} T} \nabla (C_i \nabla \Phi) + R_i \quad (2)$$

where subscripts b and i represents the buffer solution and ith sample species, C stands for concentration, D is diffusion coefficient, e is the element charge, k_b is the Boltzmann constant, R represents the reaction occurring during dispensing processes, which is neglected for most electrokinetic dispensing applications, T is absolute temperature, $\boldsymbol{u}$ is the vector of the mass-average flow velocity, z_i is the valence of the ith sample species, and Φ is the total electrical potential which is often split into two components: the electrical double layer potential, ψ, and the applied electrical potential, ϕ such as $\Phi = \psi + \phi$. The decoupling of the above two terms is often practiced in microfluidic chip applications because the relatively high concentration buffers commonly used in such applications yield a very thin double layer (i. e., 10 nm as discussed above). On one hand, the double layer potential only varies over the EDL region and has a very high electrical field strength on the order of 1×10^7 V/m, which is not likely affected by the applied electrical potential field which is generally on the order of 1×10^4 V/m and in a perpendicular direction to the EDL field. On the other hand, the net charges within such a thin double layer has negligible effects on the bulk liquid resistance and thus on the applied potential field. As shown above, the buffer concentration equation, Eq. (1), does not have the electromigration term, which is the second term on the right hand side of Eq. (2). This is because the electromigration term results from the electrical forces exerted on charged species, which generally do not exit in the bulk liquid region for buffer solutions. However, it must be considered for charged sample species. Neglecting the gravitational forces, only two forces exist for a charged particle in a stationary liquid under an applied electrical field: the drag force and the electromigration force. The balance between the drag force and the electrical migration force allows the electromigration term in Eq. (2) to be expressed as a velocity format such as

$$\boldsymbol{u}_{\mathrm{ep}_i} = -\frac{D_i z_i e}{k_\mathrm{b} T} \nabla \phi \quad (3)$$

where $\boldsymbol{u}_{\mathrm{ep}_i}$ is the electrophoretic velocity vector of the ith species and the negative sign indicates that a negatively charged species will migrate towards the anode under an applied electrical field. Based on the above assumptions, the species concentration equation, Eq. (2), is reduced to:

$$\frac{\partial C_i}{\partial t} + \left(\boldsymbol{u} + \boldsymbol{u}_{\mathrm{ep}_i}\right) \cdot \nabla C_i = D_i \nabla^2 C_i \quad (4)$$

It should be noted that for most electrokinetic dispensing applications, the buffer concentration is uniform across the chip and thus Eq. (1) is ignored in the problem. However, for the applications of sample pumping (multiple sample species are transported together without separation by utilizing a higher-conductivity buffer to carry samples) and sample stacking (sample species are separated more efficiently and sample concentrations are increased on-chip by using a lower-conductivity buffer to carry samples) [6], the driving buffer conductivity is different from the sample-carrying buffer. In such a scenario, the buffer concentration must be solved [7] to determine the electrical conductivity distribution, which will affect the applied electrical potential field and thus the flow field. Considering the similarity of the boundary and initial conditions for Eq. (1) and Eq. (4), only the boundary and initial conditions for Eq. (4) are introduced below.

For the loading step, Eq. (4) is subject to the following boundary conditions: $C_i = C_{i0}$ at the sample reservoir and zero flux boundary conditions, $\boldsymbol{n} \cdot \nabla C_i = 0$, at all the other boundaries across the chip, where $\boldsymbol{n}$ is the unit normal to the surface and C_{i0} is an initially applied concentration for the ith species. The initial conditions for Eq. (4) are $C_i = C_{i0}$ at the sample reservoir and $C_i = 0$ at all the

other places across the chip. For the dispensing step, the boundary conditions are similar to that for the loading step, however, the initial conditions are the concentration distribution of the loading step when it reaches steady state, $C_i = C_{i_\text{loading}}$.

The Flow Field

For an incompressible, Newtonian liquid flow, which is common for most electrokinetic dispensing applications, the flow field is described by the continuity equation,

$$\nabla \cdot \boldsymbol{u} = 0 \tag{5}$$

and the Navier–Stokes (N–S) equation,

$$\rho \left[\frac{\partial \boldsymbol{u}}{\partial t} + (\boldsymbol{u} \cdot \nabla)\, \boldsymbol{u} \right] = -\nabla P + \eta \nabla^2 \boldsymbol{u} + \rho_\text{e} \boldsymbol{E} \tag{6}$$

where ρ is the density of the liquid, P is pressure, η is the viscosity of the liquid, $\boldsymbol{E} = -\nabla\phi$ is the local electrical field strength which can be determined by solving the applied potential equation, and ρ_e is the net charge density in the liquid, which can be determined by solving the EDL potential equation. For most microfluidic applications, the viscous force is dominant and the time for the flow to reach steady state is very small, which is on the order of ms ($t \approx \rho D_\text{h}^2/\eta = 10^{-2}$ s where $\rho = 1.0 \times 10^3\,\text{kgm}^{-3}$, $\eta = 1.0 \times 10^{-3}\,\text{kgm}^{-1}$, and D_h is the characteristic length chosen as $D_h = 100\,\mu\text{m}$). Therefore the transient term in the N–S equation can be neglected. Because of small channel dimensions and flow velocities (the typical velocity in microfluidic devices is on the order of mm/s), the Reynolds number, $\text{Re} = \rho u D_\text{h}/\eta$, which represents the ratio between the inertial force and the viscous force, ranges approximately from 0.001 to 0.1. Therefore, the flow in microfluidic devices is in the laminar flow regime and the convection term on the left hand side of the N–S equation can be ignored. For most microfluidic applications, no pressure difference is applied; however, the induced pressure gradients do exist due to the presence of two-dimensional flow in the intersection of the microchannel. Even for a straight channel, the induced pressure gradient most likely exists because of the Laplace pressure originating from the presence of different meniscus curvatures in the reservoirs. It is difficult to quantify the induced pressure effects because meniscus curvatures vary from experiments to experiments. The possible solutions to minimize the Laplace pressure are to increase the reservoir sizes and/or increase the flow resistance which can be realized by reducing the channel cross section and increasing the length of the flow path without increasing the channel length in one direction. This is because increasing the channel length in one direction will increase the chip size, which mitigates the key advantages that microfluidic chips can offer. Considering the above assumptions, Eq. (6) can be simplified as:

$$-\nabla P + \eta \nabla^2 \boldsymbol{u} + \rho_\text{e} \boldsymbol{E} = 0 \tag{7}$$

When no external pressure gradients are applied, Eq. (7) is subject to the following boundary conditions: zero pressure gradient, $\boldsymbol{n} \cdot \nabla P = 0$, at solid walls, atmospheric pressure, $P = P_\text{a}$, at all the reservoirs, no slip velocity, $\boldsymbol{u} = 0$, at solid walls (no slip boundary) and fully-developed flow velocity, $\boldsymbol{n} \cdot \nabla u = 0$, at all the reservoirs. No tangential velocity is applied to the inlets and outlets (reservoirs). In fact, the velocities at the reservoirs are not known at the beginning. However, for a pure EOF flow, the body force is the electrical driving force, which generates a velocity in the reservoirs. This velocity is part of the solution; therefore, it is reasonable to assume the fully-developed flow boundary conditions at the reservoirs. If external pressure gradients are applied, the velocity boundary conditions are the same, but the pressures at the reservoirs will be changed to the applied pressures.

The EDL Potential Field

In order to solve the flow field, the net charge density must be known. According to the theory of electrostatics, the relationship between the net charge density and the electrostatic potential, ψ, is described by the Poisson equation:

$$\varepsilon_\text{r} \varepsilon_0 \nabla^2 \psi = -\rho_\text{e} \tag{8}$$

where ε_r is the dielectric constant of the liquid, and ε_0 is the permittivity of vacuum ($\varepsilon_0 = 8.854 \times 10^{-12}$ C/Vm). The corresponding boundary conditions for the above equation are, zeta potential, $\psi = \zeta$, at solid walls and zero potential gradient, $\boldsymbol{n} \cdot \nabla \psi = 0$, at the reservoirs. The above boundary conditions are valid for most LOC applications where uniform surface properties are assumed, however, for some applications where heterogeneous surface properties exist, the boundary conditions must be modified to account for the variation of the solid-liquid interface properties. The net charge density in Eq. (8) is given by, $\rho_\text{e} = \sum_i z_i e n_i$, where n_i is the ionic concentration of the ith species within the EDL and given by the Nernst–Planck conservation equation,

$$\nabla \cdot \left(\boldsymbol{u} n_j - D_j \nabla n_j - \frac{D_j z_j e \nabla \phi}{k_\text{b} T} n_j \right) = 0 \tag{9}$$

The above equation is subject to the zero flux boundary conditions, $\boldsymbol{n} \cdot \nabla n_j = 0$ at both solid walls and reservoirs.

E

As one can see that the Nernst-Planck equation is coupled with the Poisson equation and the N–S equation, which is very difficult to solve simultaneously. Another difficulty arises when all the species of a multi-species buffer must be considered for determining the net charge density. Two alternative solutions are commonly used for simplifying this problem. In the first method, the EDL potential equation is neglected and thus the electrical driving force term in the modified N–S equation (Eq. (7)) is ignored, which will be considered by applying the slip velocity boundary condition to solve the flow field. This treatment is reasonable for most LOC applications because of the presence of thin double layers as discussed above. The slip velocity boundary condition can be determined by the Helmholtz–Smoulchowski equation such as

$$u_{\mathrm{eo}} = \mu_{\mathrm{eo}} E_{\mathrm{x}} = -\frac{\varepsilon_{\mathrm{r}}\varepsilon_0\zeta}{\eta} E_{\mathrm{x}} \tag{10}$$

where u_{eo} is the electroosmotic velocity which is uniform in the cross-stream direction, and $\mu_{\mathrm{eo}} = -\varepsilon_{\mathrm{r}}\varepsilon_0\zeta/\eta$ is the electroosmotic mobility.

The second method is to neglect the convection term in Eq. (9) considering that the flow velocity is small for both EOF flow and electrophoretic flow, which decouples the flow field and the EDL potential field. In the second approach, the assumption of a two-species buffer and the application of the Boltzmann distribution are commonly made in order to solve the potential field easily, which yields the well-known Poisson–Boltzmann Equation:

$$\nabla^2\psi = \frac{2zen_0}{\varepsilon_{\mathrm{r}}\varepsilon_0}\sinh\left(\frac{ze\psi}{k_{\mathrm{b}}T}\right) \tag{11}$$

By solving Eq. (11), the EDL potential and net charge density can be determined, which can be used to determine the electrical driving force in the modified N–S equation for the flow field.

The Applied Potential Field

EOF is generated by applying external electrical potentials to the liquid in a microchannel. Therefore, the applied electrical potential field must be known in order to solve the flow field. When an electric field is applied along a microchannel, the current is setup along the channel. For most microfluidic applications where electrically neutral dilute solutions are often used, the local electric current vector is given by,

$$\boldsymbol{i} = \lambda\nabla\phi \tag{12}$$

where λ is the electric conductivity of the electrolyte solution and takes the form of

$$\lambda = \frac{e^2N_a}{kT}\Sigma\, z_j^2 D_j C_j \tag{13}$$

Eq. (13) is an expression of the Ohm's law for electrically neutral dilute solutions or solutions in a microchannel having a thin double layer, where C_j can be determined by a set of concentration equations. The charge conservation in the liquid, $\nabla\cdot\boldsymbol{i} = 0$, must be satisfied, which yields the equation of the applied electrical potential field:

$$\nabla\cdot(\lambda\nabla\phi) = 0 \tag{14}$$

The boundary conditions for the above equation are specified potentials at the reservoirs, $\phi_i = \phi_{\mathrm{applied}}$, and zero potential gradient at solid channel walls, $\boldsymbol{n}\cdot\nabla\phi = 0$. It should be pointed out that if there is no spatial conductivity gradient (λ is a constant), Eq. (14) takes a simpler format,

$$\nabla^2\phi = 0 \tag{15}$$

Depending on the problem of interest, a numerical model can be developed and numerically solved with appropriate boundary conditions to obtain the concentration distribution of the loaded and dispensed sample. The solution to the model can also be used to investigate the effects of the controlling parameters on the sample size, which may potentially provide an optimized configuration for particular dispensing applications.

Numerical Methods

The above governing equations can be numerically solved with the corresponding boundary conditions. Although many commercially available softwares such as FEMLAB have been widely applied in microfluidic studies benefiting from their capability of coupling different fundamental equations and user-friendly interfaces, most of them focuses primarily on simulation of fluid flow. The species transport, which is one of the most important phenomena in electrokinetic dispensing applications, has been paid less attention. Therefore, developing special codes is often practiced in numerically solving the above governing equations towards the design and control of electrokinetic dispensers.

The goal of numerical simulation is to obtain the distribution of a set of dependent variable at a set of discrete locations (often referred to as grid or node) in the domain of interest by solving a set of differential equations. In order to do so, the derivatives of the differential equations must be interpreted using the values at a certain point and its neighboring points. This process is called discretiza-

tion. Different discretization techniques lead to different numerical methods. Three commonly used numerical methods for microfluidic chip applications are the finite difference method, finite control volume method and finite element method. The finite difference method uses the Taylor series formulation to get the derivatives of interest where higher order derivatives are neglected assuming they are less important. The result is the discretized equation at each grid point which relates the values of a dependent variable at this grid and its neighboring points. This method is relatively simple; however, it lacks flexibility in dealing with complex geometry. The finite element method divides the domain of interest into subdomains (i. e., triangles) and approximates a solution to the equation on each subdomain. By using the method of weighted residual, the discretized equation can be constructed over each domain and then assembled for the entire domain. In this method, the selection of the weighting function is very important. The advantage of this method lies in its capability in dealing with complex geometries, such as structural analysis. The disadvantage of this method arises from the difficulty in choosing a successful weighting function for particular applications. The finite control volume method divides the domain of interest into many small and non-overlapping control volumes (grid points). The differential equation is integrated over each control volume which requires the value at each point and the assumption of the variation of a dependent variable between different neighboring control volumes. The result is the discretized equation for a dependent variable at each grid point. The solution obtained using the finite control volume method fully satisfies the integral conservation of quantities over each control volume and the entire domain. Therefore it is well suited for fluid dynamics problems. The disadvantage of this method is its difficulty in dealing with complex geometries as compared to the finite element method. Some techniques have been developed such as orthogonal curvilinear coordinates to overcome this difficulty. More recently, a control-volume based finite element method has been developed to combine the advantages of the both methods [7].

Singularity in Modeling Electrokinetic Dispensing

Most microfluidic chips for electrokinetic dispensing applications have a channel layout containing 90-degree corners, which will cause singularity problems at the corners in the applied electrical potential field and the EDL potential field. This is because the direction of the applied potential field (the direction of the potential gradient) at that corner changes dramatically (90 degree from x-direction to y-direction) and the potential is not differentiable at the corners. The possible solution to reduce the singularity effects on the numerical solutions is to choose fine grids near the corners, which will reduce the error caused by singularity. However, the potentials near the corners will not be very accurate. The more detailed mathematical derivation and discussion about singularity problems can be found elsewhere [8].

Experimental Approaches

As mentioned above, electrokinetic dispensing normally employs a straight cross-linked microchannel to dispense a small amount of sample. In this approach, EOF flow is used as a pumping method, which requires electrical potentials to be applied to the liquid in the microchannel through electrodes (i. e., platinum electrodes) plugged into the four reservoirs as shown in Fig. 1. Generally, an electrokinetic dispensing process includes two steps which are the loading step and dispensing step.

During the loading step, the sample solution is electrokinetically pumped from the sample reservoir into the intersection of the microchannel. The sample size in the intersection has significant influences on the dispensed sample size. Therefore, it is very important to control the loaded sample size, which can be achieved by manipulating applied potentials, changing channel dimensions, and modifying channel surfaces. For example, considering the fixed potentials applied in the reservoir 1 and 3 as shown in Fig. 2, the higher the applied potentials in the reservoir 2 and 4, the more focused sample plug can be obtained in the intersection.

After the loading step reaches steady state, the loaded sample can be dispensed in the perpendicular direction to the loading direction (i. e., towards the reservoir 4) by switching the applied potentials, as shown in Fig. 2. Many on-chip processes such as sample separation and mixing start from a small and well-controlled sample plug. Take sample separation as an example, the resolution of sample separation is highly dependent on the dispensed sample size and volume. Generally, a thin, highly concentrated sample plug gives a higher separation resolution. However, it should be noted that if the dispensed sample plug is too thin, it is very difficult to detect the sample peaks because the sample concentrations decrease quickly due to diffusion before they can reach the detector. Since there are many parameters (i. e., channel dimensions, applied potentials, buffer solutions, channel surface properties, etc.) which affect the dispensed sample size and volume, it is essential to perform parametric studies on electrokinetic dispensing using numerical simulation tools before proposing any design for expensive experimental tests.

Key Research Findings

Electrokinetic dispensing using EOF pumping has major applications in chemical, biological and biomedical analysis where a desired amount of sample must be dispensed in a controllable manner. There are too many studies about electrokinetic dispensing using EOF pumping to be listed here. A few numerical studies where relatively special numerical techniques were used for the purpose of electrokinetic dispensing are discussed here.

The earliest numerical study of EOF pumping in a cross-linked microchannel as shown in Fig. 1 was conducted by Patankar and Hu [8] in 1998. By justifying that the sample diffusion is much less important than the convection transport in such a small chip, this study focused on the investigation of the electroosmotic flow field. A three-dimensional numerical model was presented and numerically solved using the finite control volume method where the semi implicit method was used to deal with the pressure term [7]. It is found that the sample plug at the intersection during the loading step can be controlled by manipulating the potentials at the side reservoirs (the buffer reservoir and buffer waste reservoir). The higher potentials in these side reservoirs are applied, the more focused sample can be obtained. The loaded sample plug can also be controlled by applying pressures at the side reservoirs, which can be easily understood that more buffer solutions are driven into the intersection from the side reservoirs to focus the sample stream.

Almost at the same time, Ermakov et al. [3] presented a numerical model for electrokinetic transport in a simple cross-linked microchannel and a T-intersection microchannel. This model considered two sample species and was numerically solved using the finite difference method, where an intermediate velocity was introduced to generate an equation for the pressure and the continuity equation was used as a condition to ensure the mass conservation is satisfied. Sample focusing in the cross microchannel and sample mixing in the T-intersection channel were studied and the effects of the electroosmotic mobility, electrophoretic mobility and applied potentials on the sample plug in the intersection were investigated using the developed model. Their numerical results agreed well with their experimental results. Later, this model was applied to study more electrokinetic dispensing applications such as pinched and gated injection techniques by the same group.

Fu et al. [4] presented a numerical model for electrokinetic dispensing in microfluidic chips where simple cross, double-T and triple-T configurations were considered. In this model, the Nernst–Planck equation was employed to describe the ionic concentration instead of the Boltzmann distribution, which is a more general approach. The model was numerically solved using the finite difference method where the artificial compressibility method was employed to deal with the pressure term in the N–S equation. It is found that the applied potentials play an important role in controlling the loaded and dispensed sample shape. The unique feature of this study is the concept of the multi-T injection system which can function as a simple cross, double-T, or triple-T injection unit. Their numerical results agreed well with their experimental results. More injection techniques were also developed by the same group later.

Ren and Li [5] also presented a numerical model of sample transport in a microfluidic chip containing a simple cross microchannel aiming to provide an optimized configuration in terms of a set of controlling parameters for electrokinetic dispensing. This model was numerically solved using the finite control volume method where the pressure term was dealt with using the SIMPLE method. In addition to the applied potentials, the electroosmotic mobility of the buffer solution, and the electrophoretic mobility of the sample, the effects of the diffusion coefficient of the sample and the channel aspect ratio (the ratio between the horizontal channel and the vertical channel) on the sample dispensing were also studied. It is found that under the same applied potentials, a more focused sample can be achieved by utilizing a channel with an aspect ratio of $1/2$ (the horizontal channel has a half width of the vertical channel). This provides an opportunity to lower down the required voltages for achieving a certain focused sample plug, which is very helpful for integration. Later, by realizing that the flow and mass transport is one dimensional in the long separation channel and the places far away from the intersection, the same group presented another numerical model. In this new model, artificial boundaries were used to truncate the physical domain into a small computational domain containing the intersection and the information outside this domain was brought into consideration through the carefully designed boundary conditions. This approach allows the computation power to be concentrated on the two-dimensional phenomena near the intersection [9] and found that this method took 97.3% less computation time than a full domain simulation for particular cases. This model was further improved by the same group to consider conductivity gradients in the buffer solution, which has major applications in sample pumping and sample stacking [10].

Future Directions for Research

The ultimate goal of LOC devices is to integrate all the sample processes such as sample preparation, mixing, reaction and detection onto a single microfluidic chip.

Among all the processes, the sample preparation is the most challenging one to be integrated because it has to deal with original samples (i. e., a blood drop) which are often non-newtonia fluids. The study of electrokinetic dispensing for non-newtonia fluids will be very important for realizing the concept of the LOC device.

Nanofluidic chips have attracted increasing attention recently; however, the fluid flow in such a small scale might not be well described by the traditional Navier–Stokes equation, which has been used for most numerical models for electrokinetic dispensing. Therefore, the development of numerical models for electrokinetic dispensing in nanofluidic chips will be of great importance for the design and control of such small scale chips. In these models, other theories such as molecular dynamics might be used to describe the flow field.

Numerical simulation has been proven to be a very useful tool for microfluidics and nanofluidics research. The goal of numerical simulation is to make a set of analysis tools available for precise design and operational control of LOC devices. To this end, the traditional study of electrokinetic dispensing will continue to be attractive. The development of numerical models studying the effects of the complex channel layout, channel surface heterogeneities, buffer conductivity gradient, and multiple sample species on electrokinetic dispensing will be a promising direction.

Electrohydrodynamic mixing; Electrokinetic instability

Definition

Electrokinetic and electrohydrodynamic flow instabilities develop at a fluid-fluid interface due to the unstable growth of interfacial perturbations when electrical stresses are applied. The electrical stresses develop at the interface primarily due to a conductivity or permittivity gradient between two fluid phases. Electrokinetic and electrohydrodynamic instabilities have been demonstrated in both single phase aqueous systems with conductivity gradients as well as in two phase organic aqueous microflows and are modeled using classical linear stability analysis considering momentum transport equations and both kinematic and interfacial stress boundary conditions. These models test the stability of the fluid flow to infinitesimal disturbances. These instabilities have been applied primarily to enhancing mixing processes in microfluidic devices.

Overview

In most microfluidic devices, mixing occurs between two inlet streams of the same fluid where the two streams must be dispersed to remove any concentration gradients of dissolved components between the two streams. One category of active mixing has been reported using electrokinetic or electrohydrodynamic instabilities in microflows. Research on electrokinetic and electrohydrodynamic instabilities has been conducted either to promote mixing or to understand how the instabilities develop in order to design devices which avoid them. A full understanding of how the instability develops is especially important when dealing with samples and buffers in lab on a chip applications such as capillary electrophoresis or isoelectric focus-

ing whose conductivity and/or conductivity gradients are either unknown, poorly controlled or both.

The early work on modeling electrohydrodynamic instabilities performed a linear stability analysis of the electrical and fluid interfacial boundary conditions using the transfer relations developed by Melcher [1]. Melcher developed a dielectric model which describes liquids as being both polarizable and having free charge in an imposed electric field. Electrohydrodynamic instabilities have been demonstrated in macroscale systems [2, 3] by Hoburg and Melcher at an oil-oil interface with a discrete conductivity change at the interface under the influence of an applied electric field. Here, the instability is modeled as charge accumulation at a perturbed interface where the electrical force on the interface is balanced by the fluid interfacial stress tensor. The instability model is applied to determine the interfacial stability as to whether the perturbations will grow or decay exponentially. Melcher determined that a natural velocity scale for this instability is the electroviscous velocity which represents a balance between the electrical and viscous stresses at the fluid-fluid interface. This instability is analogous to many instabilities such as the Rayleigh–Taylor instability of a two fluid system when a denser fluid is placed on top of a lower density fluid in a vertical gravitational field.

Basic Methodology

Several different types of instability mixing have been reported: electrokinetic instability mixing in a single phase solution without conductivity gradients [4], electrokinetic [5, 6] and electrohydrodynamic [7] instability mixing with conductivity gradients, and multiphase electrohydrodynamic instability mixing [8]. In order to understand how electrohydroyanmic mixing will proceed, it is important to understand the stability criteria at the organic-aqueous interfaces. The instability can be modeled for single phase systems with a conductivity gradient along a fluid-fluid interface where all other physical properties (e. g., viscosity, permittivity) are constant across the interface [5–7]. A model for multiphase systems consists of a non-conducting fluid sandwiched between two perfectly conducting layers maintaining an initially flat interface, with a DC potential, V_0, applied across two parallel plate electrodes [8]. These models very closely resemble the physical flow profile of reported experimentally stratified flows.

For each of these models, a linearized perturbation analysis is performed by linearizing the flow and electrical field equations of the system. This process is modeled using stability analyzes applying the kinematic and stress conditions at the interface. Stability analysis is based upon superimposing a perturbation flow profile over the base flow and determining whether the perturbations will grow or decay in time. These analysis can predict the conditions for incipience of instability and initial instability growth rates. As the system is driven beyond the small signal linear range, computational methods may be employed to further characterize instability progression into mixing.

Governing Equations

The flow profiles of the two fluids are determined by conservation of mass assuming incompressible fluids and the Navier–Stokes equation which includes the imposed electrical forces

$$\nabla \cdot \boldsymbol{u} = 0 \tag{1}$$

$$\rho \left[\frac{\partial \boldsymbol{u}}{\partial t} + (\boldsymbol{u} \cdot \nabla)\, \boldsymbol{u} \right] = -\nabla p + \rho \boldsymbol{g} + \mu \nabla^2 \boldsymbol{u} + \boldsymbol{F}_\mathrm{e} \tag{2}$$

where $\boldsymbol{u}$ is the velocity vector, ρ is the fluid density, p is the pressure, μ is the fluid viscosity and $\boldsymbol{F}_\mathrm{e}$ is the electrical volume force density. The volume force density is related to the divergence of the electrical stress tensor and is

$$\begin{aligned} \boldsymbol{F}_\mathrm{e} &= \nabla \cdot \bar{\bar{\mathbf{T}}}^\mathrm{e} \\ &= \rho_f \boldsymbol{E} - \frac{1}{2} |\boldsymbol{E}|^2 \nabla \varepsilon + \nabla \left(\frac{1}{2} \rho \, |\boldsymbol{E}|^2 \left(\frac{\partial \varepsilon}{\partial \rho} \right)_T \right) \end{aligned} \tag{3}$$

where $\bar{\bar{\mathbf{T}}}^\mathrm{e}$ is the electrical stress tensor, ρ_f is the free charge density, $\boldsymbol{E}$ is the electric field and ε is the space varying dielectric permittivity. The first term on the right side of Eq. (3) represents the electrophoretic component of the force which is the electrical force exerted on the free charges in the electric field. In a perfectly conducting solution, the free volume charge in each fluid layer is zero ($\rho_\mathrm{f} = 0$), but there can be a surface charge on the fluid-fluid interface. The second term is the dielectrophoretic term and is the force density term exerted on a dielectric fluid. The third term is an electrostrictive force density and can be ignored for incompressible fluids as it can be lumped with the pressure term in Eq. (2). For multiphase systems using two incompressible liquids which are assumed to be completely immiscible [8], the dielectric permittivity and conductivity are modeled as a step function across each interface so that the permittivity and conductivity gradients are Dirac delta functions right on the interface. Since the dielectric permittivity and conductivity are constant in each layer, the total electric force density in each layer is zero except along the interface where the step change in permittivity and conductivity contributes to an interfacial surface force density. In addition, in systems where there is

a conductivity gradient within a single fluid, there will be a free charge density which results in a coulombic (electrophoretic) force density.

In electrostatic systems the electric field has zero curl so the electric field may be expressed in terms of a scalar electric potential

$$\nabla \times \boldsymbol{E} = 0 \Rightarrow \boldsymbol{E} = -\nabla \phi \tag{4}$$

Gauss's law may be written as

$$\nabla \cdot (\varepsilon \boldsymbol{E}) = \rho_{\mathrm{f}} \tag{5}$$

and for ohmic media with convection current

$$\boldsymbol{J} = \sigma \boldsymbol{E} + \rho_{\mathrm{f}} \boldsymbol{u} \tag{6}$$

where $\boldsymbol{J}$ is the current density and σ is the solution conductivity. Charge conservation requires that

$$\nabla \cdot \boldsymbol{J} + \frac{\partial \rho_{\mathrm{f}}}{\partial t} = 0 \tag{7}$$

Assuming the permittivity and conductivity are space varying Eqs. (5–7) reduce to

$$\begin{aligned} \frac{\varepsilon}{\sigma}\left(\frac{\partial \rho_{\mathrm{f}}}{\partial t} + \boldsymbol{u} \cdot \nabla \rho_{\mathrm{f}}\right) + \rho_{\mathrm{f}} &= \sigma \boldsymbol{E} \cdot \nabla\left(\frac{\varepsilon}{\sigma}\right) \\ &= -\varepsilon \boldsymbol{E} \cdot \frac{\nabla \sigma}{\sigma} + \boldsymbol{E} \cdot \nabla \varepsilon \end{aligned} \tag{8}$$

In the presence of a conductivity gradient in which ion transport is considered, the solution conductivity can be described by a convective-diffusion equation as

$$\frac{\partial \sigma}{\partial t} + \boldsymbol{u} \cdot \nabla \sigma = D_{\mathrm{eff}} \nabla^2 \sigma \tag{9}$$

where σ is the solution conductivity and D_{eff} is the effective diffusivity of the ions. It was also shown by Hoburg and Melcher that the velocity may be rescaled in terms of an electroviscous velocity, U_{ev}, which represents the balance between the viscous force and electric body force as

$$U_{\mathrm{ev}} = \frac{\varepsilon E_0^2 H}{\mu} \tag{10}$$

where E_0 is the applied electric field and H is the characteristic length scale of the system (e. g., the half width of a microfluidic channel for a two layer stratified system).

Kinematic and Stress Conditions

In the presence of an electric field the surface charge density and polarization force density at the interface influences the interfacial force balance boundary condition and the electric field can affect fluid flow. The interfacial stress balance boundary condition in the i direction on a surface whose normal, $\boldsymbol{n}$, is in the j direction is

$$\left\| \mathbf{T}_{ij}^{\mathrm{f}} n_{\mathrm{j}} \right\| + \left\| \mathbf{T}_{ij}^{\mathrm{e}} \right\| - \gamma \left(n_{j,j}\right) n_i = 0 \tag{11}$$

where $\mathbf{T}_{ij}$ is the stress tensor, the vertical bars represent the difference in stress across the interface, γ is the interfacial tension between the phases (if applicable), and the superscript refers to either the fluid (f) or electrical (e) contributions. For two dimensional problems with a planar interface with no variation in the y direction, with an equilibrium normal in the x direction and an interfacial displacement, $\xi(z)$, the small signal normal to first order terms is

$$\boldsymbol{n} = \boldsymbol{i}_x - \frac{\partial \xi}{\partial z} \boldsymbol{i}_z \tag{12}$$

The fluid and electrical stress tensor components are

$$\mathbf{T}_{ij}^{\mathrm{f}} = -p \boldsymbol{\delta}_{ij} + \mu \left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right) \tag{13}$$

and

$$\mathbf{T}_{ij}^{\mathrm{e}} = \varepsilon E_i E_j - \frac{1}{2} \boldsymbol{\delta}_{ij} \varepsilon E_k E_k \tag{14}$$

where $\boldsymbol{\delta}_{ij}$ is the Kronecker delta. The electrical stress tensor in Eq. (14) is derived from the volume force density in Eq. (3) due to the coulombic and polarization force densities.

Perturbation Variables

The primary objective of stability analysis is to test the stability of the fluid flow to infinitesimal disturbances. Here the perturbations are superimposed over the base flow so that interfacial displacements are represented as

$$\xi(z, t) = \xi_{\mathrm{equil}} + \mathrm{Re}\left[\hat{\xi} e^{j(\omega t - kz)}\right] \tag{15}$$

where ξ_{equil} is the equilibrium displacement, ω is the natural frequency of interfacial displacement, $\hat{\xi}$ is the complex amplitude of the interfacial displacement, k is the wavenumber component in the z direction and $j = \sqrt{-1}$. The wavenumbers are related to the wavelengths (λ) of the interfacial displacements as

$$k = \frac{2\pi}{\lambda} \tag{16}$$

Electric scalar potential perturbations may be described as

$$\phi(z,t) = \phi_{\text{equil}} + \text{Re}\left[\hat{\phi}e^{j(\omega t - kz)}\right] \quad (17)$$

Similarly, pressure and velocity perturbations may be described as

$$p(z,t) = p_{\text{equil}} + \text{Re}\left[\widehat{p}e^{j(\omega t - kz)}\right] \quad (18)$$

$$U_x(z,t) = U_{\text{xequil}} + \text{Re}\left[\hat{U}_x e^{j(\omega t - kz)}\right] \quad (19)$$

$$U_z(z,t) = U_{\text{zequil}} + \text{Re}\left[\hat{U}_z e^{j(\omega t - kz)}\right] \quad (20)$$

where the subscripted equil refers to the equilibrium base flow. The stability of the system may be modeled by linearizing the electrical and flow equations and applying the interfacial boundary conditions to test whether the interfacial perturbation will grow. The generalized analysis in [10] has proved that the incipience of instability occurs when $\omega = 0$. If the system is stable, ω is complex with a positive or zero imaginary part and if unstable the real part of ω is zero while the imaginary part is negative. When ω is negative imaginary it can be seen that the perturbation modeled by Eq. (15) will grow exponentially in time.

Key Research Findings

Some of the early work on electrokinetic (EK) instability mixing was done by Santiago and colleagues [4]. Here, mixing was produced using AC electrical excitation at a frequency of 10 Hz. With increasing applied voltage the flow became unstable and material line stretching and folding was observed (Fig. 1). Due to the fully three dimensional flow profile which developed at higher field strengths the observed phenomena was attributed to a flow instability. The instability was observed using a variety of channel materials and buffer solutions. However, a mechanism for the instability was not fully explored and it was unclear whether the instability was due to the electrical excitation or due to the flow oscillations as the authors note "At this time, we do not know if this instability is particular to electrokinetic flows in this regime or if the instability would also be observed in viscous channel flows with oscillating walls." However, more recent analysis using a multispecies electrokinetic instability model has demonstrated that the flow instability may be promoted when the conductivity ratio between two fluid streams is as low as 1.01 [5]. Thus, the instability seen in [4] may be due to a slight conductivity difference due to the fluorescent dye used for flow visualization.

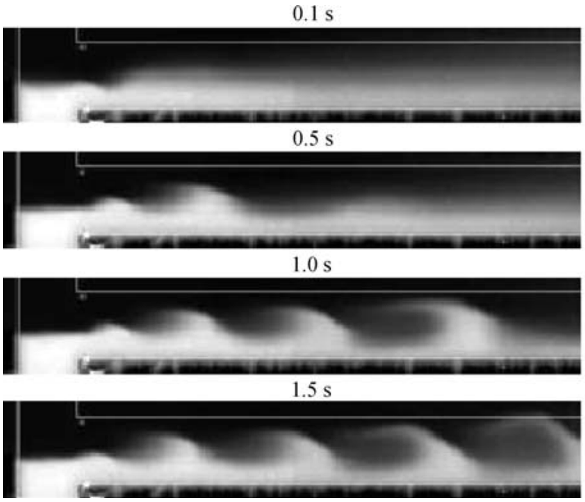
Further mixing experiments were conducted using a two layer stratified aqueous electrokinetic flow with a conductivity gradient where one layer of fluid was at least 10 times more conductive than the other [6, 7]. Even though the instability originates in the bulk electrolyte, the terminology *electrokinetic instability* was chosen due to the relevance of the work to electrokinetic microdevices. Here, with the application of a critical electric field, the electrokinetic instability is seen to grow with characteristic instability waves as shown in Fig. 2. It was noted that the disturbance originates where the two fluids meet, increases in magnitude with increasing electric field and is convected downstream within the microchannel. Santiago and colleagues adapted the electrohydrodynamic model proposed by Melcher to electrokinetic flows to consider interfacial electrokinetic effects. Their model expanded upon the work done by Melcher and Hoburg to include "advective effects due to electroosmotic flows, an initial conductivity profile consistent with our experiments, and a diffusive component of the conductivity conservation equation critical in modeling EK instabilities." This diffusive component may stabilize the flow, so modeling the diffusive component is critical for determining the critical electric field for instability. In addition to this expansion of the instability model, a full three dimensional model was proposed and many of the salient experimental features observed were captured by computational simulation.

An example of an electrohydrodynamic mixer was demonstrated by El Moctar et al. [8]. Here, an oil–oil two layer system was chosen where one oil phase was doped with an oil miscible charge carrier to increase its conductivity and permittivity. Here a dimensionless timescale for interface charging was considered for AC excitation

$$T = \frac{\tau}{1/f} = \tau f \quad (21)$$

where $\tau = \varepsilon/\sigma$ is the charge relaxation time and f is the applied AC frequency. The authors consider the influence of using a DC applied electric field (Fig. 3), AC sinusoidal electric field and square-wave excitation. The electric field needed for efficient mixing was seen to decrease as AC and then square wave excitation was used. However, lower frequencies were preferred as it was noted that if T is much greater than 1 then the charges do not have time to accumulate along the fluid–fluid interface when higher frequencies are used. Thus, at higher frequencies the coulombic component of the interfacial force tensor is negligible and the polarization force due to the permittivity gradient dominates. However, it was also noted, that the permittivity difference between the two fluids also becomes very small

(**b**) Particles oscillate in plane with a transverse component at a larger applied voltage of 4 kV. (**c**) Particle trajectories in the unstable state at 8 kV. Here the flow field is three-dimensional, as particles traverse the depth of field of the microscope moving in and out of focus. (*Right*) Images obtained from the electrokinetic instability micromixer during the mixing process with an initially stable interface and transition into instability mixing [4]



Electrokinetic/ElectroHydrodynamic Flow Instability, Figure 2 Time series images of instability waves due to an electrokinetic instability in a conductivity gradient at an applied field of 1.25 kV/cm. The two solutions are Borate buffers of 1 mM and 10 mM which are introduced into the device at a stable electric field of 0.25 kV/cm. The high-conductivity stream is seeded with a neutral fluorescent dye [6]

at high frequency excitation so that the polarization force also becomes small.

Zahn and Reddy recently demonstrated multiphase mixing using a three layer stratified system [9] consisting of a low conductivity organic layer sandwiched between two high conductivity aqueous layers. Here, the two fluid layers were immiscible so mixing in this context was not defined as molecular dispersion to remove concentration gradients but rather as an increase in interfacial area between the two phases from droplet formation to reversible dispersion of the two phases. The process was modeled using linear stability analysis and an analytical stability criteria for any two phase system consisting of an insulating fluid layers sandwiched between two conductive fluid layers was determined as the product of two terms, each of which may be zero

$$\left(((c_\mathrm{a}-c_\mathrm{b})+d_\mathrm{b})^2+\left(\left(a_\mathrm{a}+a_\mathrm{b}-\frac{\varepsilon_\mathrm{b}E_0^2k}{j\omega}\coth kb+\frac{\gamma k^2}{j\omega}\right)\right.\right.$$
$$\left.\left.+\left(b_\mathrm{b}+\frac{\varepsilon_\mathrm{b}E_0^2k}{j\omega\sinh kb}\right)\right)((e_\mathrm{a}+e_\mathrm{b})-f_\mathrm{b})\right)$$

where b is the thickness of the organic layer, E_0 is the applied electric field, a through f are the elements defined in Eq. (23) and the subscript a or b relates to which layer, the aqueous (a) or organic (b), is used to evaluate the components. It was previously shown [1] that the perturbation x and z directed first order complex amplitude stresses may be described for a generic fluid layer of thickness Δ, density ρ and viscosity μ, to define the components a through f

$$a=\frac{-\mu\left(\delta^2-k^2\right)}{kD}\left(\frac{k}{\delta}\coth\delta\Delta-\coth k\Delta\right)$$

$$b=\frac{\mu\left(\delta^2-k^2\right)}{kD}\left(\frac{k}{\delta}\operatorname{csch}\delta\Delta-\operatorname{csch}k\Delta\right)$$

$$c=\frac{j\mu}{D}\left[\delta\left(1+\frac{3k^2}{\delta^2}\right)(\operatorname{csch}k\Delta\operatorname{csch}\delta\Delta\right.$$
$$\left.-\coth k\Delta\coth\delta\Delta)+k\left(3+\frac{k^2}{\delta^2}\right)\right]$$

$$d=\frac{-j\mu\left(\delta^2-k^2\right)}{\delta D}(\coth\delta\Delta\operatorname{csch}k\Delta-\coth k\Delta\operatorname{csch}\delta\Delta)$$

$$e=\frac{-\mu\left(\delta^2-k^2\right)}{\delta D}\left(\frac{k}{\delta}\coth k\Delta-\coth\delta\Delta\right)$$

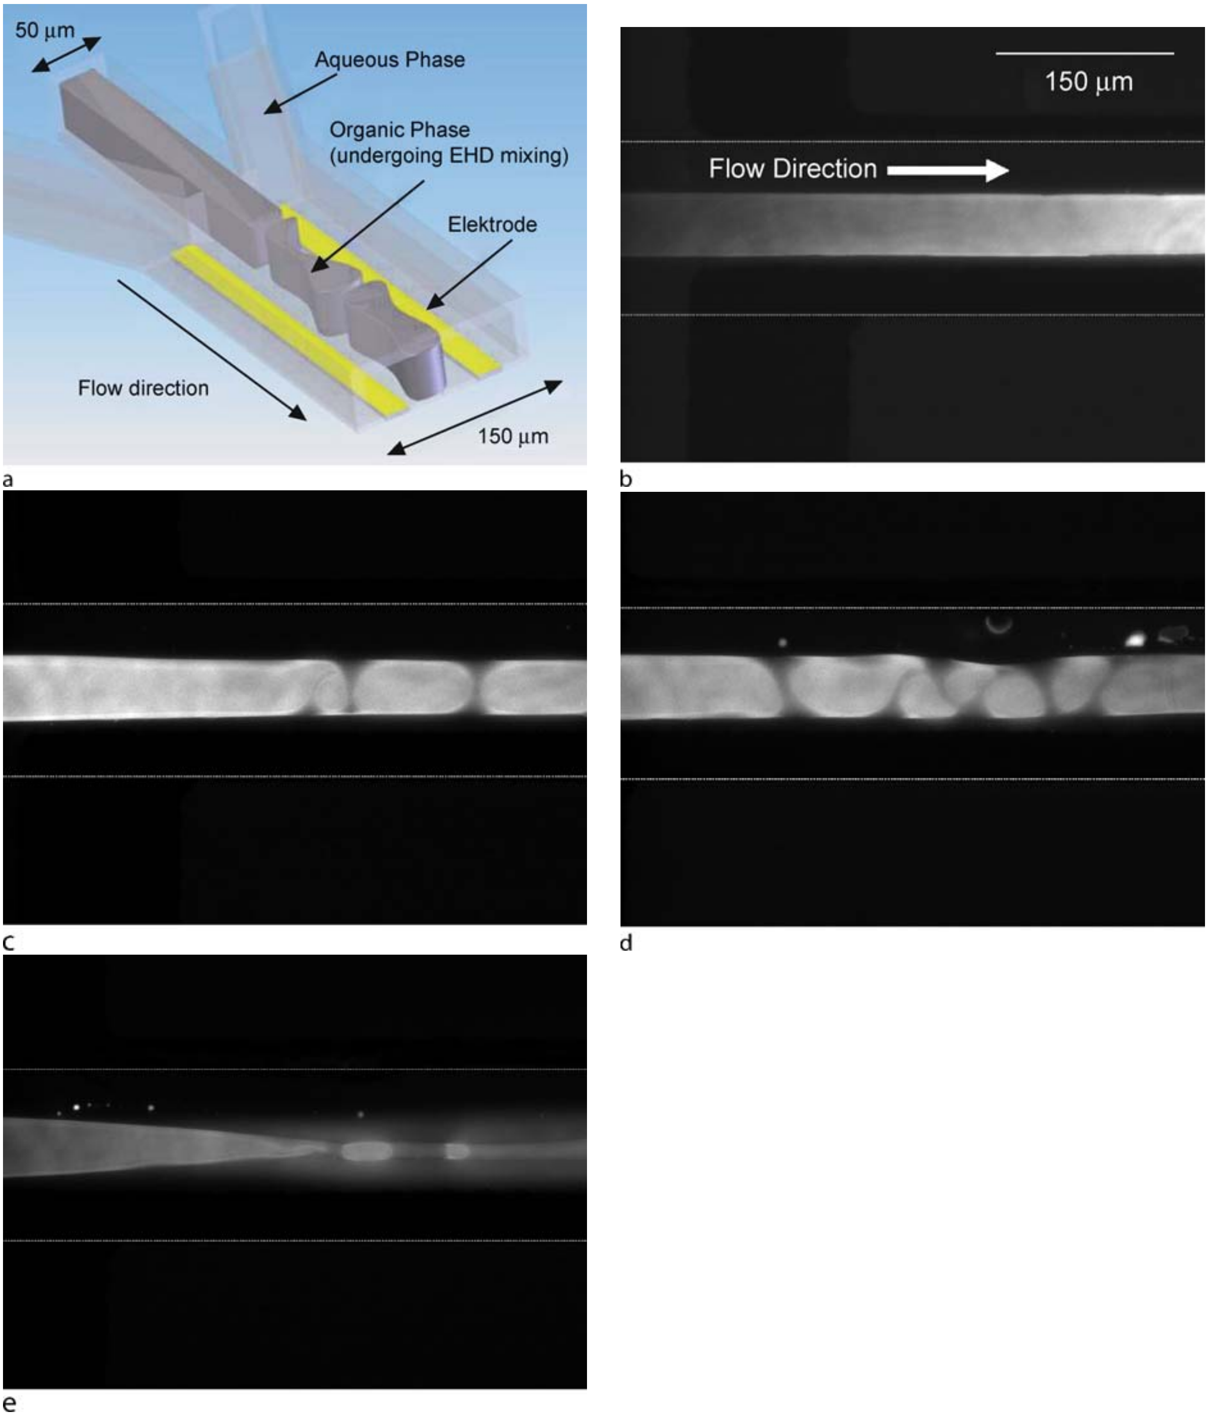
$$f=\frac{-\mu\left(\delta^2-k^2\right)}{\delta D}\left(\operatorname{csch}\delta\Delta-\frac{k}{\delta}\operatorname{csch}k\Delta\right)$$

$$D=1+\frac{k^2}{\delta^2}+\frac{2k}{\delta}(\operatorname{csch}k\Delta\operatorname{csch}\delta\Delta-\coth k\Delta\coth\delta\Delta)$$

$$\delta=\left[k^2+(j\omega\rho/\mu)\right]^{\frac{1}{2}} \tag{23}$$

Using the physical values for the fluids used and layer thicknesses $a = b = 50$ μm, negative imaginary roots of ω were found as a function of wavenumber and increasing applied field when the applied field was beyond the incipience of instability as shown in Fig. 4. The fastest growth wavenumber is the minimum of the negative imaginary roots.

Experimentally, the instability was demonstrated by labeling the organic phase with a fluorescent dye and applying electrical excitation through patterned electrodes. A schematic of the experimental system is shown in Fig. 5a. Here, high frequency AC excitation was used to avoid electrolysis of the aqueous phase. Due to the large permittivity difference between the organic and aqueous phases a large polarization force density can be applied to the interface at high frequencies as compared to the single phase system where only a conductivity gradient exists limiting the interfacial force to the coulombic



Electrokinetic/ElectroHydrodynamic Flow Instability, Figure 5 (**a**) Schematic of the three inlet geometry with electrodes and instability mixing. The channel height is 30 μm and the electrode to electrode spacing is 75 μm. (**b**) A stable flow in the absence of an electric field. (**c**) The disruption of flow after a 41 V_{RMS} potential (initial applied field $E_0 = 8.2 \times 10^5$ V/m) is applied at 250 kHz to the electrodes. (**d**) EHD instability at 44 V_{RMS} (initial applied field $E_0 = 8.8 \times 10^5$ V/m), 700 KHz. (**e**) Dispersion of the two phases at 45 V_{RMS} (initial applied field $E_0 = 9 \times 10^5$ V/m) and 10 MHz. The electrodes are spaced 75 μm apart in the aqueous phase above and below the organic phase but appear dark in the epifluorescent images. All images were taken using a 20× microscope objective and each image window size is 340 × 461 μm^2. The horizontal white lines delineate the channel boundaries [9]

force density. Increasing the electric field increases the instability growth rate and results in an increase in the level of mixing. The results show an increase in conductive aqueous fluid entrainment into the nonconducting organic fluid core (Fig. 5b to e) measured as a percentage of area of entrainment into the fluorescently labeled organic phase. The entrainment area increased from 1.9% to 28.6% as the applied field was increased from 8.0×10^5 to 9.0×10^5 V/m.

Future Directions for Research

Electrokinetic and electrohydrodynamic instability mixing in microsystems is a complex phenomenon which researchers are only beginning to exploit and understand. Future work requires a further development of experimental models and expansion of computational simulations to better understand how the instabilities form and grow. Specific applications of electrokinetic and electrohydrodynamic instabilities are still limited. The application of these instabilities to improve mixing between components should be explored. One example is through the use of multiphase systems where electrohydrodynamic instabilities are utilized to improve component partitioning for liquid extraction devices.

Electrokinetic Flow

Synonyms

Electrokinetic transport; Electrokinetic motion

Definition

Electrokinetic flow covers in principle the transport of liquids (electroosmosis) and samples (electrophoresis) in response to an electric field. Both motions are associated with the electric double layer that is formed spontaneously at the solid–liquid interface in which there is a net charge density. Compared to the traditional pressure-driven flow, electrokinetic flow is more suited to miniaturization due to its nearly plug-like velocity profile and much lower flow resistance. However, Joule heating is a ubiquitous phenomenon in electrokinetic flow that will affect the transport of both liquids and samples via temperature sensitive material properties.

Northwestern University, Evanston, IL, USA
s-ghosal@northwestern.edu

Synonyms

Electroosmotic flow; Ion conductance in nanochannels; Ion transport in nanopores; Nanopore conductance

Definition

A nano-channel is a conduit between two reservoirs of fluid with a characteristic internal diameter of roughly one to several tens of nanometers. A nanometer is a billionth of a meter (10^{-9} m). The fluid is assumed to be an electrolyte, that is, water with some dissolved salts that dissociate into positive and negative ions. Electrokinetic flow refers to fluid flow generated in such a channel when an externally applied electric field is the primary motive force. Ion transport refers to the average drift of the ions along the channel due to the electric field superimposed on the random molecular motion and collisions with the surrounding water molecules and channel walls.

Overview

Nano vs. Micro-Fluidics

The phrase *one to several tens of nanometers* in the above definition may seem both arbitrary and vague and therefore needs further elucidation. Since the subject of discussion is the flow of water through narrow channels, they must be wide enough to allow the passage of a molecule of water, which is about 0.1 nm. On the other hand, if they are much wider than this size, let us say more than a 100 nm or 0.1 micron we are in the domain of microfluidics, where water can safely be regarded as a continuous material as we do in everyday engineering practice. Thus, the specification of *one to several tens* derives from the scale provided by the water molecule, the subject of discussion is channels that are neither too narrow nor too wide in comparison to the size of a water molecule. These definitions however are based on common usage and are necessarily imprecise; there is no exact boundary as to where nanofluidics ends and microfluidics begins. Nanochannels can be long, that is the length may be many times the characteristic width or short, that is, the length can be of the order of the width. The terms nanopore and nanochannel are usually used interchangably and we will do so here.

Nanochannels in Nature

Nanochannels and ion transport across nanochannels is a very common feature in living cells [1]. Cells contain various internal and external membranes made out of lipid molecules. These are called lipid bilayers. The nanochannels are made of proteins which form a pore on the lipid bilayer. Various kinds of such channels are known with different biological functions. For example, nerve cells contains channels that are permeable to Sodium, Pottasium or Calcium ions. Channels open or close in response to various factors. For example, voltage gated channels open in response to a change in the electrical potential across it. A ligand gated channel opens if a specific chemical (a ligand) binds to it. Proton pumps in the cell membrane cause the interior of the cell to be maintained at a small negative electric potential relative to the outside. The opening of the ion channels cause an equilibration of the ionic concentrations on either side of the membrane causing a collapse of the potential. Neighboring channels sense this drop in the potential and being voltage gated they respond by opening up and collapsing the potential in their own neighborhood. The effect propagates by the domino effect causing a zone of collapsed potential to propagate outward along the membrane. This is a nerve impulse and it is the mechanism behind all neuronal activity in living things. Another nanochannel in living systems help regulate the water content of cells; these are called aquaporins. They play an important role for example in the functioning of the kidney. The genetic material of a cell is stored in its nucleus. However, the proteins that are coded by the genes are actually manufactured outside the nucleus in the cytoplasm by organelles known as ribosomes. Some of these proteins are actually needed inside the cell nucleus itself or in the mitochondria. How do they cross the mitochondrial or the nuclear membrane? For this, the membranes of these bodies contain nanopores. The proteins are actually unfolded and they translocate across the membrane as a linear polypeptide chain through these nanopores. The details of the mechanism by which this happens is a subject of current research in cell biology.

Nanochannels in Technology

A number of applications of nanochannels have emerged recently in biotechnology partly inspired by their respective biological counterpart. One such application could lead to novel technologies for sequencing DNA that is orders of magnitude faster than what is currently possible. The idea had its origins in the Coulter counter for counting and sorting cells. The Coulter counter consists of a single micron size pore in an impervious membrane that separates two chambers both filled with an electrolyte. When a voltage is applied, a small current flows due to ion movement through the pore. If one of the chambers contain objects such as cells, occasionally a cell will enter the pore. When this happens, the volume of electrolyte in the pore, and therefore the conductance of the pore is reduced and this can be detected as a drop in the current. Thus, the device can be used to count cells and make estimates of their size. In a 1996 paper it was shown by Kasianowicz et al. [2] that if the microchannel in the membrane is replaced by a nanochannel the device is able to detect the passage of single molecules of DNA and RNA. The nanopore was a recon-

structed version of a natural ion channel from the bacteria Staphylococcus aureus. It is formed by a protein called α-hemolysin which self assembles under the right conditions on a lipid bilayer membrane and remains open and stable for extended time periods. Recently, techniques involving a combination of micro lithography followed by treatment using the beam from an electron microscope has been used to create artificial nanopores in the 1 to 10 nm range. These tend to be more stable and are easier to work with than the protein nanopores from living cells. It has been shown that the current signal from the nanopore can be used to determine the lengths of biopolymers and to tell apart homopolymers of identical length. However, the goal of actually reading off the sequence of bases as the polymer threads through the pore (in a manner similar to how the magnetic head in a tape recorder reads the signal encoded in a magnetic tape) still remains elusive. Recently the idea of the *Thousand Dollar Genome*: the goal of reducing the cost of a complete sequence of the three billion base pairs in a human genome to one thousand US dollars or less, has received much attention. This cost level is considered a threshold below which one may expect to see a large scale impact of this technology on the practice of medicine and on the national economy. For the sake of comparison, the Human Genome Project cost 3 billion dollars over a thirteen year period (about $1 per base). The latest advancement in automation has reduced this to 5 cents per base. It is believed that a revolutionary rather than evolutionary change in sequencing technology is needed to reach the 3 cents per 100,000 bases envisioned by the goal of a thousand dollar genome. The concept of sequencing using nanopores could be just the required revolutionary sequencing technology and is discussed in more detail later in this article (see [6] and [8]).

Nanochannels have been used to make an analogue of semiconductor transistors [3]. Charged surfaces in contact with electrolytes attract a layer of ions of the opposite sign (counter-ions) that neutralize the electric field. If the electrolyte is *ordinary* water (that is, water that has not been de-ionized through special treatment) the electric field near most charged surfaces drops to essentially zero over a distance of several nanometers. Because of this shielding effect, any electric field applied externally across the channel has essentially no effect on the conductance of the channel because the bulk of the electrolyte within the channel simply does not "see" the applied electric field. In nanochannels, the situation changes because now the penetration depth of the external voltage, which is of the same order as the thickness of the layer of counterions is comparable to the channel thickness. As a result, the electric conductance of the nanochannel can be controlled by applying a gate voltage across the channel, just as in a MOSFET transistor. If controlling the current with a gate voltage was the sole application of this technology, it would be of little interest, since semiconductor transistors achieve the same effect far more efficiently and it is a mature technology. Of much greater importance is the fact that the permeability to charged macromolecules can also be selectively controlled with a gate voltage. This is because, a negatively charged macromolecule would naturally be excluded from a nanochannel with negatively charged walls until the potential barrier is lowered through the application of a gate voltage. Thus, a pore that is selectively permeable to specific molecules can be created and the selectivity can be tuned. This is analogous to the gated pores in biological systems, though the gating is achieved in perhaps a different manner. Large scale practical uses of the technology is likely, but is still in the future.

Basic Methodology

There are primarily two approaches to modeling flow and transport in nanochannels: continuum models and molecular models.

In the first approach, the fluid and the various charged species in the electrolyte are considered to be continuous and are described by quantities such as $c(\boldsymbol{x}, t)$ (the concentration of a given species) which are continuous functions of space and time. The continuum model is an approximation to reality because an electrolyte really consists of discrete particles: the individual molecules of the solute, solvent and dissociated ions. The continuum model has a high degree of accuracy as long as the relevant length scales in the problem (such as width of the channel) are much larger than the typical distance between molecules. For liquids, such as water, the molecules are closely packed together. Therefore, the distance between molecules is about the same as the size of the molecules themselves which is on the order of 0.1 nm. For this reason, one can expect the continuum approach to give reasonably accurate results in the case of liquid flow through channels that are tens of nanometers wide. The distance between molecules in gases at atmospheric pressure is about ten times larger so it is easier to detect deviations from classical continuum models in the case of flow of gases in nanochannels. In high vacuum these intermolecular distances are even larger and the continuum approximation can break down even on macroscopic scales. The degree of validity of the continuum approximation is often characterized by the ►Knudsen number defined as $\mathrm{Kn} = \lambda/L$, where λ is the ►mean free path (the average distance a molecule travels before bumping into a neighbor) and L is a characteristic length of the problem of interest. Then, the regime of validity

of continuum models may be characterized by a Knudsen number that is much smaller than one ($\mathrm{Kn} \ll 1$).

In many cases, such as in most of the nanochannels found in biological systems, the channel diameter is so small that the continuum model would be clearly inappropriate. There are even nanochannels that are too small to permit the passage of even a single molecule of water. In such cases, one is forced to recognize the underlying molecular structure of matter and perform what is called a ▶ molecular dynamics (MD) simulation. It is important to recognize, just like the continuum approximation, the MD approach is also an approximation to reality but at a different level. In the MD approach one ignores the fact that the water molecule for example contains protons, neutrons and electrons which interact with the protons, neutrons and electrons of every other water molecule via quantum mechanical laws. Such a description would be enormously complicated! Instead, each molecule is treated as a discrete indivisible object and the interaction between them is described by empirically supplied pair interaction potentials. For example, the simplest MD model is the hard sphere model where each molecule is modeled by a sphere, and the molecules do not interact except when they touch in which case they rebound elastically like billiard balls.

There also exists a range of possibilities that fall between the continuum and molecular models. These are approaches that combine some features of both. For example, in the description of Brownian motion of macromolecules or latex beads in the 10 – 100 micron size range, one uses classical hydrodynamic results such as the Stokes law for drag on a sphere while at the same time modeling fluctuating forces from molecular collisions that arise at the level of the molecular description. In the theory of ionic solutions, the individual ions are considered to be discrete particles but the surrounding water is treated as if it was a continuous dielectric medium with a constant dielectric permittivity.

Continuum Models

The Basic Equations of Electrokinetics

In the continuum model, electrokinetic flows are described by the incompressible Navier-Stokes equations with a volume density of electrical forces $-\rho_e \nabla\phi$ where ρ_e is the electric charge density and ϕ is the electric potential:

$$\rho_0(\partial_t \boldsymbol{u} + \boldsymbol{u} \cdot \nabla \boldsymbol{u}) = -\nabla p + \mu \nabla^2 \boldsymbol{u} - \rho_e \nabla\phi \,. \qquad (1)$$

This is supplemented by the continuity equation which takes into account the fact that in a liquid the density changes almost not at all even for large changes in pressure :

$$\nabla \cdot \boldsymbol{u} = 0. \qquad (2)$$

In the above, ρ_0 is the (constant) density of the water, p is the pressure, $\boldsymbol{u}$ is the flow velocity. The relative size of the term on the left of Eq. (1) (due to fluid inertia) and the second term on the right (due to viscosity) is characterized by the ▶ Reynolds number

$$\mathrm{Re} = \frac{UL\rho_0}{\mu} \qquad (3)$$

where U and L denote a characteristic velocity and length for the flow. In most applications of nanoscale flows, $\mathrm{Re} \ll 1$ so that the left hand side of Eq. (1) is neglected (the ▶ Stokes approximation). The potential ϕ is related to the charge density through the Poisson equation of electrostatics (in CGS units):

$$\varepsilon \nabla^2 \phi = -4\pi \rho_e \,, \qquad (4)$$

ε being the permittivity of the liquid. If the electrolyte contains N species of ions with charges ez_k and concentration $n_k (k = 1, \ldots, N)$, e is the magnitude of the charge on an electron then $\rho_e = \sum_{k=1}^{N} ez_k n_k$. Each ion species obeys a conservation equation

$$\frac{\partial n_k}{\partial t} + \nabla \cdot \boldsymbol{j}_k = 0 \,. \qquad (5)$$

Here $\boldsymbol{j}_k$, the flux vector for the species k, can be modeled by the Nernst-Planck equation for ion transport

$$\boldsymbol{j}_k = -\nu_k z_k e n_k \nabla\phi - D_k \nabla n_k + n_k \boldsymbol{u} \,. \qquad (6)$$

In Eq. (6) ν_k is the ▶ ion mobility: the velocity acquired by the ion when acted upon by unit force. It is obviously related to the ▶ electrophoretic mobility: the velocity per unit of electric field as $\mu_k^{(ep)} = ez_k \nu_k$. The diffusivity of the kth species is D_k and $\boldsymbol{u}$ is the fluid velocity.

Boundary Conditions. The boundary conditions are those of no slip (see [9] for a discussion on the applicability of this condition to small scale systems) for the velocity at rigid boundaries,

$$\boldsymbol{u} = 0 \qquad (7)$$

and no ion flux normal to the wall

$$\boldsymbol{j}_k \cdot \hat{\boldsymbol{n}} = 0 \qquad (8)$$

where $\hat{\boldsymbol{n}}$ is the unit normal directed into the fluid. In the absence of external electric fields, the chemistry at the electrolyte substrate interface leads to the establishment

of a potential, $\phi = \zeta$. This so called ▶zeta-potential at an interface depends on a number of factors including the nature of the substrate and ionic composition of the electrolyte, the presence of impurities, the temperature and the buffer pH. The ion distribution near a planar wall at $z = 0$ with potential $\phi(z)$ is known from statistical thermodynamics: $n_k = n_k(\infty)\exp(-z_k e\phi/k_B T)$ where k_B is the Boltzmann constant and T is the absolute temperature of the solution. In order that this expression be a steady solution of Eq. (5) we must have the ▶Einstein relation

$$D_k/\nu_k = k_B T\,. \tag{9}$$

Therefore Eq. (6) can also be written as

$$\boldsymbol{j}_k = -n_k \nu_k \nabla\psi_k + n_k \boldsymbol{u} \tag{10}$$

where $\psi_k = ez_k\phi + k_B T \ln n_k$ is called the chemical potential for the species k.

The Equilibrium Debye Layer

Suppose that the system is in the steady state and that there is no fluid flow or imposed electric fields. Further suppose that the geometry is such that the electrolyte-substrate interface is an iso-surface of ψ_k. Then it readily follows from Eqs. (5) and (10) and the boundary condition of no flux into the wall that $\nabla\psi_k = 0$ everywhere. Therefore, $n_k = n_k^{(\infty)}\exp(-z_k e\phi/k_B T)$ where $n_k^{(\infty)}$ is the ion concentration where the potential $\phi = 0$; usually chosen as a point very far from the wall. Using the solution for n_k in the charge density ρ_e and substituting in Eq. (4), we get the non-linear Poisson-Boltzmann equation for determining the potential

$$\nabla^2\phi = -\frac{4\pi e}{\varepsilon}\sum_{k=1}^{N} n_k^{(\infty)} z_k \exp(-z_k e\phi/k_B T)\,. \tag{11}$$

with the boundary condition $\phi = \zeta$ on walls. Equation (11) was the starting point of a detailed investigation of the structure of the ▶electric Debye layer (EDL) by Gouy and Chapman. The description in terms of Eq. (11) is therefore known as the Gouy-Chapman model of the EDL.

Equation (11) is a nonlinear equation. It can be linearized by expanding the exponential terms on the right hand side in Taylor series and discarding all terms that are quadratic or of higher order in ϕ, which gives

$$\nabla^2\phi - \kappa^2\phi = 0 \tag{12}$$

where

$$\kappa = \left[\sum_{k=1}^{N}\frac{4\pi z_k^2 e^2 n_k^{(\infty)}}{\varepsilon k_B T}\right]^{1/2} \tag{13}$$

is a constant determined by the ionic composition of the electrolyte. In arriving at Eq. (12) we used the condition $\sum_{k=1}^{N} n_k^{(\infty)} z_k = 0$ which expresses the fact that the bulk solution ($\phi = 0$) is free of net charge. It is easily verified that κ has units such that $\lambda_D = \kappa^{-1}$ defines a length scale that is called the Debye-Length, and the linearization of Eq. (11) that lead to Eq. (12) is known as the Debye–Hückel approximation. The solution to Eq. (12) near a charged plate of potential ζ may be written as $\phi = \zeta\exp(-\kappa z) = \zeta\exp(-z/\lambda_D)$ where z is distance normal to the plate. Thus, the potential due to the charged plate is shielded by the free charges in solution and the effect of the charge penetrates a distance of the order of the ▶Debye-length λ_D; which gives a physical meaning to this very important quantity. For *ordinary* water the Debye length is typically $1-10$ nm. The linearization proposed by Debye–Hückel is justified provided that $|z_k\phi| \ll k_B T/e$ uniformly in all space and for all k. At room temperature $k_B T/e \approx 30$ mV. However, for silica substrates $|\zeta| \sim 50-100$ mV in typical applications. Thus, the ▶Debye–Hückel approximation is often not strictly valid. Nevertheless, it is a very useful approximation because it enormously simplifies mathematical investigations related to the Debye layer.

Equation (12) is linear and can be solved analytically under fairly general conditions. If appears in several other contexts such as in the solution of the diffusion equation and in wave propagation problems with evanescent waves. If κ^2 were negative Eq. (12) would be identical to the Helmholtz equation.

Exact solutions to Eq. (11) are known only for symmetric electrolytes (that is, $N = 2$, $z_1 = -z_2 = Z$ where Z is positive) in certain special geometries.

Half Plane. In front of an infinite charged flat plate (defined as $z = 0$) charged to a fixed ζ potential, the solution to Eq. (11) is

$$\tanh\left[\frac{Ze\phi}{4k_B T}\right] = \tanh\left[\frac{Ze\zeta}{4k_B T}\right]\exp(-\kappa z) \tag{14}$$

where $z > 0$. This solution can also be used to describe the Debye layers at the walls of a planar channel provided that the channel walls are sufficiently far apart that their Debye layers do not overlap. Clearly, if ϕ and ζ are both sufficiently small that the hyperbolic tangent terms can be approximated by their respective one term Taylor

expansion, $\tanh x = x + \ldots$, then the Debye–Hückel theory $\phi(z) = \zeta \exp(-\kappa z)$ is recovered.

Between Parallel Plates. An exact solution of Eq. (11) can be written [4] for a pair of plates separated by a distance $2H$ and each held at a potential ζ. The origin $z = 0$ is chosen on one of the plates so that the second plate is located at $z = 2H$. It is convenient to introduce the intermediate variables $k = \exp(-Ze\zeta/k_B T)$ and Φ defined by $\sin\Phi = k^{-1/2}\exp[-Ze\phi/(2k_B T)]$. Then the solution may be expressed in terms of the elliptic integral $F(\Phi, k)$ defined as

$$F(\Phi, k) = \int_0^{\Phi} \frac{d\theta}{(1 - k^2 \sin^2\theta)^{1/2}} \,. \tag{15}$$

This solution (originally due to Langmuir) is

$$\kappa z = 2k^{1/2}[F(\pi/2, k) - F(\Phi, k)] \,. \tag{16}$$

For small potentials (in the Debye–Hückel limit) this can be shown to reduce to

$$\phi(z) = \zeta \frac{\cosh[\kappa(H - z)]}{\cosh(\kappa H)} \tag{17}$$

Circular Cylinders. An analytical solution for the region inside infinitely long circular cylinders is available only for Eq. (12). The potential is

$$\phi(r) = \zeta \frac{I_0(\kappa r)}{I_0(\kappa a)} \tag{18}$$

where r is the radial distance and a is the radius of the cylinder.

Electro-Osmotic Flow

In the presence of fluid flow exact analytical solutions of the full electrokinetic equations are rare. An exceptional situation arises when the applied electric field and streamlines of the flow are both in a direction of homogeneity along which there is no variation of any physical quantity. In such cases, the effect of the external influence (such as the applied field) is to produce motion such that all movement of charges are along surfaces of constant charge density and therefore the equilibrium charge density is not altered by the flow. Examples of such a situation are

1. An electric field is applied parallel to a flat plate driving an electro-osmotic flow with streamlines that are also parallel to the plate.
2. An electric field is applied between a pair of parallel plates driving an electro-osmotic flow with streamlines that are also parallel to the plate.
3. An electric field is applied along the cylinder axis resulting in a flow along the axis of the cylinder.

The component of Eq. (1) in the flow direction then reduces to

$$\mu\nabla^2 \boldsymbol{u} - \rho_e^{(eq)} \nabla\phi^{(ext)} = \mu\nabla^2 \boldsymbol{u} + \frac{\varepsilon}{4\pi}\nabla^2\phi^{(eq)}\nabla\phi^{(ext)} = 0 \,, \tag{19}$$

where $\phi^{(eq)}$ is the potential distribution in the equilibrium EDL and $\nabla\phi^{(ext)}$ is the constant applied field in the homogeneous direction. This may be integrated to give the flow velocity at any location

$$\boldsymbol{u} = \frac{\varepsilon\nabla\phi^{(ext)}}{4\pi\mu}[\zeta - \phi^{(eq)}] \,. \tag{20}$$

If the solution to the problem of the equilibrium double layer $\phi^{(eq)}$ is known, then the velocity is determined by the above formula. Thus, the solutions to the respective flow problems for the equilibrium situations considered in the previous subsection are readily written down. Solution to the electrokinetic equations is facilitated if the Debye layer thickness λ_D may be assumed small compared to the characteristic channel width w_0. This however is not usually the case in nanochannels since w_0 and λ_D are both on the order of nanometers. Exact analytical solutions are therefore rare except in situations with a high degree of symmetry such as noted above.

Molecular Models

At scales approaching a nanometer or less, the continuum equations are entirely inappropriate. In such situations the fluid must be described as a collection of interacting atoms. The equations of motion of these atoms can be evolved in time by computer simulation, a procedure known as Molecular Dynamics. A very brief overview of Molecular Dynamics is provided here, for further details see the entry on that topic in this volume.

Dynamical Equations

The equations of motion of the individual atoms are given by the second law of Newton:

$$m_i \frac{d^2\boldsymbol{r}_i}{dt^2} = -\nabla_i V \,. \tag{21}$$

Here m_i is the mass of the ith atom and $\boldsymbol{r}_i$ is the position vector at time t. The symbol ∇_i indicates the gradient operator with differentiation with respect to the co-ordinates of the ith atom only, that is, in cartesian co-ordinates the right hand side has components $-\partial V/\partial x_i$, $-\partial V/\partial y_i$ and $-\partial V/\partial z_i$. The potential V which depends on the instantaneous location of every atom contains all the information

about how the atoms are held together within individual molecules as well as how two different molecules interact. A full determination of the potential V from first principles will require the solution of the quantum mechanical problem involving interactions of all of the nuclei and electrons. Such a computation is not practical in general but approximations that involve neglecting effects that are not dominant allow approximate interaction potentials to be obtained.

Interaction Potentials

First, the potential V is split into two parts, the *bonded* and *non-bonded* ones

$$V = V_{\text{bonded}} + V_{\text{non-bonded}}\,. \tag{22}$$

The first, V_{bonded} takes into account all of the forces that keep the atoms bound together into a molecule, the second, $V_{\text{non-bonded}}$ describe the interactions between the atoms within a molecule with those within another molecule.

The Bonded Potential As a simple example one might consider a diatomic molecule. Here one may write

$$V_{\text{bonded}} = \frac{1}{2}k_r(r - r_{\text{e}})^2 \tag{23}$$

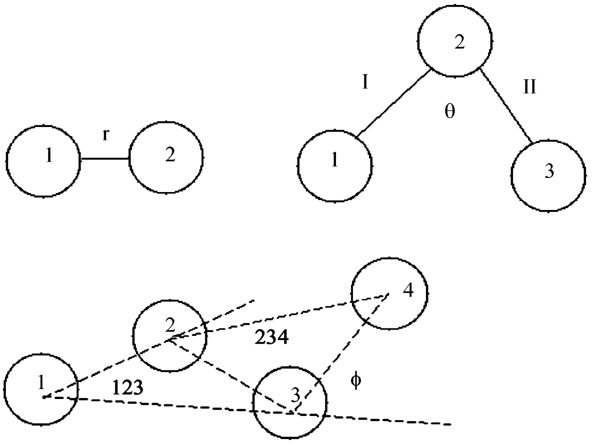
where r_{e} is the equilibrium bond length, r is the instantaneous distance between the atoms and k_r is a positive constant (like a *spring constant*) that determines the frequency of oscillation of the dumbell shaped molecule about its equilibrium shape.

If there are three atoms 1, 2 and 3 connected by two bonds I and II then there will be two terms like Eq. (23), one for bond I and one for bond II with possibly different values of k. In addition, there would be a contribution

$$V_{\text{bonded}} = \frac{1}{2}k_\theta(\theta - \theta_{\text{e}})^2 \tag{24}$$

due to the fact that the bond can flex so that the bond angle undergoes small oscillations about the equilibrium value $\theta = \theta_{\text{e}}$.

If there are four atoms then there is an additional mode of distortion of the molecule. Atoms 1, 2 and 3 always lie on a plane, call this the plane 123. This plane however may not coincide with the plane 234 on which atoms 2, 3 and 4 lie. If it does, then we have a coplanar molecule, otherwise there is a non-zero angle ϕ between the two planes which could change as the molecule moves around and interacts with neighboring ones (see Fig. 1). In general there is a contribution to the potential that determines changes in ϕ. This piece of the bonded potential is usually written as



Electrokinetic Flow and Ion Transport in Nanochannels, Figure 1 Sketch showing the bonded interactions in the case of two, three and four atom molecules in an MD simulation

$$V_{\text{bonded}} = \frac{1}{2}\sum_{m=1}^{\infty} k_\phi^{(m)}\left[1 + \cos(m\phi - \phi_m)\right]. \tag{25}$$

The right hand side is nothing but one way of writing a Fourier series expansion of the potential in ϕ. Since the potential has to be periodic with period 2π it can always be written in this way for some values of the constants $k_\phi^{(m)}$ and ϕ_m. For $m = 1$, the ϕ dependence is given by $[1 + \cos(\phi - \phi_1)]$. This is identical to the potential that describes the motion of a simple pendulum where ϕ is the angular displacement and $\phi = \phi_1$ the position of stable equilibrium. It is useful to recall that the pendulum has two kinds of motion, oscillations about the position of stable equilibrium and rotation about its point of support. Similarly, Eq. (25) allows both small oscillations about equilibrium as well as full 360° rotations. For example, the ethane molecule C_2H_6 rotates very easily around the C–C bond. For longer molecules V_{bonded} is constructed by first identifying all bonds between atom pairs and adding up the contributions of the form of Eq. (23). Then all the bond angles are identified and each contributes a term like Eq. (24). Finally, all of the angles between planes of atoms are identified and each such angle will result in a contribution of type Eq. (25). This procedure describes the simplest kind of bonded interactions possible. The forms of Eqs. (23), (24) and (25) are not the only possible description of these interactions, different cross terms (such as *stretch-bend*) may be included for greater accuracy.

The Non-Bonded Potential It is convenient to decompose the non-bonded potential into 1-body, 2-body, 3-body, ... interactions:

$$V_{\text{non-bonded}} = \sum_{i} U_i + \sum_{i<j} U_{ij} + \cdots \tag{26}$$

Here U_i is the potential of atom i due to some external field (such as an applied electric field or due to confinement in a finite domain such as within the walls of a nanotube). The i–j pair interactions describe the force between atoms i and j in the absence of all other atoms. This however is only an approximation to the true force, because the presence of a third atom in the vicinity would generally cause some distortion in the electron cloud around atoms 1 and 2 and therefore change the interaction force. Such three and higher body interactions are however relatively small and are usually neglected. That is, the series Eq. (26) is usually truncated at the second term. We now discuss the most common types of pair interactions.

If a pair of atoms i–j on two different molecules carry a net charge of Q_i and Q_j then there is a Coulomb contribution to the non-bonded potential that arises out of this pair interaction

$$V_{\text{non-bonded}} = \frac{Q_i Q_j}{r_{ij}} \tag{27}$$

(in CGS units) where r_{ij} is the distance between the pair. There is an analogous contribution for each distinct pair of atoms and the total potential is given by the sum of all such terms. For example, in an ionic solution the ions will interact via such Coulomb interactions. In addition, every pair of atoms (charged or not) that sit on different molecules interact via an intermolecular potential for which most often the Lennard-Jones form is used:

$$V_{\text{non-bonded}} = 4\varepsilon \left[\left(\frac{\sigma}{r_{ij}}\right)^{12} - \left(\frac{\sigma}{r_{ij}}\right)^{6} \right]. \tag{28}$$

The parameters ε and σ depends on the kinds of atoms in the i–j pair. The important thing about the ▶Lennard-Jones potential is that it is repulsive at short range (characterized by a length scale σ) and attractive at long range with the attractive interaction inversely proportional to the sixth power of the distance. The short range repulsion is caused by the mutual repulsion of the electron clouds of the atoms that keep the atoms apart. The attractive interaction at long range is known as the ▶Van-der Waals attractions. For an explanation of its origin the reader is referred to the contribution on that subject in this volume. In addition particular classes of applications require the addition of special kinds of interaction potentials (e. g. hydrogen bonds, hydrophobic effects etc.) and these are described in more specialized books and papers.

Numerical Integration

Computer simulation of the molecular motion calls for the numerical integration of Eq. (21) for each atom starting from some random initial conditions. Various algorithms for doing this are known with their advantages and drawbacks. The simplest most robust and almost universally used technique is the Velocity-Verlet algorithm also known as the *Leap Frog Method*. To apply this algorithm, we first write Eq. (21) as a pair of first order equations:

$$\frac{\mathrm{d}\boldsymbol{r}_i}{\mathrm{d}t} = \frac{\boldsymbol{p}_i}{m_i} \tag{29}$$

$$\frac{\mathrm{d}\boldsymbol{p}_i}{\mathrm{d}t} = \boldsymbol{f}_i = -\nabla_i V\,. \tag{30}$$

Here $\boldsymbol{p}_i$ is the momentum of atom i and $\boldsymbol{f}_i$ is the force on it. The velocity Verlet algorithm with step size δt is:

$$\boldsymbol{p}_i(t + \frac{1}{2}\delta t) = \boldsymbol{p}_i(t) + \frac{\delta t}{2}\boldsymbol{f}_i(t) \tag{31}$$

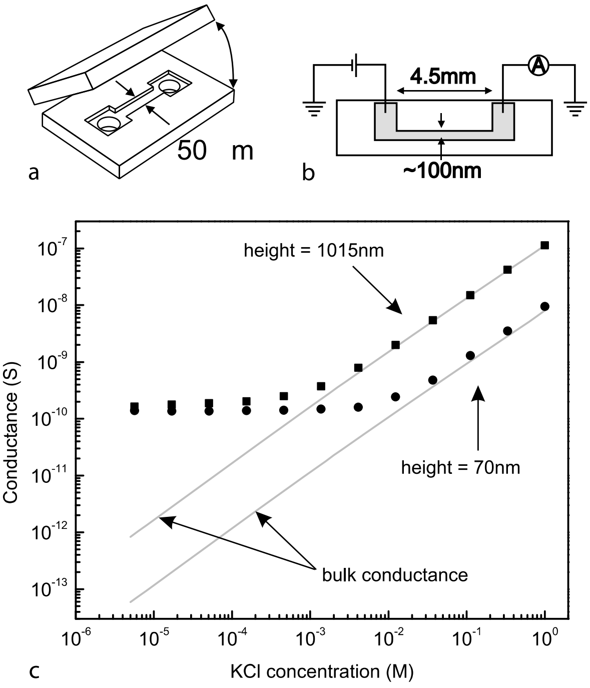
$$\boldsymbol{r}_i(t + \delta t) = \boldsymbol{r}_i(t) + \boldsymbol{p}_i(t + \frac{1}{2}\delta t)\frac{\delta t}{m_i} \tag{32}$$

$$\boldsymbol{p}_i(t + \delta t) = \boldsymbol{p}_i(t + \frac{\delta t}{2}) + \frac{\delta t}{2}\boldsymbol{f}_i(t + \delta t). \tag{33}$$

Key Research Findings

The research literature on nanopores or nano-channels of biological origin is vast and spans more than half a century. These channels are a fraction of a nanometer to a few nanometer wide and are made of proteins embedded in lipid bi-layer membranes. The main scientific questions here relate to the physical mechanism of selectivity and gating, that is, questions such as what makes a sodium channel permeable to only sodium ions but not to potassium or calcium ions which are very similar. Further, by what physical mechanism do these channels open and close in response to voltage changes, ligand binding and other events? Electrokinetic flows is usually not the focus in this area of study and hence this is an area that we do not touch upon. The reader whose primary interest is in nanopores in the biological context could use [1] as an introduction to that subject.

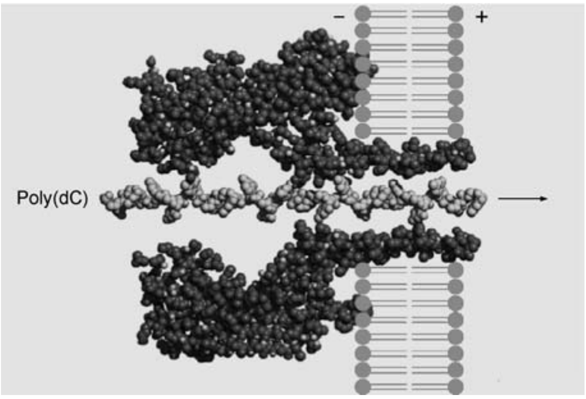
In the realm of artificial nano-channels in the biotechnology context, a key issue concerns the electrical conductance of such channels. Artificial nano-channels are



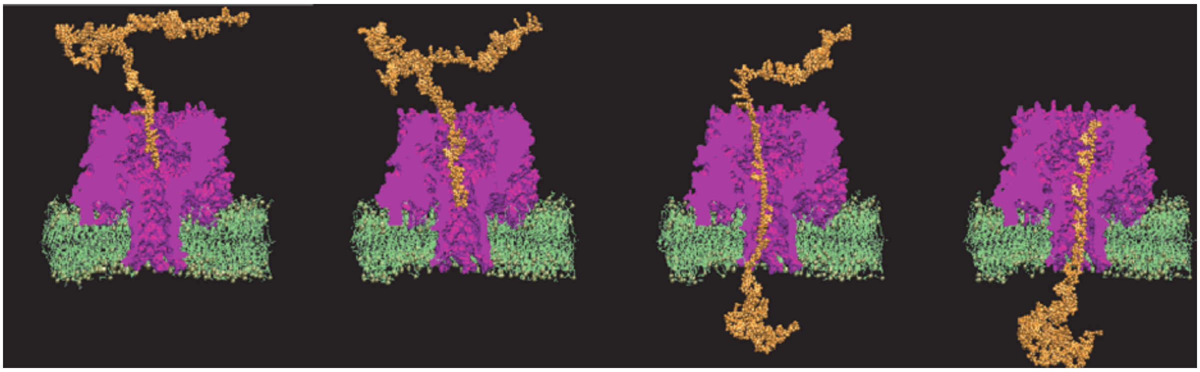
Electrokinetic Flow and Ion Transport in Nanochannels, Figure 2 The measured conductance of a nanochannel as a function of electrolyte concentration showing the transition from the expected behavior (lines) to a conductance determined by the surface charge. Panels (**a**) and (**b**) show the set up of the experiment [11]

tens of nanometers wide, so a length of the channel equal to its diameter contains of the order of a million water molecules. The interface between the channel wall and the water that it contains typically has an electrostatic charge which is characterized by its zeta-potential typically in the range of tens of millivolts. In an ionic solution the wall charge results in the formation of a Debye Layer of counter-ions next to it. Nano-channels differ from micro-channels with respect to the thickness of this Debye layer relative to the channel diameter: whereas in microchannels this fraction is extremely small, in a nanochannel it is typically of order unity. As a result, the conductance of nano-channels differ from the bulk conductance (conductance per unit volume of the electrolyte in the absence of confining walls multiplied by the volume of the channel). The channel conductance is found to depend on the electrolyte concentration as well as on the surface charge density of the channel. The dependence is shown in Fig. 2 and may be summarized as follows: at sufficiently high concentrations of the electrolyte the measured conductance approaches the bulk conductance which is proportional to the electrolyte concentration. As the concentration is lowered, the conductance deviates from the proportionality relation and approaches a value independent of the concentration. This constant value is higher the higher the surface charge density is in the nano-channel. Further, the transition from constant to proportionate behavior with respect to the electrolyte concentration shifts upwards with higher surface charge. This is because at high electrolyte concentrations, the Debye Layer is very thin so that most of the current is carried by the ions in the core of the channel. Thus, the conductance approaches the bulk conductance. At low concentrations, there are very few co-ions and the nano-channel attracts a sufficient number of counter-ions so that the channel as a whole is charge neutral. The conductance is determined by the number of such counter-ions present and this is determined by the surface charge not on the ion density in the bulk electrolyte. Thus, the conductance becomes independent of the electrolyte concentration and increases with the surface charge. A quantitative calculation based on the above physical picture gives reasonably good agreement with the measured data as seen in Fig. 2. In view of the fact that the conductance is controlled by the surface charge, it has been suggested that it may be possible to control the conductance of a channel by controlling the surface charge by an externally applied voltage. In fact, not just the electrical conductance but the flux of macro-ions can be controlled this way creating a *nano-transistor* that can be tuned to be selectively permeable to specific biomolecules much like the "gated" nanopores in biological systems.

Just as a voltage can drive charged macro-ions through nanopores, long chains of such ions or ▶polyelectrolytes (charged polymers) can also be driven through nanopores (see Fig. 3 and Fig. 4). Research in this area is driven by the possibility of developing a new technology for super



Electrokinetic Flow and Ion Transport in Nanochannels, Figure 3 Molecular model showing a single strand of poly(dC) DNA passing through an α-hemolysin protein pore in a lipid bi-layer membrane. The surrounding water molecules have not been shown [12]



Electrokinetic Flow and Ion Transport in Nanochannels, Figure 4 A sequence of four frames (movie available on the online version of this volume) from a MD simulation movie showing a single stranded DNA molecule being pulled through an alpha Hemolysin nanopore by the application of an electric field [13]

fast DNA sequencing. The central fact is that the passage of a polyelectrolyte through a nanopore produces a measurable change in the pore conductance. It has been shown that using this effect DNA in solution can be detected and counted at the single molecule level. Further, based on the duration of the blockage the length of the DNA can be characterized with a margin of error of the order of a few tens of bases. Using a combination of translocation time and intensity of the current blockage, homopolymers of DNA and RNA made of pyridine bases can be distinguished from pyrimidines. Furthermore, block co-polymers such as AAAAAA.....CCCCC..... containing more than about 30 or so repeating units can be distinguished from other similar structures. A fundamental theoretical question in this area related to electrokinetic flows is: what determines the translocation time of a single polyelectrolyte across a nanopore? It has been shown that the shape of the distribution function for translocation times can be explained by means of a probabilistic *drift diffusion process*. A calculation of the average speed of translocation of polyelectrolytes of moderate size based on the continuum electrokinetic equations yields values consistent with the measured ones for solid state nanopores (diameter ~ 10 nm). The majority of theoretical papers in this area have focussed on the issue of how the mean translocation time scales with the length of the polymer and there appears to be different scaling regimes for short vs. long polymers (see [5] and references within).

Another key question relates to electroosmotic flow of water in nanochannels where the focus is on the question on whether or not any deviations from the predictions of the classical continuum electrokinetic equations is observable. Computer simulations by MD has shown that the flow profile shows considerable deviation from the classical regime in certain parameter ranges that can be attributed to a variety of effects (hydrogen bonding of water to negatively charged surfaces, the effect of charge oscillations due to correlations etc.) A fundamental question which is broader than the subject of electrokinetic flows concerns the applicability of the no-slip boundary condition to micro/nanoscale flows. It appears that the so called *Navier slip boundary conditions* $b\,\partial_z U + U = 0$ better describes the flow at small scales where U is the velocity along the impermeable surface and z is the direction perpendicular to it. The value of b depends on the wetting properties of the surface among other things and is closer to *no-slip* ($b = 0$) for hydrophyllic surfaces. Further discussion on this issue may be found in the contribution *Boundary Slip of Liquids* in this volume.

Future Directions for Research

The subject of flow and transport in nanochannels is a very young one and there are many avenues for theoretical as well as experimental investigations and the potential for many novel devices that might be developed as a result of these investigations. The idea of a *Nano Transistor* that can be tuned to be selectively permeable to certain macromolecules while blocking others is an area that may see some rapid development on the practical side. The same can be said about the idea of sequencing biopolymers using nanopore translocation. There are deep theoretical questions surrounding the issue of how fluid and ions flow through nanochannels and in what ways such transport differs from expectations based on classical hydrodynamics and the Poisson-Boltzmann equation [10]. The effect of correlations, finite size of molecules, hydrogen bonding and other short range interactions, wettability are all

expected to play a role and it is in extending our understanding of fluid flow and ion transport to account for these effects that the future challenge lies.

Synonyms

Electroosmotic flow in porous media; Electroosmosis in porous media

Definition

A porous medium is referred to as a solid frame or matrix permeated by an interconnected network of pores (voids) filled with a fluid (liquid or gas). In the field of micro- and nanofluidics, the term electroosmotic flow (usually interchangeable with electroosmosis or electrokinetic flow) is defined as the migration of bulk ionic liquid due to the interaction between an applied electric field tangentially along a charged surface and the excess net charge density in the electric double layer of such a charged surface. Therefore, electrokinetic flow in porous media is referred to as the motion of bulk ionic liquid flowing through a porous medium as a result of the interplay of an applied electric field and the excess charge density in the electric double layer of the charged porous structure.

Overview

Fluid flow through porous media is a subject of much interest and has a wide spectrum of applications in applied science and engineering. The discovery of electrokinetic flow in porous media can be traced back to the early 1800s when Reuss observed water migration through porous clay diaphragms under an applied electric field. Applications of electrokinetic flow in porous media can be found in many technological processes, such as dewatering of waste sludge and removing poisonous heavy metal ions from contaminated soils for environmental remediation [1].

The charging mechanisms of the porous solid–liquid interface are complex, possibly including the asymmetric dipoles of water molecules residing at the solid–liquid interface, adsorption of ions, disassociation of ionic groups, charge separation, etc. The presence of surface charges will influence the distribution of nearby ions in the solution. Counter-ions (i. e., ions of opposite charge)

are attracted towards the surface, while co-ions (i. e., ions of like charge) are repelled from the surface. This electrostatic interaction, together with the random thermal motion of the ions, leads to the formation of the so-called *electric double layer* (EDL). The model of EDL was developed by Gouy and Chapman in 1906, and then improved by Stern in 1924 [1]. According to Stern's model, the EDL consists of two layers: a compact layer and a diffuse layer. The compact layer, usually less than 1 nm, exists immediately next to the solid surface, where counter-ions are strongly attracted to the solid surface and are thus immobile. The diffuse layer of the EDL is the layer from the compact layer to the bulk liquid, and its thickness ranges from several nanometers to micrometers, depending on liquid properties. Compared to the ions in the Stern layer, the ions in the diffuse layer are less influenced by the charged surface and hence are mobile.

Within the diffuse layer of the EDL, there is an excess of counter-ions over co-ions, and thus the net charge density is not zero so as to neutralize the surface charge. If an electric field is applied tangentially along a charged surface, the electric field will exert a Coulombic force on the ions in the diffuse layer, resulting in a net migration of the liquid in the EDL region. This is called *electroosmosis* (EO). In a charged microcapillary, due to viscous forces the flow can be developed beyond the EDL region to the rest of the liquid in the microcapillary, leading to a bulk *electroosmotic flow* (EOF).

With the rapid development of micro- and nanofluidics in the past decade, electroosmosis has attracted wide attention due to its pumping capability. Compared to conventional mechanical pumping, EO pumping has numerous advantages including ease of fabrication and control, no need for moving parts, high reliability, no noise, etc. Extensive theoretical and experimental studies on EOF have been reported to further physical understanding and realize more advanced applications of this electrokinetic phenomenon.

Since electroosmosis is an interfacial phenomenon, use of capillaries packed with solid porous structures can greatly enlarge the interfacial area, and thus significantly enhance the pressure-building capacity of EOF. Taking advantage of such high pressure-building capacity of the EOF in packed capillaries, two technologies have been developed, namely capillary electrochromatography [2] for chemical analyses and molecular detection, and high-performance electrokinetic micropumps [3]. The first effort made to design electrokinetic micropumps may be attributed to Paul et al. who reported the ability to generate high pressures using electrokinetic pumping of liquid through porous media. Pressures in excess of 8000 psi have been achieved using silica capillaries packed with micrometer-size silica beads. Since then, a variety of electroosmotic micropumps have been developed [4].

Of the numerous methods developed to pack stationary porous medium/column in a microcapillary, two widely used approaches involve the packed beads column and the in situ polymerized monolithic column [5]. The preparation of the packed beads column includes the fabrication of retaining frits within a microcapillary as well as subsequent packing of micro-sized silica particles into the capillary. To avoid the problems associated with frit formation and bead packing, an alternative method is to prepare the monolithic column by performing in situ silicate- or photo-polymerization within a capillary using either thermal or UV initialization of polymer mixture solutions.

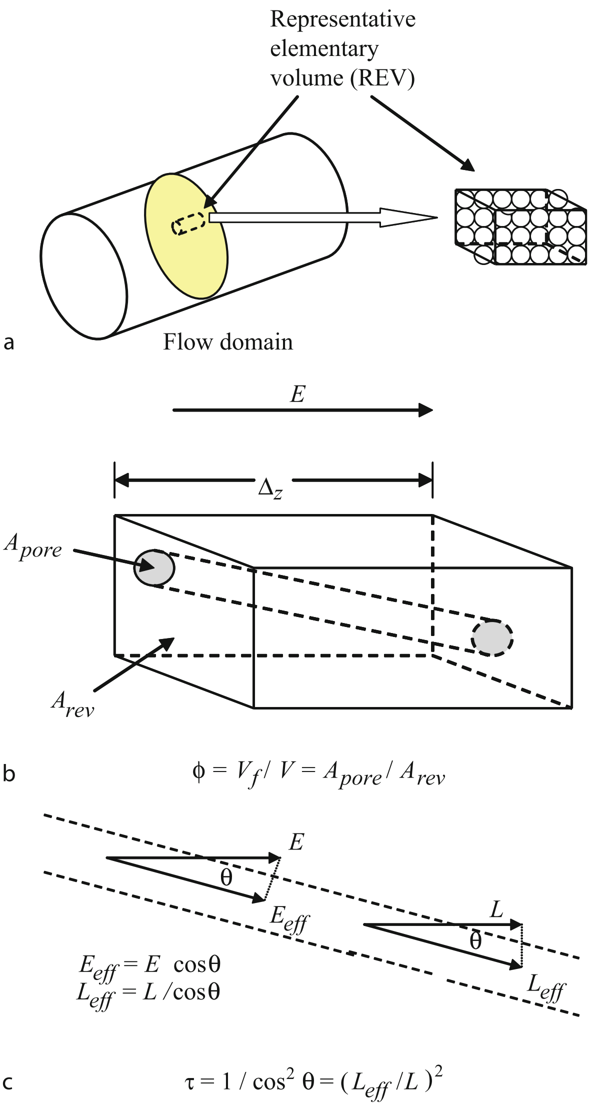
E

Basic Methodology

Method of Volume Averaging

In a natural porous medium, the distribution of pores with respect to shape and size is irregular. On the pore scale (microscopic scale) the flow quantities such as velocity, pressure, etc., are also irregular. But in typical experiments the quantities of interest are measured over areas that cross many pores and such space-averaged (macroscopic) quantities change in a regular manner with respect to space and time and hence are amenable to theoretical treatment. A macroscopic variable is defined as an appropriate mean over a sufficiently large *representative elementary volume* (REV). It is assumed that the result is independent of the scale of the REV. As illustrated in Fig. 1a, the length scale of the REV is much larger than the pore scale, but considerably smaller than the length scale of the macroscopic flow domain.

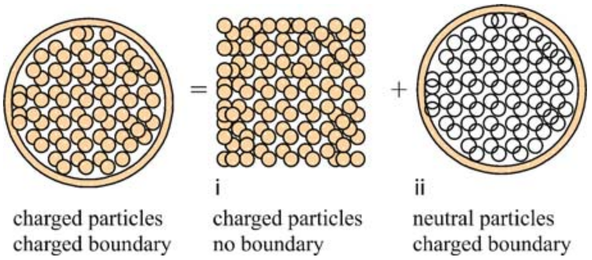
Under the volume averaging method, two major geometric constraint factors to characterize a porous medium are called porosity and tortuosity. The porosity is defined as $\phi = V_f/V$, where V_f and V are the void and total volumes of the porous medium, respectively, as illustrated in Fig. 1b. The other factor, as illustrated in Fig. 1c, tortuosity includes the non-alignment of most flow channels with the electric field, which is applied along the capillary axis. The fluid flow in a capillary packed with solid spherical particles will occur only within the interparticulate spaces. The individual flow channels comprise a highly complex, directionally non-uniform network, of which only a fraction will be aligned axially with the electric field. Most flow channels will be off-axis with respect to the field resulting in a lower effective field strength (decreased by a factor of $\cos\theta$). In addition, the fluid flowing in an off-axis channel must travel a greater distance (increased by a factor of $1/\cos\theta$) for a given displacement along the capillary axis. The tortuosity is defined



Electrokinetic Flow in Porous Media, Figure 1 Schematic illustration of (**a**) representative elementary volume (REV), (**b**) porosity, and (**c**) tortuosity. The length scale of the REV is much larger than the pore scale, but considerably smaller than the length scale of the macroscopic flow domain

as $\tau = 1/\cos^2\theta = (L_{\rm eff}/L)^2$, where $L_{\rm eff}$ is the effective length of travel for flow along the pore path and L is the physical length of the porous structure [6]. Combination of above factors results in the reduction of the velocity component along the axis by a factor of ϕ/τ.

For simplicity, we consider a charged cylindrical microcapillary of radius $R_{\rm w}$ packed with charged mono-sized microparticles of diameter $d_{\rm p}$. The liquid in the microcapillary is assumed to be an incompressible, Newtonian, mono-valence electrolyte of density ρ and viscosity μ. The zeta potentials of the inner wall surface and the particle



Electrokinetic Flow in Porous Media, Figure 2 Schematic illustration of decomposition of the overall macroscopic EOF velocity in a packed capillary into two separate components due to: (i) the contributions from homogeneous densely packed with charged microparticles, and (ii) the contributions from the charged capillary wall with neutral packing

surface are $\zeta_{\rm w}$ and $\zeta_{\rm p}$, respectively. When an external electric field, E_0, is applied along the axis of the microchannel, the electrolyte in the microcapillary will move due to the electroosmosis resulting from the interaction of the EDL (close to the interface of the particles as well as the channel wall) and the applied electric field. Joule heating effect due to axially imposed electric field is ignored in our model development. The overall macroscopic EOF velocity in the packed capillary is decomposed into two separate components due to the contribution from homogeneous densely packed charged microparticles and the contribution from the charged capillary wall with neutral packing, as illustrated in Fig. 2.

Macroscopic EOF in Homogeneous Charged Microspheres

Interstitial EOF Velocity

The present model development is based on a semi-heuristic model of flow through solid matrices using the concept of hydraulic diameter, which is also known as the *Carman–Kozeny theory* [7]. The theory assumes the porous medium to be equivalent to a series of parallel tortuous tubules. The characteristic diameter of the tubules is taken to be a hydraulic diameter or effective pore diameter; this diameter is conventionally defined as [6]

$$d_{\rm pore} = \frac{4 \times \text{Void Volume}}{\text{Surface Area}} = \frac{4\,\phi_\infty}{A_{\rm o}(1-\phi_\infty)} \qquad (1)$$

where ϕ_∞ is the average porosity of the porous medium. $A_{\rm o}$ is the volumetric or specific area based on the solid volume, i. e., $A_{\rm fs}/V_{\rm s}$, where $A_{\rm fs}$ is the interfacial area between the fluid and the solid phase and $V_{\rm s}$ is the solid volume. For spherical particles considered in this work $A_{\rm o} = 6/d_{\rm p}$, where $d_{\rm p}$ is the diameter of spherical particles. So the

hydraulic diameter can be expressed as

$$d_{\text{pore}} = \frac{2\,\phi_\infty}{3\,(1-\phi_\infty)} d_{\text{p}} \tag{2}$$

The interstitial tubules are cylindrical with an effective diameter (pore size) $d_{\text{pore}} = 2R_{\text{pore}}$. The inner wall of the cylindrical tubules is charged with zeta potential ζ_{p}. Because of the low Reynolds number flow, the interstitial EOF velocity $u_{\text{i}}(r)$ in each tubule is governed by the Stokes equation [7]

$$\mu \frac{1}{r}\frac{\text{d}}{\text{d}r}\left[r\frac{\text{d}u_{\text{i}}(r)}{\text{d}r}\right] + E_0\rho_{\text{e}}(r) + P_{\text{z}} = 0 \quad (0 \leqslant r \leqslant R_{\text{pore}}) \tag{3}$$

where $P_{\text{z}} = \Delta P/L$ is the global pressure gradient along the flow direction (L is the physical length of the flow domain). In the present discussion, no global pressure gradient is applied, i. e., $P_{\text{z}} = 0$. It should be pointed out here that from a microscopic point of view, a local backpressure gradient may be induced where the EOF becomes non-uniform due to the complicated geometry and packing conditions. For instance, at narrow constrictions the local electric field strength becomes higher if the porous packing has a lower permittivity than the working fluid. As we know, the EOF velocity is proportional to the electric field strength. Thus the local EOF tends to be strengthened to increase local velocity. When the EOF is non-uniform, local pressure-driven backflow must be induced to maintain the local mass conservation [8]. However, the geometrical non-uniformity and the induced local pressure are highly random within the bulk packing except at the end of the packed capillary – the interface of the retaining frits, where the flow path may subject to drastic decrease in cross-sectional area, depending on the quality of the frits. In the present discussion the end frit effect is ignored and we focus on the electroosmosis-driven flow through the porous packing. Under the space averaging method, the overall effect of the random local pressure gradient vanishes. Therefore the porous media is assumed as equivalent parallel tubules of uniform cross-sectional area without global pressure gradient.

Parameter $\rho_{\text{e}}(r)$ in Eq. (3) is the local volumetric charge density due to the presence of the EDL inside each interstitial tubule, and it is governed by the Poisson equation [1]:

$$\frac{1}{r}\frac{\text{d}}{\text{d}r}\left[r\frac{\text{d}\psi_{\text{i}}(r)}{\text{d}r}\right] = -\frac{\rho_{\text{e}}(r)}{\varepsilon_{\text{r}}\varepsilon_0} \quad (0 \leqslant r \leqslant R_{\text{pore}}) \tag{4}$$

where ε_{r} is the dielectric constant of the electrolyte and ε_0 is the permittivity of vacuum. Substituting Eq. (4) into Eq. (3), and using the following boundary conditions

$$\left.\frac{\text{d}u_{\text{i}}}{\text{d}r}\right|_{r=0} = 0 \quad \left.\frac{\text{d}\psi_{\text{i}}}{\text{d}r}\right|_{r=0} = 0 \tag{5a}$$

$$u_{\text{i}}|_{r=R_{\text{pore}}} = 0 \quad \psi_{\text{i}}|_{r=R_{\text{pore}}} = \zeta_p \tag{5b}$$

we can obtain an analytical expression for the velocity distribution, which takes the form

$$u_{\text{i}}(r) = -\frac{\varepsilon_{\text{r}}\varepsilon_0}{\mu}E_0\zeta_{\text{p}}\left[1 - \frac{\psi_{\text{i}}(r)}{\zeta_{\text{p}}}\right] \tag{6}$$

Under the volume averaging method, the macroscopic superficial velocity (also called the Darcy velocity) of the fluid over the representative elementary volume can be expressed by taking into account the tortuosity τ and the porosity ϕ, as

$$\begin{aligned} u_{\text{Di}} &= \frac{\phi}{\tau}\langle u_{\text{i}}\rangle = \frac{\phi}{\tau}\frac{2}{R_{\text{pore}}^2}\int_0^{R_{\text{pore}}} r u_{\text{i}}(r)\text{d}r \\ &= -\frac{\varepsilon_{\text{r}}\varepsilon_0}{\mu}E_0\zeta_{\text{p}}\frac{\phi}{\tau}(1-G) \end{aligned} \tag{7}$$

where

$$G = \frac{2}{\zeta_{\text{p}}R_{\text{pore}}^2}\int_0^{R_{\text{pore}}} r\psi_{\text{i}}(r)\text{d}r$$

and $\phi = \phi(r)$ is the local porosity distribution of the porous medium. In the literature, $\phi(r)$ is assumed to take a form of [7]

$$\phi(r) = \phi_\infty\left[1 + C_0\exp\left(-N\frac{R_{\text{w}}-r}{d_{\text{p}}}\right)\right] \quad (0 \leqslant r \leqslant R_{\text{w}}) \tag{8}$$

where $C_0 = 1.4$ and $N = 5$ are empirical constants.

Interstitial EDL Potential Field

The interstitial EDL potential distribution ψ_{i} in each tubule is governed by the Poisson–Boltzmann (P–B) equation, which is expressed as [1]

$$\frac{1}{r}\frac{\text{d}}{\text{d}r}\left[r\frac{\text{d}\Psi_{\text{i}}(r)}{\text{d}r}\right] = \kappa^2\sinh\Psi_{\text{i}}(r) \quad (0 \leqslant r \leqslant R_{\text{pore}}) \tag{9}$$

where $\kappa = (2n_0e_0^2/\varepsilon_{\text{r}}\varepsilon_0k_{\text{b}}T)^{1/2}$, dimensionless EDL potentials $\Psi_{\text{i}} = e_0\psi_{\text{i}}/k_{\text{b}}T$ and $\Psi_{\text{ip}} = e_0\zeta_{\text{p}}/k_{\text{b}}T$, e_0 is the elementary charge, n_0 is the ionic concentration in the bulk phase (i. e., far from the charged tubular wall), k_{b} is the Boltzmann constant, and T is the absolute temperature.

The boundary conditions given by Eq. (5a,5b) can be rewritten as

$$\left.\frac{\mathrm{d}}{\mathrm{d}r}\Psi_\mathrm{i}\right|_{r=0} = 0 \qquad \Psi_\mathrm{i}|_{r=R_\mathrm{pore}} = \Psi_\mathrm{ip} \tag{10}$$

Because of nonlinearity, the Poisson–Boltzmann equation (i. e., Eq. (9)) can be solved numerically. Using the Debye–Hückel approximation, an analytical solution of Eq. (9) for the EDL potential can be obtained as

$$\Psi_\mathrm{i}(r) = \Psi_\mathrm{ip}\frac{I_0(\kappa r)}{I_1(\kappa R_\mathrm{pore})} \quad \text{or} \quad \psi_\mathrm{i}(r) = \zeta_\mathrm{p}\frac{I_0(\kappa r)}{I_1(\kappa R_\mathrm{pore})} \tag{11}$$

where I_0 and I_1 are the zero-order and first-order modified Bessel functions, respectively.

Macroscopic EOF in a Charged Microcapillary Packed with Neutrally Charged Microspheres

EOF Velocity Field

Now we consider a charged cylindrical microcapillary of radius R_w, with the inner surface charged with zeta potential ζ_w. Inside the microchannel there are densely packed, neutrally charged spherical microparticles of diameter d_p. The Brinkman momentum equation, which originally was derived for a pressure-driven Darcy flow in porous media, then has been generalized by Brinkman to account for the inertial forces, pressure gradient, body forces, and shear stresses [6]. In the present situation, no pressure is exerted and hence no pressure gradient is present. Further, due to low Reynolds number flow in micro-sized pores, the macroscopic inertial force is ignored. The body force is the columbic force due to the interaction of the EDL and the external electric field. Thus the modified Brinkman momentum equation used for describing the macroscopic EOF of an incompressible, Newtonian electrolyte solution in a packed microcapillary under a steady state can be expressed as

$$\mu_\mathrm{eff}\frac{1}{r}\frac{\mathrm{d}}{\mathrm{d}r}\left[r\frac{\mathrm{d}u_\mathrm{Dw}}{\mathrm{d}r}\right] + E_0\phi\rho_\mathrm{ef}(r) - \left[\frac{\mu\phi u_\mathrm{Dw}}{K} + \rho\frac{F\phi u_\mathrm{Dw}^2}{\sqrt{K}}\right] = 0 \quad (0 \leqslant r \leqslant R_\mathrm{w}) \tag{12}$$

Here $u_\mathrm{Dw}(r)$ is the macroscopic EOF velocity (Darcy velocity) field through the neutrally charged porous medium inside the microcapillary. $\phi = \phi(r)$ is the local porosity distribution of the porous medium, determined by Eq. (8). The Darcy permeability K is defined by the *Carman–Kozeny* equation [7], $K = \phi^3 d_\mathrm{p}^2/a(1-\phi)^2$, and the inertial coefficient $F = b/\sqrt{a}\phi^{3/2}$, with $a = 150$ and $b = 1.75$ being the Ergun constants [6]. Parameter μ_eff is the effective fluid viscosity, a function of the fluid viscosity and the geometry of the permeable medium. For an isotropic porous medium, $\mu_\mathrm{eff}/\mu = 1/\phi\tau$ [6]. Parameter $\rho_\mathrm{ef}(r)$ is the average volumetric charge density due to the presence of the EDL, and it is assumed to satisfy the Boltzmann distribution:

$$\rho_\mathrm{ef}(r) = -2n_0e_0\sinh\left[\frac{e_0\psi_\mathrm{w}(r)}{k_\mathrm{b}T}\right] \quad (0 \leqslant r \leqslant R_\mathrm{w}) \tag{13}$$

Equation (12) is subject to the boundary conditions

$$\left.\frac{\mathrm{d}u_\mathrm{Dw}}{\mathrm{d}r}\right|_{r=0} = 0 \qquad \left.\frac{d\psi_\mathrm{w}}{\mathrm{d}r}\right|_{r=0} = 0 \tag{14a}$$

$$u_\mathrm{Dw}|_{r=R_\mathrm{w}} = 0 \qquad \psi_\mathrm{w}|_{r=R_\mathrm{w}} = \zeta_\mathrm{w} \tag{14b}$$

EDL Potential Field

The EDL potential distribution is governed by the Poisson–Boltzmann equation

$$\frac{1}{r}\frac{\mathrm{d}}{\mathrm{d}r}\left[r\frac{\mathrm{d}\Psi_\mathrm{w}(r)}{\mathrm{d}r}\right] = \kappa^2\sinh\Psi_\mathrm{w}(r) \quad (0 \leqslant r \leqslant R_\mathrm{w}) \tag{15}$$

which is subject to the boundary conditions

$$\left.\frac{\mathrm{d}\Psi_\mathrm{w}}{\mathrm{d}r}\right|_{r=0} = 0 \qquad \Psi_\mathrm{w}|_{r=R_\mathrm{w}} = \frac{e_0\zeta_\mathrm{w}}{k_\mathrm{b}T} \tag{16}$$

In the same fashion as for solving Eq. (9), the numerical method has to be used to solve Eq. (15). Of course, with the Debye–Hückel approximation, an analytical solution of the same format as Eq. (11) can also be sought, and is given by

$$\psi_\mathrm{w}(r) = \zeta_\mathrm{w}\frac{I_0(\kappa r)}{I_0(\kappa R_\mathrm{w})} \tag{17}$$

Analytical Solution of the Modified Brinkman Momentum Equation

No analytical solution is available for the modified Brinkman momentum equation (Eq. (12)), which can only be solved numerically. However, due to the low Reynolds number flow in the microcapillaries, we can safely ignore the high Reynolds number term, i. e., $\rho F\phi u_\mathrm{Dw}^2/\sqrt{K} \approx 0$. To emphasize only the electrokinetic wall effect, we can further assume that the porosity is uniform in the porous medium, i. e., $\phi = \phi_\infty$. Under these assumptions, we can

exclude the geometrical wall effect, and thus Eq. (12) can be simplified to

$$\frac{1}{r}\frac{\mathrm{d}}{\mathrm{d}r}\left(r\frac{\mathrm{d}u_{\mathrm{Dw}}}{\mathrm{d}r}\right)-\frac{a\tau(1-\phi_\infty)^2}{\phi_\infty d_\mathrm{p}^2}u_{\mathrm{Dw}} = -\frac{\phi_\infty^2\tau E_0}{\mu}\rho_\mathrm{e}(r) \quad (0\leqslant r\leqslant R_\mathrm{w}) \tag{18}$$

According to Poisson's equation

$$-\frac{\rho_\mathrm{e}(r)}{\varepsilon_\mathrm{r}\varepsilon_0}=\frac{1}{r}\frac{\mathrm{d}}{\mathrm{d}r}\left[r\frac{\mathrm{d}\psi_\mathrm{w}(r)}{\mathrm{d}r}\right] \tag{19}$$

Substituting Eq. (19) into Eq. (18) gives

$$\frac{1}{r}\frac{\mathrm{d}}{\mathrm{d}r}\left[r\frac{\mathrm{d}(u_{\mathrm{Dw}}-\eta\psi_\mathrm{w})}{\mathrm{d}r}\right]-\beta^2u_{\mathrm{Dw}}=0 \tag{20}$$

where

$$\eta=\frac{\phi_\infty^2\tau\varepsilon_\mathrm{r}\varepsilon_0E_0}{\mu} \quad \text{and} \quad \beta=\sqrt{\frac{a\tau(1-\phi_\infty)^2}{\phi_\infty d_\mathrm{p}^2}}$$

Introducing

$$v=u_{\mathrm{Dw}}-\eta\psi_\mathrm{w} \tag{21}$$

Eq. (20) becomes

$$\frac{1}{r}\frac{\mathrm{d}}{\mathrm{d}r}\left(r\frac{\mathrm{d}v}{\mathrm{d}r}\right)-\beta^2v=\beta^2\eta\psi_\mathrm{w} \tag{22}$$

In combination with Eq. (17), Eq. (22) can be rewritten as

$$\frac{1}{r}\frac{\mathrm{d}}{\mathrm{d}r}\left(r\frac{\mathrm{d}v}{\mathrm{d}r}\right)-\beta^2v=\beta^2\eta\zeta_\mathrm{w}\frac{I_0(\kappa r)}{I_0(\kappa R_\mathrm{w})} \tag{23}$$

This is a non-homogeneous zero-order modified Bessel equation, subject to the boundary conditions

$$\left.\frac{\mathrm{d}v}{\mathrm{d}r}\right|_{r=0}=0 \qquad v|_{r=R_\mathrm{w}}=-\eta\zeta_\mathrm{w} \tag{24}$$

A homogeneous solution and a particular solution to Eq. (23) are given respectively by

$$v_0(r)=-\frac{\kappa^2}{\kappa^2-\beta^2}\eta\zeta_\mathrm{w}\frac{I_0(\beta r)}{I_0(\beta R_\mathrm{w})} \tag{25a}$$

$$v_\mathrm{p}(r)=\frac{\beta^2}{\kappa^2-\beta^2}\eta\zeta_\mathrm{w}\frac{I_0(\kappa r)}{I_0(\kappa R_\mathrm{w})} \tag{25b}$$

The general solution to Eq. (23) can be constructed as

$$v(r)=v_0(r)+v_\mathrm{p}(r)=-\frac{\kappa^2}{\kappa^2-\beta^2}\eta\zeta_\mathrm{w}\frac{I_0(\beta r)}{I_0(\beta R_\mathrm{w})} + \frac{\beta^2}{\kappa^2-\beta^2}\eta\zeta_\mathrm{w}\frac{I_0(\kappa r)}{I_0(\kappa R_\mathrm{w})} \tag{26}$$

Making use of Eq. (17) and Eq. (21), we can obtain an analytical solution for the EOF velocity distribution in a charged microcapillary packed with neutrally charged microspheres:

$$u_{\mathrm{Dw}}(r)=v(r)+\eta\psi_\mathrm{w}(r) = -\frac{\varepsilon_\mathrm{r}\varepsilon_0}{\mu}E_0\zeta_\mathrm{w}\phi_\infty^2\tau\frac{\kappa^2}{\kappa^2-\beta^2} \times\left[\frac{I_0(\beta r)}{I_0(\beta R_\mathrm{w})}-\frac{I_0(\kappa r)}{I_0(\kappa R_\mathrm{w})}\right] \tag{27}$$

Overall Macroscopic EOF Velocity

We re-couple the two velocity components from the charged wall and the charged packing particles, and obtain the overall macroscopic EOF velocity in a charged cylindrical microcapillary with charged microsphere packing. The excess zeta potential is taken into account by such a treatment that the zeta potential of the capillary wall is replaced by $(\zeta_\mathrm{w}-\zeta_\mathrm{p})$, which is responsible for the electrokinetic wall effect:

$$u_\mathrm{D}=u_{\mathrm{Dw}}\left(1-\frac{\zeta_\mathrm{p}}{\zeta_\mathrm{w}}\right)+u_{\mathrm{Di}} \tag{28}$$

Specifically, in the case when $\zeta_\mathrm{w}=\zeta_\mathrm{p}$, Eq. (28) is reduced to $u_\mathrm{D}=u_{\mathrm{Di}}$, indicating no electrokinetic wall effect.

Key Research Findings

The mathematical models governing the EOF in a capillary packed with microspheres have been developed. In this section we will study how the EOF in a packed microcapillary is affected by the geometrical and electrokinetic parameters. In the calculations, the following parameters are bounded: ionic strength $=7.5\,\mu\mathrm{M}$, fluid viscosity $=1.0\times10^{-3}\,\mathrm{kg\,m^{-1}s^{-1}}$, density $=998\,\mathrm{kg\,m^{-3}}$, dielectric constant $=6.9\times10^{-10}\,\mathrm{C\,V^{-1}m^{-1}}$, and corresponding Debye length $\lambda_\mathrm{D}=0.11\,\mu\mathrm{m}$, which is the characteristic thickness of the EDL regime. Other fixed parameters are: zeta potential $=-100\,\mathrm{mV}$, porosity $=0.37$, and tortuosity $=1.5$. For all of the case studies, the reference velocity is $u_0=-\varepsilon_\mathrm{r}\varepsilon_0E_0\zeta_0/\mu$, where $E_0=300\,\mathrm{V\,cm^{-1}}$ and $\zeta_0=-100\,\mathrm{mV}$.

The results are obtained on the basis of (**a**) the numerical solution of Eq. (12) and (**b**) the analytical solution based on Eq. (27)

Electrokinetic Flow in Porous Media, Figure 5 Electroosmotic flow rate versus applied electric field for different values of particle diameter, d_p, and zeta potential ratio, $\zeta_\mathrm{w}/\zeta_\mathrm{p}$

are chosen to vary from positive to negative, relative to the polarity of the particle zeta potential. According to Eq. (28), it can be readily understood that when the zeta potential ratio $\zeta_\mathrm{w}/\zeta_\mathrm{p} = 1$ there is no electrokinetic wall effect. The velocity distributions exhibit a uniform profile along the cross-sectional area (i. e., a straight horizontal line), and this homogeneous velocity is equal to u_Di. The prediction results in Figs. 3a and b show that when the capillary wall is more negatively charged than the particles, i. e., $\zeta_\mathrm{w}/\zeta_\mathrm{p} > 1$, the EOF close to the wall is enhanced. In these cases, the EOF velocity starts to increase from u_Di on the wall to a maximum velocity, and then decreases to u_Di at the location around $0.98\,R_\mathrm{w}$. The local enhancement is due to the interaction between the applied electric field and the excessive EDL potential, which is limited within a region of several Debye lengths from the wall. In our calculation, the portion where the enhanced EOF occurs is limited in an annular region with thickness of around 0.75 μm, i. e., about 7 Debye lengths. Beyond this regime, the fluid remains uniform. This velocity enhancement by the channel wall cannot extend to the rest portion of the channel because the presence of packing particles causes a frictional force between the fluid and the surface of packing particles. This trend was experimentally verified by Tallarek et al. [8]. They used the pulsed field gradient nuclear magnetic resonance (PFG-NMR) and NMR imaging techniques to study the electroosmotic flow in packed capillaries. It was reported that higher EOF close to the capillary wall is detected when the channel wall is more negatively charged than the particles. Furthermore, the model predictions show that when the capillary wall is less negatively charged than the particles ($0 < \zeta_\mathrm{w}/\zeta_\mathrm{p} < 1$), neutral ($\zeta_\mathrm{w} = 0$), or positively charged ($\zeta_\mathrm{w} > 0$), the EOF close to the capillary wall becomes weakened, even leading to change of flow direction.

Comparison of Figs. 3a and b shows that at the center region of the capillary, the two methods give nearly the same results for velocity distributions, while adjacent to the charged channel wall the discrepancy is observed. It is shown that the enhanced regime under the analytical solution (i. e., Eq. (27)) is wider than that under the numerical solution of Eq. (12). This is due to the Debye–Hückel approximation used in the derivation of the analytical solutions. It is well known that use of the Debye–Hückel approximation usually overestimates the EDL region, and thus the area affected by the excessive zeta potential becomes larger. Nonetheless, evaluation of Figs. 3a and b indicates that compared to the numerical solution, the analytical solution underestimates the electrokinetic wall effect.

Figures 4a and b show the size effect of the packing particles on the EOF in a packed capillary. Three different sizes of spherical particles with diameters of 2, 5, and 8 μm are considered here. Two typical conditions are presented: with wall effect ($\zeta_w/\zeta_p = 1.5$) and no wall effect ($\zeta_w/\zeta_p = 1$). As discussed earlier, if there is no wall effect, the velocity exhibits a uniform profile along the channel radius. In this situation, use of larger packing particles can generate a higher uniform velocity u_{Di}. This is because, according to Eq. (2), the intraparticle pore size increases with increasing packing particle size. Moreover, the value of G in Eq. (7), which denotes the average EDL potential inside the intraparticle pore, decreases with increasing pore size. Thus the EOF velocity inside larger packing particles is higher. In terms of the wall effect, larger packing particles can generate stronger enhancement of local EOF velocity in the vicinity of the capillary wall. This can be explained by the fact that the void space between the particles is larger for larger particle sizes. Thus the drag force of the packing particles should be smaller.

Of practical interest for micropumps, we also study the effect of the channel wall and packing particles on the overall electroosmotic flow rate in a microcapillary. Flow rate versus applied external electric field, for different packing particle size and the zeta potential ratio ζ_w/ζ_p, is plotted in Fig. 5. It is noted that the flow rate increases linearly with increasing applied voltage. For larger packing particles, the flow rate is always higher. This is for the same reason that larger packing particles can generate higher velocity as shown in Fig. 4. For a given packing structure, the flow rate slightly increases when $\zeta_w/\zeta_p > 1$, and decreases when $\zeta_w/\zeta_p < 1$, due to the electrokinetic wall effect.

In addition to the aforementioned research findings, an analytical model for AC EOF in both open-end and closed-end cylindrical microcapillaries packed with uniform spherical particles was reported by Kang et al. [9]. It is shown that in a microcapillary with its two ends connected to reservoir and subject to ambient pressure, the oscillating Darcy velocity profile depends on both the pore size and the excitation frequency; such effects are coupled through an important aspect ratio of the tubule radius to the Stokes penetration depth. In a microcapillary with closed ends, a backpressure is induced to ensure a zero net flow rate. For a fixed excitation frequency, use of smaller packing particles can generate higher backpressure. When an AC electric field is used, the induced backpressure can be converted to forces for actuation if the sealed ends are made of movable or deformable components. This offers a potential application for the development of novel electrokinetic microactuators. Furthermore, Kang et al. [10] developed a numerical model to examine the transient Joule heating-induced temperature field and its effect on the electroosmotic flow in a capillary packed with microspheres. It is shown that the occurrence of Joule heating causes a noticeable axial temperature gradient in the thermal entrance region and causes a significant temperature increment inside the microcapillary. The temperature changes in turn greatly affect the electroosmotic velocity by means of the temperature-dependent fluid viscosity, dielectric constant, and local electric field strength. Also, the model predicts an induced pressure gradient to counterbalance the axial variation of the electroosmotic velocity so as to maintain the fluid mass continuity.

Future Directions for Research

It should be pointed out that the present model is based on the space averaging method which is commonly utilized in classic pressure-driven transport phenomena in porous media. This averaging method focuses on the equivalent macroscopic physics without considering the local complexity in the microscale. However, the EOF in porous media originates from the interaction of the external electric field and the EDL at internal surfaces of the porous structure. In reality from a microscopic viewpoint, the driving force is dependent on the local configuration of the interface and local pressure gradient is usually induced because of the complicated geometric structure and overlapped EDLs, which makes the real scenario very complex. Therefore, more accurate three-dimensional pore-size level modeling instead of the space averaging modeling should be developed to include such effects. In addition, the model presented in this study is based on the classic electroosmosis of the first kind resulting from the usual quasi-equilibrium EDL. As the complex porous sub-microstructure containing ion-exclusion regions can lead to concentration polarization under high electric field strengths, non-equilibrium EDL can be formed. Accordingly the electroosmosis of the second kind will be developed, giving rise to nonlinear electrokinetic flow in porous media that has not been studied yet.

Electrohydrodynamic focusing

Definition

Electrokinetic focusing refers to the application of electrokinetic sheath flows to confine a sample flow into a thin stream for dispensing. The most common configuration is a simple cross-linked microchannel.

Overview

Electrokinetic focusing is one of the major techniques used in many biological and biomedical applications. As an example, on-chip electrophoresis separation utilizes electrokinetic focusing to create a very thin sample stream before dispensing a small plug for separation [1]. Electrokinetic focusing is also applied in cell cytometry and cell sorting to dispense cells one at a time before they are transported to the detection region [2]. The most common geometry for on-chip electrokinetic focusing is a cross-channel where two sheath flows originating from the side channels constrict the sample flow into a thin stream at the outlet channel [3]. In the case of electrokinetic focusing, fluids are transported using electroosmotic flow as opposed to hydrodynamic focusing where pressure driven flow is used [4]. The amount of focusing is characterized by the width of the focused stream which is defined by the two streamlines that separate the sheath and sample flows. The width depends on the relative flow rates of the sample and sheath flows; thus the performance is related to the electroosmotic flow parameters including the applied electric potentials, solid–liquid properties of the channel walls and channel width ratio of the sample and sheath channels [5]. The width of the sample focusing stream can be experimentally determined through fluorescence-based visualization techniques. However, due to dye diffusion across the streamlines the cross-stream intensity profile does not exactly indicate streamline locations. The stream line location is estimated by evaluating the intensity profile using the full width at half maximum intensity (FWHM) method [6] by applying a Gaussian model. The advantage of the Gaussian fitting model is that it estimates the streamline locations independent of the physical properties of the dye sample employed in the experiments [5]. The reliability of electrokinetic focusing is coupled to the stability of the electroosmotic flow and the suppression of undesired pressure driven flow caused by small head differences and Laplace pressure differences at the reservoirs.

Definition

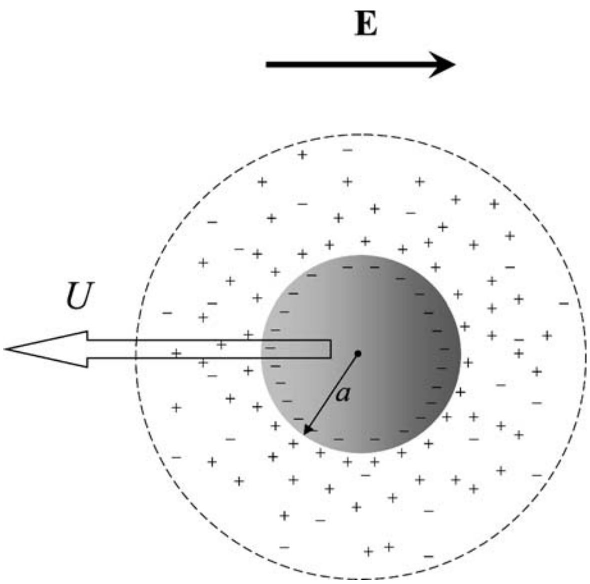
The migration of electrically charged cells or particles in liquid solution or suspension in an applied electric field.

Overview

Most substances acquire a surface charge when brought into contact with a polar medium because of chemical reaction at the interface. The charging mechanisms include ionization, ion adsorption, and ion dissolution [1]. Charge separation occurs at the solid/liquid interface when a particle is suspended in a liquid solution. As shown in Fig. 1, a negatively charged particle is surrounded by a diffuse layer



Electrokinetic Motion of Cells and Nonpolarizable Particles, Figure 1
Electrophoretic motion of a spherical particle

which contains an excess number of mobile ions of opposite charge relative to ions of like charge. Charged particles move toward electrodes of opposite electrical polarity under an external electric field. This movement is due to the Coulomb force, generated by the interaction between the net charge on the particle and the applied electric field. The electrophoretic velocity with which the particle moves with respect to its suspending medium is proportional to the strength of the applied electric field, the proportionality factor being called the *electrophoretic mobility*. The electrophoretic mobility μ_e is proportional to the magnitude of the net charge on the particle, and is inversely proportional to the size of the particle:

$$\mu_e = \frac{U}{E} = \frac{q}{f} , \tag{1}$$

where U is the electrophoretic velocity, E is the external electric field strength, q is the net charge carried by the particle, and f is the frictional coefficient. If the diffuse layer is thick, the particle may be treated as a point charge in an unperturbed electric field E_x, and the electrophoretic velocity of the particle can be expressed by the *Hückel equation*,

$$U = \frac{2}{3}\frac{\varepsilon\zeta E_x}{\mu} , \tag{2}$$

where ε is the permittivity of the particle, μ is the viscosity of the suspending medium, and ζ is the zeta potential of the particle, which is a measure of the surface

charge density. If the diffuse layer is thin, which is true for high ionic strengths or large particles of micron size, the electrophoretic velocity is given by the *Helmholtz–Smoluchowski equation*,

$$U = \frac{\varepsilon \zeta E_x}{\mu}\,, \tag{3}$$

Since electrophoresis can differentiate charged particles with great selectivity on the basis of their electrophoretic mobility, it has found extensive application in separation systems used in the biomedical industry, such as capillary electrophoresis [2], gel electrophoresis, and electrochromatography [3]. With the rapid development of modern microfluidic technology, electrophoresis has been successfully applied in the manipulation of microparticles and biological cells, by techniques such as isoelectric focusing [4] and electrokinetic dispensing [5].

Definition

The electrokinetic motion of heterogeneous particles, having non-uniform composition and/or irregular shape, involves translation, rotation, and deformation due to the combined effects of ► electrophoresis, ► induced-charge electrophoresis, and ► dielectrophoresis.

Overview

The electrokinetic motion of colloidal particles and molecules in solution in response to applied electric fields can be rather complicated, so many approximations have been made in theoretical treatments. The classical theory of ► electrophoresis, dating back over a century to Smoluchowski, considers homogeneous particles, which are

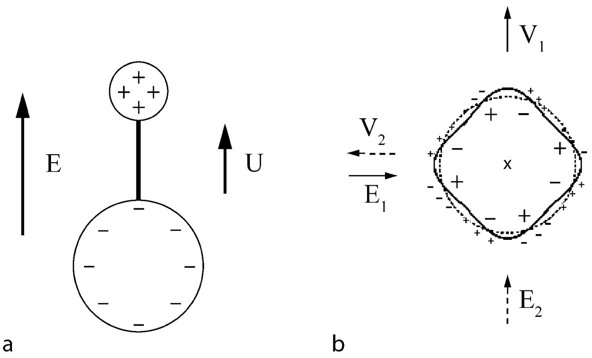
1. non-polarizable,
2. spherical,
3. uniformly charged,
4. rigid,
5. much larger than the thickness of the electrical double layer,
6. in an unbounded fluid, very far from any walls or other particles, and subjected to
7. uniform and
8. weak fields, applying not much more than the thermal voltage ($kT/e = 25$ mV) across the particle in
9. dilute electrolytes.

Under these assumptions, the particle's velocity is linear in the applied electric field, $U = bE$, where the electrophoretic mobility $b = \varepsilon\zeta/\eta$ is given by the permittivity ε and viscosity η of the fluid and the zeta potential ζ of the surface. In Smoluchowski's theory, the latter is equal to the voltage across the double layer, which is proportional to the surface charge at low voltage.

Much less attention has been paid to the electrokinetic motion of heterogeneous particles, which have non-spherical shape and/or non-uniform physical properties. By far the most theoretical work has addressed the case linear electrophoresis of non-polarizable particles with a fixed, equilibrium distribution of surface charge [1]. In that case, relaxing only assumption 2 leads to the classical prediction that the mobility of a particle of uniform composition (uniform zeta) is independent of the shape and size of the particle. Perhaps it was this insensitivity to geometry that led to the common belief that the electrophoretic mobility measures some kind of *average* surface charge, until the Anderson was the first to clearly point out that this is generally not the case [2]. By care-

fully relaxing only assumption 3, he predicted that a sphere of non-uniform zeta potential can move in a different direction from the field and that its mobility is not simply related to its total charge. Generalizing work of Fair and Anderson on doublet particles [3], Long and Ajdari showed that relaxing *both* 2 and 3 leads to even more complicated behaviour, including particles that rotate continuously or translate perpendicular to a uniform DC field [4]. Relaxing assumption 4, the electrophoresis of flexible heterogeneous particles has also been studied, such as DNA molecules connected to beads [5] and interacting with obstacles [6].

► Nonlinear electrokinetic phenomena, such as the ► electrokinetic motion of polarizable particles, have only been studied for a few decades, and attention is just beginning to be paid to the nonlinear motion of heterogeneous particles due to ► induced-charge electrophoresis [7–9]. Recent theoretical work has relaxed assumptions 1–3, but much remains to be done. Surprising new possibilities include particles that rotate continuously or translate perpendicular to a uniform AC field [9].



Electrokinetic Motion of Heterogeneous Particles, Figure 1 Examples of unusual linear electrophoretic motion of heterogeneous particles. (**a**) A dumbbell consisting of two oppositely charged spheres of connected by a rigid rod rotates to align as shown and moves in the direction of the electric field (positive mobility), even though the total charge is negative, if the positive sphere is smaller. (**b**) A particle of zero total charge with four-fold and eight-fold perturbations in shape and surface charge, respectively, moves perpendicular to the electric field, regardless of its orientation, from [4]

Basic Methodology

The underlying physical mechanisms for the electrokinetic motion of particles are described in other articles on ► electro-osmotic flow, electrophoresis, ► dielectrophoresis, nonlinear electrokinetic phenomena and electrokinetic motion of polarizable particles, along with various mathematical models. The effects of relaxing the assumptions above in these models, however, are often unexpected and have not yet been fully explored, either theoretically or experimentally. Here, we simply give a few examples of how heterogeneous particles can move in electric fields.

Key Research Findings

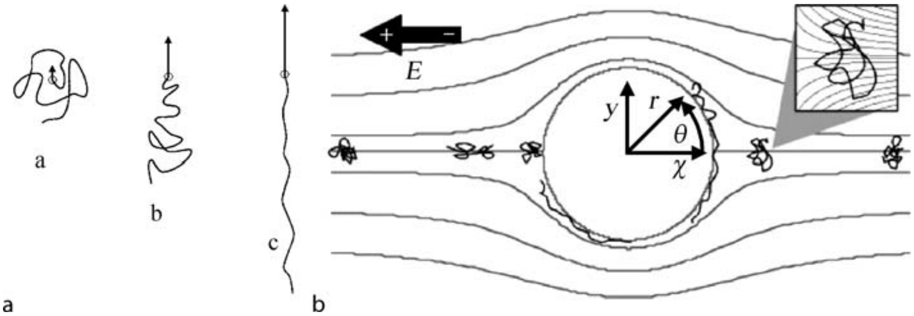
Linear Electrophoresis

It is tempting to think of the electrophoretic mobility of a heterogeneous particle as a measure of its *average charge*, when in fact it has a nontrivial dependence on the spatial distribution of surface charge [1–5]. This is clearly demonstrated by a counter-example of Long and Ajdari, motivated by chain-like polyelectrolytes, such as DNA molecules [5]. Consider a dumbbell-shaped particle consisting of two uniformly charged spheres with electrophoretic mobilities b_1 and b_2 and hydrodynamic drag coefficients ξ_1 and ξ_2, held together by an uncharged, rigid rod. As a first approximation, the rod has negligible drag and is long enough that hydrodynamic and electrostatic interactions between the spheres can be neglected. In a uniform electric field, the dumbbell rotates to a stable configuration aligned with the field axis, as shown in Fig. 1a and moves a velocity, $U = bE$, where b is the overall mobility. In order for each particle ($i = 1, 2$) to move at the same velocity, the rod must exert a force $F_i = \xi_i (U - b_i E)$. Force balance on the rod, $F_1 = -F_2$, then yields the mobility

$$b = \frac{\xi_1 b_1 + \xi_2 b_2}{\xi_1 + \xi_2} \propto \frac{Q_1}{R_1} + \frac{Q_2}{R_2} \tag{1}$$

which is the drag-weighted average of the two mobilities. In the last step, we have used Stokes formula, $\xi_i = 6\pi\eta R_i$ (where η is the fluid viscosity), and assumed that the *local* mobility (slip coefficient) is proportional to the surface charge density, $b_i \propto Q_i/4\pi R_i^2$, where Q_i is the total charge of each sphere. We see that, depending on the geometry, the mobility can have either sign, regardless of the sign the total charge $Q_1 + Q_2$. For example, as shown in Fig. 1a, a small sphere of charge $Q > 0$ connected to a larger sphere of charge $-2Q$ can have a positive mobility, even though its total charge is negative, as long as $R_2 > 2R_1$.

Variations in charge density and shape can lead to even more surprising *transverse* electrophoretic motion, which departs from the field axis. In linear electrophoresis, a spherical particle of non-uniform surface charge (or zeta potential) can move perpendicular to the field, but only for certain orientations; it can also rotate, but only transiently to align its dipole with the field axis [1]. If both the surface charge and the shape are perturbed, however, then these restrictions do not apply [4]: Figure 1b shows a cylindrical



Electrokinetic Motion of Heterogeneous Particles, Figure 2 (**a**) Linear electrophoresis of a flexible, charged chain connected to a neutral bead in regimes of small, moderate, and large velocity as a model of end-labeled free-solution DNA electrophoresis, from [5]. (**b**) Centerline trajectories of DNA electrophoresis around a cylindrical obstacle in a microchannel, showing compression and extension of the molecule, from [6]

particle of zero total charge, which always moves perpendicular to the electric field, regardless of its orientation. It has four-fold shape perturbation and eight-fold surface charge perturbation, such that each bump on the surface has positive surface charge to the left and negative to the right. By constructing appropriate chiral perturbations of the shape and surface charge, it is also possible to design heterogeneous particles, which rotate continuously around a particular axis without translating, for a particular direction of the electric field.

Flexible objects undergoing electrophoresis also display complicated dynamics. Motivated end-labeled free-solution DNA electrophoresis, Long and Ajdari also considered the electrophoresis of flexible charged chains connected to larger beads [5]. As shown in Fig. 2, there are three different dynamical regimes for small, intermediate and large velocities, where the chain goes from its equilibrium configurations to a completely elongated state. The same motions would result if the chain were pulled at the end by an effective force. Similar phenomena occur in the electrophoresis of block co-polymers, which consist of two different chains connected at the ends.

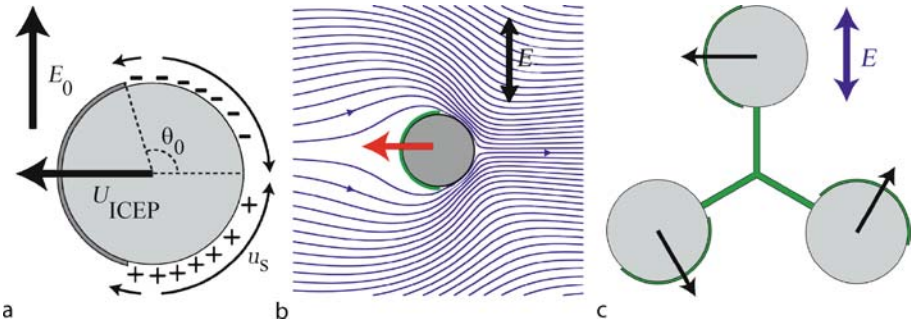
Recently, Randall and Doyle have studied the electrophoretic collision of DNA with an obstacle in a microfluidic channel, both experimentally and theoretically [6]. In that case, large deformations due to field gradients and hydrodynamic strain near the obstacle quickly stretch and compress the molecule and cause configuration-dependent hooking interactions, as shown in Fig. 2b. (See also ►dielectrophoretic motion of particles and cells.)

Induced-Charge Electrophoresis

The preceding examples involve non-polarizable objects with fixed surface charge distributions, which do not respond to the electric field. The resulting electrophoretic motion is linear in the field amplitude and vanishes for AC fields. The electrokinetic motion of polarizable particles, however, has nonlinear field dependence due to the phenomenon of induced-charge electro-osmosis (ICEO), where the field acts on induced diffuse charge in the ►electrical double layer. At frequencies low enough for capacitive charging of the double layer (typically $< 10\,\text{kHz}$), the time-averaged motion in an AC field is resembles that in a DC field. In the canonical example of an uncharged metal sphere in a uniform field, the ICEO flow is quadrupolar, drawing in fluid along the field axis and expelling it radially, but there is no net motion.

Motivated by the examples from linear electrophoresis above, Bazant and Squires pointed out that broken symmetry in ICEO flow generally causes particle motion, which they called ►induced-charge electrophoresis (ICEP) [1]. Examples of broken symmetries include particles with irregular shapes and/or non-uniform physical characteristics, as well as non-uniform applied fields. In the latter case, ICEP occurs at the same time as dielectrophoresis (DEP), although the combined effects of ICEP and DEP on heterogeneous particles remain to be explored. Besides persisting in AC fields, ICEP also depends much more sensitively on particle shape and surface properties than does linear DC electrophoresis. Cases of non-spherical particles with uniform polarizability are discussed in the article on electrokinetic motion of polarizable particles, so here we focus on ICEP due to heterogenous surface polarizability.

The canonical example is that of a ►Janus particle with one metallic and one insulating hemisphere [9], using the standard low-voltage model for electrokinetic motion of polarizable particles. In response to an applied electric field, the Janus particle rotates to align the interface between the two hemispheres with the field axis, due to both ICEP (electrohydrodynamics) and DEP (electrostatics). At the same time, for any orientation, the particle



Electrokinetic Motion of Heterogeneous Particles, Figure 3 Induced-charge electrophoresis of Janus particles, illustrated for the case of metal partially coated with insulating thin films, from [9]. (**a**) Stable orientation in a uniform field, showing induced charge and slip velocities on the metallic side, resulting in motion toward the insulating end, perpendicular to the field. (**b**) Streamlines of ICEO flow. (**c**) An ICEP pinwheel, consisting of three Janus particles connected by rigid rods, which tilts to align and then spins continuous around the field axis

translates in the direction of its insulating end, propelled by ICEO flow on the metallic end, with a velocity

$$U = \frac{9\varepsilon RE^2}{64\eta\,(1+\delta)} \tag{2}$$

where ε is the permittivity, R is the particle radius, and δ is a dimensionless measure of the compact-layer capacitance. In particular, once the particle aligns in the field, it continues to move perpendicular to the electric field, with an azimuthal angle set by its initial orientation.

All the generic features of the dynamics still hold if the particle's insulating end is smaller or larger than the metallic end, since it is determined by the broken symmetry. Motion transverse to a uniform AC field cannot have any contribution from DEP, but it is easily understood by considering the ICEO flow in Fig. 3a. After alignment in the field, part of the usual quadrupolar ICEO flow is suppressed on the insulating end. The remaining ICEO flow over the metallic end sucks in fluid along the field axis and pushes it outward from the metallic pole, as shown in Fig. 3b, which propels the particle toward the insulating pole.

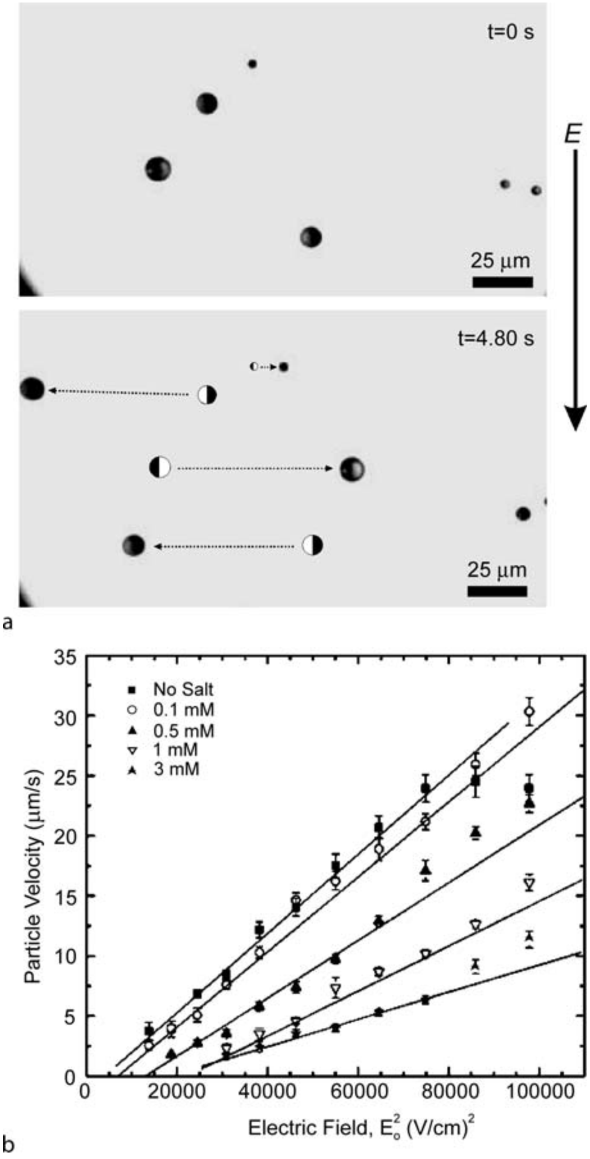
This example suggests how to design particles that spin continuously in a uniform field, as noted by Squires and Bazant [9]. Since a Janus particle always translates towards its less polarizable end, a set of three Janus particles connected by rigid rods can be set into continuous motion like a pinwheel, if connected as shown in Fig. 3c. This "ICEP pinwheel" responds to any DC or AC electric field (of sufficiently low frequency) by tilting to align the particle plane perpendicular to the field and then spinning around the field axis until the field is turned off. Perhaps such particles could be used to sense electric fields or to apply torques to attached molecules or cells.

Transverse ICEP motion of metallo-dielectric Janus particles in a uniform AC field has recently been observed by Gangwal et al. [10]. Consistent with theoretical predictions in Fig. 3, the particles align and translate perpendicular to the field in the direction of the less polarizable (light) end, as shown in Fig. 4. Larger particles move faster than smaller ones, as expected from Eq. (2), and the velocity scales like the field squared in dilute NaCl solutions. The ICEP velocity decays at higher concentrations, extrapolating to zero around 10 mM. The same concentration dependence is also observed in ►AC electro-osmotic flow and other nonlinear electrokinetic phenomena, which, although poorly understood, further reinforces that the motion is indeed due to ICEP.

Current research is focusing on how heterogeneous particles undergoing electrokinetic motion due to ICEP and DEP interact with walls and other particles. An interesting feature of the experiments in Fig. 3 is that the Janus particles are attracted to nearby glass walls, and the transverse motion is also observed close to the walls, where the theory of [9] does not strictly apply. The attraction can be understood as a consequence of ICEP torque, which redirects the Janus particle toward a nearby wall and causes it to tilt while translating transverse to the field.

Future Directions for Research

As illustrated by the examples above, the electrokinetic motion of heterogeneous particles is quite complicated and relatively unexplored. From a theoretical point of view, there are many opportunities to discover new phenomena by further relaxing the nine assumptions listed at the beginning of this article. From an experimental point of view, much remains to be done to characterize the motion of heterogenous particles in electric fields, especially by ICEP and DEP at low frequency.



Electrokinetic Motion of Heterogeneous Particles, Figure 4 Experimental observation of ICEP of metallo-dielectric Janus particles in a uniform 10 kHz AC field, from [10]. (**a**) Sequence of micrographs demonstrating motion transverse to the field in the direction of the dielectric (light) end propelled by the metallic (dark) end, where the velocity increases with the particle size as in Eq. (2) (**b**) Velocity versus field amplitude squared at different bulk concentrations of NaCl

A major motivation to develop this subject is the possibility of new applications, opened by advances in microfluidics and nanotechnology. In principle, heterogenous particles of specific irregular shapes and non-uniform electrical and/or chemical properties can be designed and fabricated for specific applications. The complex electrokinetic motion of these particles could potentially be used for separation or sample concentration in chemical or biological assays, self-assembly in the fabrication of anisotropic materials, directional transport of attached *cargo*, electric-field sensing and applying forces and torques to molecules or cells.

Definition

The electrokinetic motion of polarizable particles results from electro-osmotic flow (▶ induced-charge electrophoresis) of the first of ▶ second kind, in addition to electrostatic forces (▶ dielectrophoresis).

Overview

The classical theory of ▶ electrophoresis (particle motion due to ▶ electro-osmotic flow) assumes that surface charge remains fixed at its equilibrium value, when electric fields (or other perturbations) are applied [1]. For thin ▶ electrical double layers, the assumption of fixed charge implies that particles of uniform composition all have the same electrophoretic mobility b (velocity/field)

$$b = \frac{U}{E} = \frac{\varepsilon\zeta}{\eta} \tag{1}$$

regardless of their sizes and shapes. This naturally poses problems for electrophoretic separation and has led to the use of capillaries or gels to exploit additional effects.

In Eq. (1), the zeta potential ζ can be viewed as simply expressing the mobility in units of voltage, after factoring out the permittivity ε and viscosity η of the bulk solution. In Smoluchowski's original theory, still widely used a century later, the zeta potential is equal to the voltage ψ of the slip plane (atomically close to the surface) relative to the nearby bulk solution (just outside the diffuse part of the double layer), and, through the double-layer capacitance, it also measures the surface charge. The assumption of fixed charge thus becomes equivalent to that of constant zeta potential, and the mobility (1) reduces to a coefficient of linear response, $U \propto E$.

Since all materials are polarizable to some degree, the surface charge is generally not fixed. This leads to a broad class of ▶ nonlinear electrokinetic phenomena, where bulk electric fields interact with *induced* diffuse charge in solution to produce nonlinear electrophoretic motion, $\boldsymbol{U} = \boldsymbol{f}(\boldsymbol{E})$. In electrolytes, such effects of ▶ induced-charge electrophoresis (ICEP) occur in addition to the purely electrostatic effect of ▶ dielectrophoresis (DEP) in low-frequency AC fields (< 100 kHz), where there is enough time for diffuse-charge relaxation around the particle within each period. ICEP is a complex phenomenon, which can lead not only to nonlinear mobility (in the field direction) but also to rotation and motion in arbitrary directions, even in uniform fields.

At still lower frequencies (< 1 kHz), the passage of current through a particle, either by Faradaic reactions, surface conduction, or selective ionic conduction, can produce bulk salt concentration gradients and coupled effects of ▶ diffusiophoresis. If a ▶ superlimiting current is reached (typically in the DC limit), then ▶ electrophoresis of the second kind can occur, driven by extended ▶ space charge. Understanding all of these effects and exploiting them in microfluidic devices is an active field of research.

Basic Methodology

The theoretical description of nonlinear electrokinetic phenomena is challenging and not yet fully developed. In most of our examples below, we focus on the motion of an ideally polarizable particle, which maintains uniform potential $\varphi_0(t)$ and constant total charge Q without passing any direct current; we also neglect surface conduction and specific adsorption of ions. Under these conditions, ▶ induced-charge electro-osmotic flows are strongest, and a general mathematical framework has been developed [2–5] for the *weakly nonlinear* limit of thin double layers where the bulk salt concentration (and conductivity σ_b) remains nearly constant.

The calculation goes as follows for the motion of an isolated particle of arbitrary shape, subjected to a non-uniform, time-dependent electric field at infinity for $t > 0$. The bulk electrostatic potential satisfies Laplace's equation, $\nabla^2\varphi = 0$, subject to the far-field boundary condition,

$$\varphi \sim -\boldsymbol{E}_b \cdot \boldsymbol{r} - \frac{1}{2}\boldsymbol{r} \cdot \mathbf{G}_b \cdot \boldsymbol{r} - \ldots \quad \text{as} \quad r \to \infty \tag{2}$$

where $\boldsymbol{E}_b$ is the uniform component of the background field, $\mathbf{G}_b$ is the field-gradient tensor, etc. (Note that the constant background voltage has been set to zero.) The RC boundary condition is applied on the particle, just outside the double layer,

$$C(\psi)\frac{d\psi}{dt} = n \cdot (\sigma_b \nabla\phi) \tag{3}$$

where $C(\psi)$ is the differential capacitance of the diffuse part of the double layer, as a function of its voltage drop

$$\psi(\boldsymbol{r}, t) = \frac{\varphi_0(t) - \varphi(\boldsymbol{r}, t)}{1 + \delta} \tag{4}$$

where δ is a parameter controlling how much of the total double-layer voltage ends up across the compact layer (the ratio of the diffuse-layer and compact-layer capacitances at the point of zero charge). The particle's potential $\varphi_0(t)$

relative to the background is set by the constraint of constant total charge [2, 4],

$$Q = \oint \left(\int_0^{\psi_0} C(\psi')\mathrm{d}\psi' \right) \mathrm{d}A = \oint \left(\int_0^{\psi(\boldsymbol{r},t)} C(\psi')\mathrm{d}\psi' \right) \mathrm{d}A \quad (5)$$

This condition simplifies considerably if $C \approx$ constant, e. g. for small voltages $|\psi| \ll kT/e$ around the point of zero charge: The diffuse-layer voltage (and zeta potential) then redistributes without changing its surface average [3, 5]

$$\frac{\oint \psi(\boldsymbol{r},t)\mathrm{d}A}{\oint \mathrm{d}A} \approx \psi_0 \quad (6)$$

but it is important to remember that this assumption breaks down for large induced voltages and/or highly charged particles, since generally $\mathrm{d}C/d\psi \neq 0$. (See below.)

In the weakly nonlinear regime, the electrochemical and fluid mechanical problems decouple, except that the former provides the slip velocity driving the latter. The bulk fluid velocity satisfies the Stokes equations of viscous flow,

$$\frac{\partial \boldsymbol{u}}{\partial t} = -\nabla p + \eta \nabla^2 \boldsymbol{u} \quad \text{and} \quad \nabla \cdot \boldsymbol{u} = 0 \quad (7)$$

(keeping the unsteady term for time-dependent applied fields) subject to vanishing velocity at infinity. The boundary condition on the particle surface (just outside the double layer)

$$\boldsymbol{u} = \boldsymbol{u}_\mathrm{s} + \boldsymbol{U} + \boldsymbol{r} \times \Omega \quad (8)$$

describes electro-osmotic slip in the moving frame translating and rotating with the particle. Assuming constant permittivity and viscosity, the slip velocity is given by Smoluchowski's formula,

$$\boldsymbol{u}_\mathrm{s} = \frac{\varepsilon \psi}{\eta} \nabla_{||} \varphi \quad (9)$$

where $\psi(\boldsymbol{r},t)$ acts as the local zeta potential. Finally, as in classical ▶ electrophoresis and ▶ dielectrophoresis (effects which are both included here, along with ICEP), the translational and rotational velocities, $\boldsymbol{U}$ and Ω, are determined by the conditions of vanishing total force and torque, respectively,

$$\oint (\hat{n} \cdot \sigma)\mathrm{d}A = \oint r \times (\hat{n} \cdot \sigma)\mathrm{d}A = 0 \quad (10)$$

since viscous dissipation suppresses acceleration. In (10), the stress tensor includes viscous and electrostatic contributions

$$\sigma_{ij} = -p\delta_{ij} + \eta(\partial_i u_j + \partial_j u_i) + \varepsilon \left(E_i E_j - \frac{1}{2} E^2 \delta_{ij} \right) \quad (11)$$

and the integrals are over any surface containing the particle because the fluid is in mechanical quasi-equilibrium.

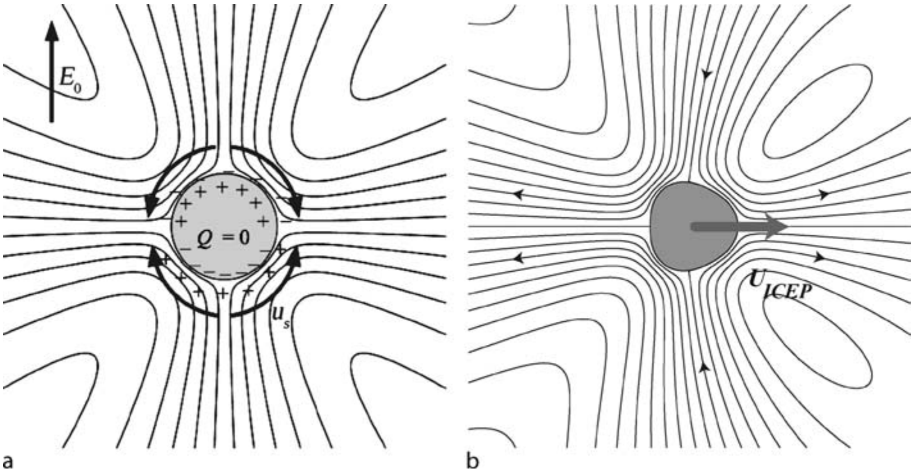
This basic methodology can be extended to more complicated situations, as outlined in the article on ▶ nonlinear electrokinetic phenomena. For example, if the particle is not ideally polarizable or has a dielectric coating, then Laplace's equation must also be solved for the electrostatic potential inside the particle, with appropriate matching conditions [3]. Channel walls can be described by replacing the conditions at infinity with appropriate electrostatic boundary conditions, including possible double-layer relaxation (3) and ICEO slip (9) on fixed metal structures or electrodes; multiple particles can also be described, usually with numerical methods. A greater complication is to allow the particle to selectively conduct ions or pass a Faradaic current and/or to adsorb significant salt from the bulk in its double layers. The resulting gradients in bulk salt concentration require solving the full Poisson–Nernst–Planck equations for the electrochemical relaxation [6] and allowing for bulk electroconvection in the fluid equations [7]. Concentration gradients also lead to ▶ diffusiophoresis, which adds a term proportional to $\nabla_{||} \log c$ to the *first kind* slip formula (9), and, if strong enough to produce bulk ▶ space charge, also to ▶ electrophoresis of the second kind [8, 18].

Key Research Findings

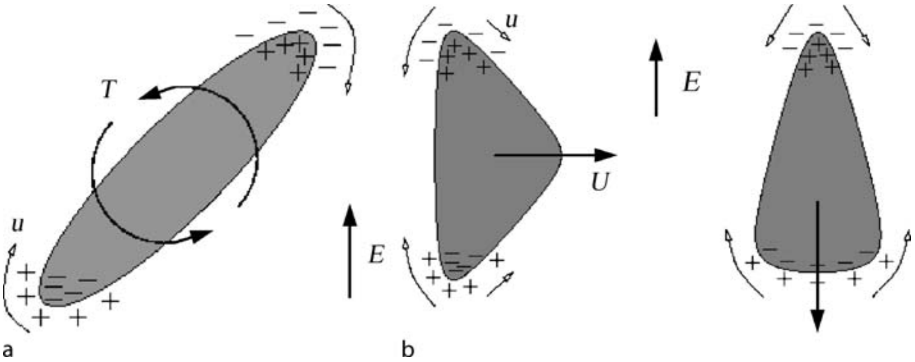
Field-Dependent Mobility

A well-known prediction of the classical theory of ▶ electrophoresis is that the mobility (1) only depends on the total charge (or average zeta potential), in the limits of thin double layers, small charge, and weak fields [1]. This remarkable result holds for any size or shape, even if the particle is polarizable and acquires a non-uniform charge (or zeta) profile in response to the applied field. It is not widely appreciated, however, that this follows from the assumption of constant double-layer capacitance, which reduces (5) to (6).

In the 1970s, S.S. Dukhin's group was perhaps the first to recognize that the electrophoretic mobility of polarizable particles must generally depend on the electric field [9]. In a series of Russian papers, which have yet to gain widespread attention, they predicted perturbations of the mobility as $\Delta b \propto E^2$ and thus nonlinear electrokinetic motion $\Delta U \propto E^3$, which they have come to call the



Electrokinetic Motion of Polarizable Particles, Figure 1 (**a**) Induced-charge electro-osmotic (ICEO) flow around a symmetric, uncharged, ideally polarizable particle [3]; (**b**) An example of ICEO flow and the resulting induced-charge electrophoretic (ICEP) velocity for an asymmetric shape [4]



Electrokinetic Motion of Polarizable Particles, Figure 2 (**a**) Mechanism for ICEP torque on a rod-like, polarizable particle in a uniform electric field, which enhances dielectrophoretic (DEP) torque. (**b**) Possible ICEP velocities for asymmetric shapes, once their long axes have aligned with the field

► Stotz–Wien effect. For the case of a steady weak field applied to an ideally polarizable sphere of radius a, A.S. Dukhin derived an expansion for the mobility,

$$b \sim \frac{\varepsilon}{\eta}\left[\zeta - \frac{3}{8}\left(\frac{d}{d\psi}\log C\right)_{\psi=\zeta}(Ea)^2 + \dots\right] \quad (12)$$

which holds for any model of the ► electrical double layer [10]. The same result can be derived from the general formalism above by expanding (5) for $\psi \approx \psi_0 = \zeta$ and keeping corrections to (6), and large fields, non-spherical shapes, and AC forcing could also be considered. In principle, any field dependence of the mobility, regardless of its true cause, can be exploited to separate particles using an ► unbalanced AC field, which cancels the linear response (since $\langle E \rangle = 0$) while amplifying mobility corrections (since $\langle E^3 \rangle \neq 0$) [9, 11].

Induced-Charge Electrophoresis

Mobility perturbations for spherical particles, however, only hint at the rich phenomena that can arise in the electrokinetic motion of polarizable particles. Murtsovkin and co-workers were the first (and until recently the only ones) to experimentally observe nonlinear electrokinetic motion in a uniform AC field in directions *oblique to the field axis* [12]. They studied irregular quartz particles moving in water near the wall of a cuvette in surprising directions apparently set only by the particle shape. If a particle rotated enough by Brownian motion when the field was off, it could be seen to reverse direction when the field was turned back on. The velocity scaled with the square of the field amplitude and increased with the particle size. No theory was proposed for this phenomenon, in part since it was only observed near the wall and not in the bulk solution.

Bazant and Squires recently predicted that polarizable particles in the bulk can undergo essentially arbitrary translation and/or rotation by ICEP in a uniform electric field, as long as they possess appropriate *broken symmetries* [2, 4], such as non-spherical shapes and/or non-uniform surface properties (e. g. due to coatings of different polarizability or compact-layer capacitance). The former cases begin to explain Murtsovkin's early observations and beg for new experiments to test a variety of specific theoretical predictions, discussed below. The latter cases, which had not previously been observed, are described in a companion article on ▶ electrokinetic motion of heterogeneous particles. For homogeneous particles, the canonical example is that of an uncharged, ideally polarizable particle of irregular shape in a weak, uniform DC field. In that case, the basic velocity scale for ICEP is

$$U_{\mathrm{ICEP}} = \frac{\varepsilon a E^2}{\eta(1+\delta)} \quad \text{(uniform field)} \tag{13}$$

where a is a characteristic radius [2]. Using the low-voltage model (6 – 11) (with $C = \text{constant}$), Yariv derived general expressions for the translational and rotational velocities, respectively,

$$U_i = U_{\mathrm{ICEP}} \sum_{jk} \mathbf{C}_{ijk} E_j E_k \quad \text{and}$$
$$\Omega_i = \frac{U_{\mathrm{ICEP}}}{a} \sum_{jk} \mathbf{D}_{ijk} E_j E_k \tag{14}$$

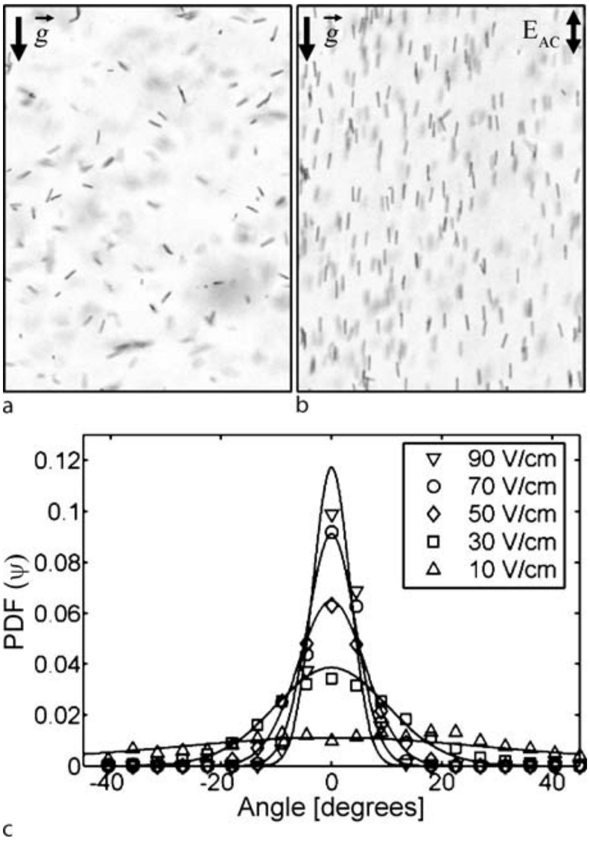
where $\mathbf{C}$ is a dimensionless tensor and $\mathbf{D}$ a pseudo-tensor, each expressible as surface integrals involving the bulk potential, just outside the double layer. Squires and Bazant treated a number of specific examples by solving (6–11) directly using perturbation methods for nearly symmetric objects and discovered some simple principles to predict the motion of a particular shape [4].

The basic mechanism of ICEP for irregular particles is shown in Fig. 1. As shown in Fig. a and described in the article on ▶ nonlinear electrokinetic phenomena, the ICEO flow around a symmetric particle is quadrupolar [2, 3, 13], drawing fluid in along the field axis and ejecting it radially. If the particle has broken left/right symmetry as shown in Fig. b, then the radial flow is stronger on one side than the other, leading to ICEP motion perpendicular to the field. Similarly, breaking only fore/aft symmetry produces ICEP motion along the field axis, and combinations of these asymmetries can cause motion in an arbitrary direction.

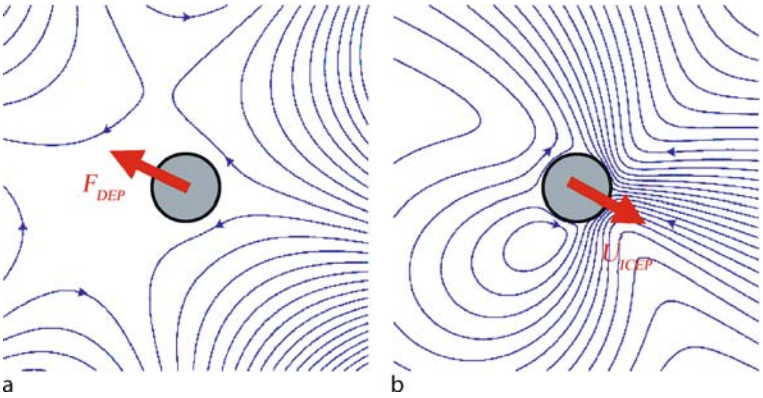
ICEP can also contribute to the rotation of polarizable particles with elongated shapes [2, 4, 5, 15], as illustrated in Fig. 2a. It is well known that ▶ DEP causes such particles to align with the axis of a uniform field, due to electrostatic torque on the induced dipole. At low AC frequency (or in the DC limit), if the field persists in one direction long enough for ICEO flow to occur, then ICEP causes a rotational velocity with a basic scale that is independent of the particle size but sensitive to its shape,

$$\Omega_{\mathrm{ICEP}} = \frac{U_{\mathrm{ICEP}}}{a} = \frac{\varepsilon E^2}{\eta(1+\delta)} \tag{15}$$

This scale happens to be the same as that of the DEP rotational velocity, so ICEP rotation is easily overlooked and mistakenly interpreted as DEP. It is possible, however, to clearly distinguish the two effects, as recently demonstrated by experiments [14] and simulations [15] involving rod-like, metal particles in uniform AC fields (see Fig. 3.).



Electrokinetic Motion of Polarizable Particles, Figure 3 Experiments on cylindrical silver particles (0.318 μm diameter, 6 μm length) sedimenting in de-ionized water by gravity alone (**a**) and in a 100 Hz, 100 V/cm AC field aligned with gravity (**b**). The experimental distribution of angles in different fields (**c**) agrees well with theoretical curves (solid) which take into account both ICEP rotation and electrostatic torque [14]



Electrokinetic Motion of Polarizable Particles, Figure 4 An ideally polarizable cylinder subjected to a non-uniform DC electric field in an electrolyte with thin double layers: (**a**) Field lines and the DEP force, typically directed down the field gradient. (**b**) Streamlines of ICEO flow and the ICEP velocity, which always directed opposite to the DEP force [4]

More complicated asymmetric particles can undergo essentially arbitrary ICEP motion, even in a uniform field. Even in the context of the simple model above, these effects have not yet been fully analyzed, but some general principles have been identified [4]. A striking example is shown in Fig. 2b, which illustrates how arrow-like particles of slightly different shapes can move in perpendicular directions in a uniform field, depending on their broken symmetries: On the left, a short, fat arrow rotates to align its long axis with the field and then moves perpendicular to the field, toward its pointed end; on the right, a long, thin arrow also rotates to align its long axis, but then moves parallel to the field, toward its blunt end. Such predictions are quite recent, however, and remain to be tested experimentally.

A telltale sign of ICEP is the presence of non-uniform ICEO flow around the particle, which leads to complex hydrodynamic interactions with other particles and walls. For example, the basic quadrupolar flow in Fig. 1a causes two symmetric particles to move toward each other along the field axis and then push apart in the normal direction [13, 15]. A finite cloud of such particles would thus become squashed into a disk-like "spreading pancake" perpendicular to the field axis [3]. The same flow field can also cause particles to be repelled from insulating walls (perpendicular to the field) [16] or attracted toward electrodes (normal to the field), but these are only guiding principles. Broken symmetries in particle shape or wall geometry, however, can cause different motion due to combined effects of DEP and ICEP, even opposite to these principles, and the interactions of multiple particles can also be influenced strongly by walls. Such effects have not yet been fully explored in experiments or simulations.

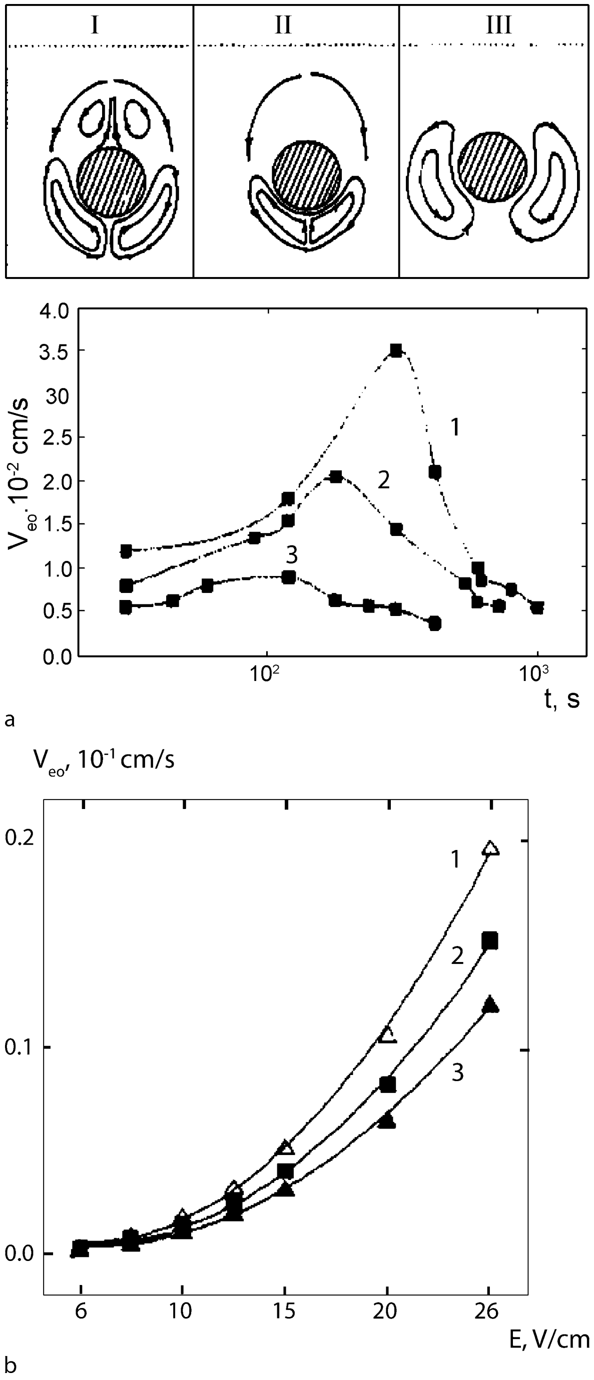
Low-Frequency Dielectrophoresis

In the 1970s, Shilov and Estrella-Lopis first recognized that electrohydrodynamics (what we now call ICEO) can contribute to the motion of particles in low-frequency, non-uniform electric fields [17], in addition to DEP, although the effect has not been studied much in theory or experiment. Shilov and Simonova analyzed the problem of an ideally polarizable sphere in a uniform field gradient and made the remarkable prediction that the particle does not move. Due to equal and opposite motions by DEP and ICEP, the sphere levitates in the field while driving a steady ICEO flow, but this is a unique case.

Squires and Bazant recently showed that broken symmetries in the field gradient and/or the particle shape generally cause a particle to move, due to subtle imbalances between ICEP and DEP [4]. Both effects have the same basic scaling,

$$U_{\text{ICEP}} = \frac{\varepsilon a^2 \nabla |E|^2}{\eta(1+\delta)} \quad \text{(non-uniform field)} \qquad (16)$$

Moreover, as illustrated in Fig. 3, the DEP force and ICEP velocity tend to act in opposite directions, at least for the case of an ideally polarizable particle with thin double layers in a non-uniform electric field (of arbitrary complexity). Similar to the case of rotational motion discussed above, ICEP can be easily overlooked and the observed translational motion attributed solely to DEP, if it is along the field gradient. Experiments clearly separating ICEP and DEP effects are still lacking, and an opportunity exists to exploit these combined effects for manipulating polarizable colloids, once the effects are better understood.



Electrokinetic Motion of Polarizable Particles, Figure 5 Experiments on electrophoresis of the second kind for cationite KU-2-8 particles in 10^{-4} MNaCl. (**a**) Velocity versus time for particles diameters 0.42 mm (1), 0.33 mm (2), and 0.21 mm (3) with sketches of the observed flow fields. (**b**) Scaling of velocity with applied field for diameters 0.31 mm (1), 0.28 mm (2), and 0.26 mm (3) [8]

Electrophoresis of the Second Kind

As described in the article on ►nonlinear electrokinetic phenomena, electro-osmosis of the second arises when the bulk salt concentration goes to zero at a surface passing a diffusion-limited current. Under conditions of ►super-limiting current, the density of counterions in the ►electrical double layer loses its classical quasi-equilibrium profile and a region of dilute ►space charge extends into the solution to the point where the bulk salt concentration becomes appreciable. In spite of the small counter-ion concentration, the expulsion of co-ions from the space charge layer leads to significant charge density and, in the presence of a tangential electric field, ►electroosmosis of the second kind [7].

If a particle is able to sustain a super-limiting current, then such flows can cause it to move by ►electrophoresis of the second kind, as first noted by S.S. Dukhin in the 1980s. As shown in Fig. 5, second-kind electrophoresis has been observed experimentally for large (> 10 μm) particles composed of cation-selective porous materials, and the flow structure has been studied in detail [8]. Due to the complexity of the phenomenon, however, the theory has mainly been limited to scaling arguments and heuristic boundary-layer approximations [18], but there is hope that the rigorous mathematical study of second-kind flows [7] could soon be extended to second-kind electrophoresis. Effects of walls, multiple particles, and broken symmetries should also eventually be studied.

Future Directions for Research

Compared to the vast literature on linear ►electrophoresis, the study of nonlinear electrokinetic motion is still its early stages. As indicated above, much remains to be done, both in making theoretical predictions and systematically testing them (or discovering new effects) in experiments. Modern mathematical methods and computational power now allow more sophisticated analysis, going beyond linear and weakly nonlinear approximations, as well as large scale simulations of interacting colloidal particles. Similarly, the advent of microfluidics provides new opportunities to observe and exploit nonlinear electrokinetic phenomena, since polarizable particles can now be fabricated with complicated shapes and material properties and electric fields controlled with submicron precision.

Applications of nonlinear electrokinetic motion are still largely unexplored. Aperiodic electrophoresis and other ICEP phenomena could be used to separate polarizable particles based on shape, size, and/or surface properties, in ways that cannot be accomplished using linear electrophoresis. Sorting, trapping, and assembling particles interacting via ICEP and DEP in microfluidic devices

could be used to engineer new materials with anisotropic electrical, mechanical, or optical properties. Polarizable particles can also be attached to biological molecules or cells and manipulated by ICEP and DEP for separation, characterization, or labeling.

Definition

Kinetic sample injection is a method which employs electroosmotic flow to load and separate the samples for chemical and biomedical analysis in many bio- or chemical labchips. It is one of the injection techniques used for the microfluidic injector within microfluidic devices. The typical volume delivered by kinetic injection is about hundreds of picoliters.

Overview

Microfluidic devices have attracted considerable attention recently due to the development of an ever-increasing

number of applications in the fields of chemical and biological analysis. A typical application of such devices is the separation of DNA in genetic engineering processes. A fundamental feature common to all of these devices is that the mobility of charged particles can be controlled when they move under the influence of an applied electric field. This induced flow motion is generally referred to as electroosmotic flow (EOF) or capillary electrophoresis (CE) [1]. Micromachining technology now permits the fabrication of a network of microchannels on a single quartz, glass or plastic (poly(dimethylsiloxane) (PDMS), polycarbonate (PC), poly(methylmethacrylate) (PMMA)) substrate to form an integrated microfluidic chip capable of performing a variety of procedures, including sample handling, mixing, chemical reaction, pretreatment, separation etc. These devices are frequently employed to separate samples using a technique which is similar to that used in conventional CE analysis, but which is more efficient and faster.

An important component of many bio- or chemical Lab-on-a-Chip devices is the microfluidic injection system, the precise control of the size and concentration of the dispensed sample in the microfluidic injection system determines the performance of these Lab-on-a-Chip devices. Two methods are commonly adopted in microfluidic injection systems: electrokinetic injection and pressure injection. Pressure driven injections have the advantage that precise voltage control is not necessary and sample injections of uniform composition can be obtained. However, pressure injections require a means to transport or pump the sample that is dissolved in a liquid. Switchable valves which direct the flow into a desired direction can achieve flow control. These valves are difficult to integrate into microfluidic devices, so the kinetic injection system prevails within the microchip [2].

Traditionally, electrokinetic injection is the most common method for sample injection and separation into the microchannel utilizing some form of electroosmotic pumping. However, depending on the sample, due to the different mobility in an electric field, a bias to anionic, neutral, or cationic analytes is possible. Careful adjustment of pH and ionic strength can reduce this effect [2]. A broad injection band and sample leakage phenomena are also important defects of the electrokinetic injection method. Both are known to reduce the separation efficiency of a device since they result in a wide sample distribution within the microchannel and an increasing signal baseline as the number of injection runs increases [3–6], respectively. Other injection methods, like pressure injection, do not show this method-dependent effect.

A variety of valves capable of providing discrete injections configurations have been presented, including the T-form, the cross-form, and the double-T form. Improved reproducibility has been obtained by the double-T and cross-form injections. Jacobson et al. [7] and Slentz et al. [8] have described the injection techniques for floating injection, gated injection, and pinched injection. Fu and Lin [5] have proposed the double-L injection to reduce the sample leakage. When the EOF is the only force to transport a sample in a capillary, an electrophoretic bias [9] and the sample leakage has to be considered during injection.

Both the theoretical studies and the experimental studies have demonstrated that the loading and dispensing of sub-nanoliter samples using a microfluidic-crossing microchannel chip can be well controlled electrokinetically. The ability to inject and transport large axial extent, concentration-dense samples has been demonstrated in the literature. Both experimental and numerical results indicate that the shape, cross-stream uniformity, and axial extent of the samples are very sensitive to changes in the electric fields applied in the loading channel. In the dispensing process, larger samples are shown to disperse less than focused samples, maintaining more solution with the original sample concentration. Li [1] has outlined the effects of: buffer electroosmotic mobility, sample diffusion coefficient, sample electrophoretic mobility, the difference in conductivity of the solutions, the applied electrical field strength, the channel size, and channel configurations on the injection and the separation process. By understanding the complicated electrokinetic processes involved in the sample dispensing processes, we can find the optimal applied voltages and improved methods to control the size, shape and concentration of the dispensed samples. Tsai et al. [6] have employed a numerical simulation technique to investigate the leakage behavior in various microfluidic devices using different control voltage strategies. Five different injection systems are considered: cross-form, T-junction, double-T junction, focused flow cross-form, and triple-T form. For each injection system, various injection techniques are proposed with the intention of reducing sample leakage. The relative performance of each injection arrangement is assessed in terms of its effectiveness in reducing the sample leakage ratio, and hence by implication, its suitability for high detection resolution applications, and by considering the degree of complexity of its electric potential control system.

Many studies have demonstrated that the injection system on a CE microchip is one of the most fundamental components of the sample handling process, and that its characteristics determine the quality of the separation. Practical applications, such as separation or detection, require that the dispensed sample volume be precisely controlled and that sample leakage to the separation channel be prevented. Hence, developing viable low-leakage injection

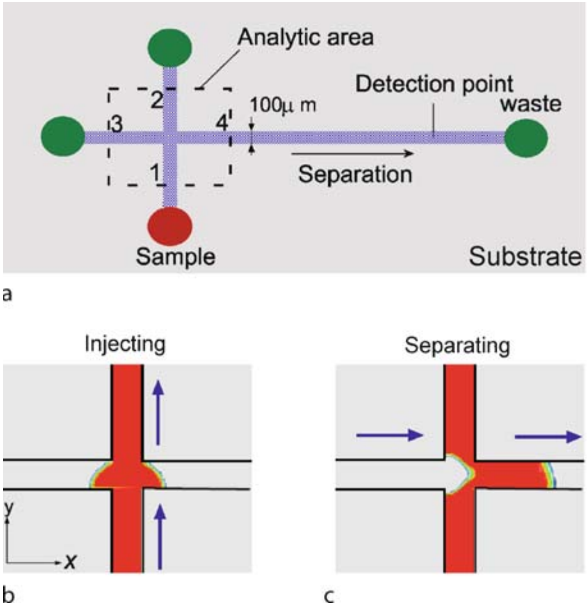
techniques with the ability to dispense samples of variable volume is fundamental in improving the performance of microfluidic devices designed for biomedical applications. More sophisticated injection system configurations capable of providing variable-volume sample plugs have also been proposed [3, 4], including the multi-T form and the double-cross form. Implementing increasingly complex and integrated functions in a single chip demands an investigation into appropriate microchannel network designs and electric potential control strategies. Additionally, the electrokinetic transport phenomena in microfluidic devices must be fully understood if the design and control of biochips are to be optimized. Accordingly, many studies, both experimental and numerical, have been performed to investigate various aspects of microfluidic devices. These studies have confirmed the power of numerical methods for modeling the flow structures associated with various operating modes in different microchannel network configurations.

Basic Methodology

Reproducible injection for capillary electrophoresis on a microdevice/Lab-on-Chip is not easy to achieve. Different injection designs (e. g., T-type, double-T type, and cross-type) and different injection techniques have been applied (pinched injection, gated injection, double-L injection) within microfluidic devices. The volume and the concentration of the dispensed sample are the key parameters of this dispensing process, and they depend on the applied electrical field, the flow field, and the concentration field during the injection and separation processes. The problems and properties of the different modes are described below.

Cross-Form Injection Method

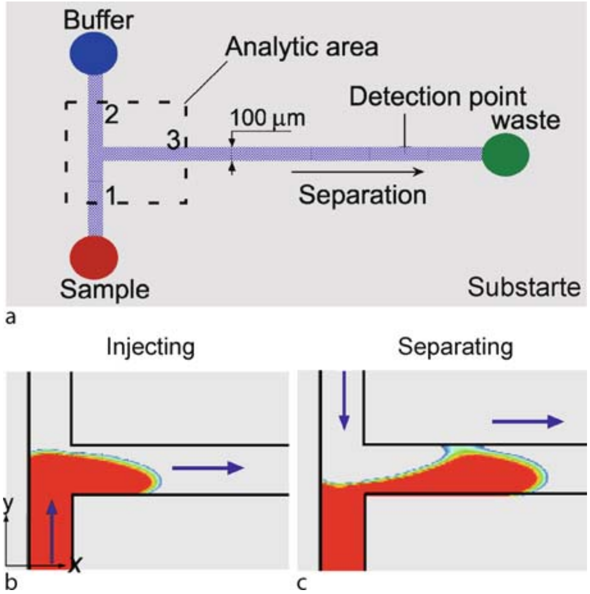
Figure 1a presents a schematic illustration of the cross-form injection system. There are four reservoirs connected to the four ends of the microchannels. Electrodes are inserted into these reservoirs to set up the electrical field across the channels. Initially, a sample solution (a buffer solution with sample analytes) is filled in the reservoir of the inlet Channel 1, the other reservoirs and the microchannels are filled with the pure buffer solution. Figure 1b shows the flow of the sample from the inlet Channel 1 to the waste Channel 2 caused by the application of a chosen injection voltage. This is the so-called injection step. When the sample has completely filled the cross-channel intersection, the electric potential distribution is switched immediately to the separation step, in which Channels 1 and 2 are maintained in an open condition and a separation voltage is applied to Channels 3 and 4. Under these conditions, the sample is forced out of the intersection into the separation channel, as shown in Fig. 1c. This is the so-called separation step. Injection of the sample involves discrete injection and separation steps, during which the controlling electrical fields are established in accordance with Kirchhoff's law. The volume and the concentration of the dispensed sample are the key parameters of this dispensing process, and they depend on the applied electrical field, the flow field, and the concentration field during the injecting and the separating processes.



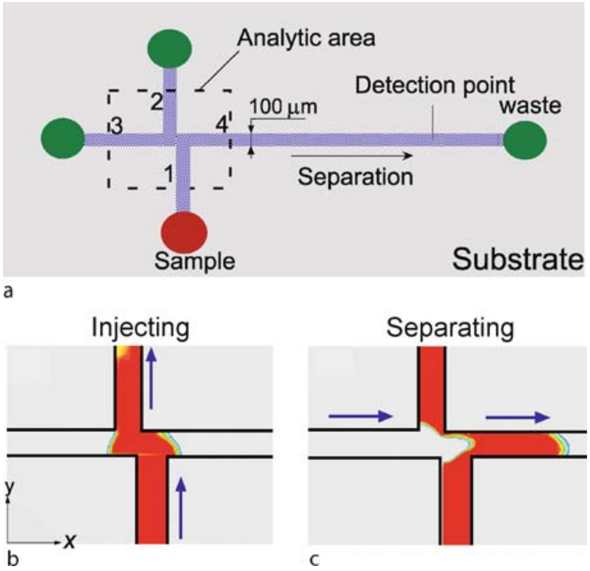
Electrokinetic Sample Injection, Figure 1 Cross-form injection method, (**a**) schematic diagram of injection system; (**b**) injection step; (**c**) separation step

T-Junction Injection Method

Figure 2a provides a schematic diagram of the T-junction injection system. Figure 2b shows the flow of the sample from the inlet channel (Channel 1) to the waste channel (Channel 3) under the influence of an injection voltage. When the sample has completely filled the junction area, the electric potential distribution is switched immediately to the separation step, in which Channel 1 is maintained in an open condition while a separation voltage is applied to Channels 2 and 3. Under these conditions, the sample is forced out of the intersection region into the separation channel, as shown in Fig. 2c. At this magnitude of separation voltage, a noticeable leakage of the sample occurs from Channel 1 as the plug is injected into the separation channel.



Electrokinetic Sample Injection, Figure 2 T-form injection method, (**a**) schematic diagram of injection system; (**b**) injection step; (**c**) separation step



Electrokinetic Sample Injection, Figure 3 Double-T injection method, (**a**) schematic diagram of injection system; (**b**) injection step; (**c**) separation step

Double-T Injection Method

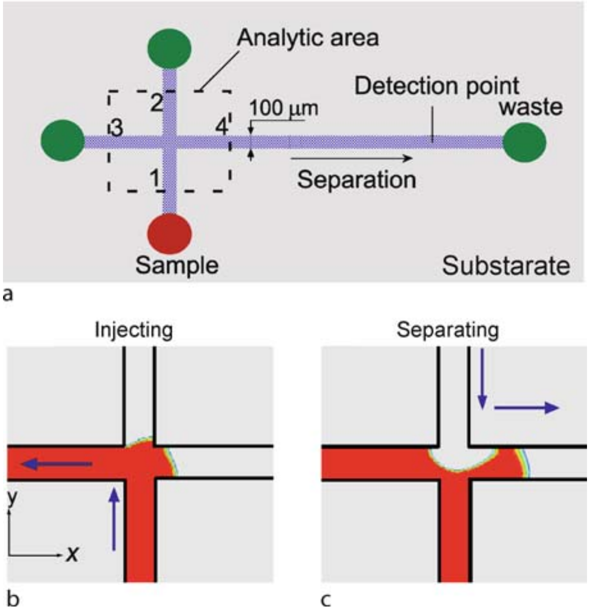
In the cross-form configuration, the volume of the sample plug is determined by the geometry of the cross-sectional area of the injection channel. Hence, the sample volume delivered by such a system is always constant. This arrangement is clearly unsuitable for applications requiring the supply of variable-volume sample plugs to the separation process. A more appropriate solution is to employ the double-T injection system shown schematically in Fig. 3a. This configuration serves as a basic component in a more sophisticated injection system such as multi-T injection system. Fig. 3b shows the flow of the sample from the inlet channel to the waste channel under the influence of an injection voltage. When the sample has completely filled the cross-channel intersection, the electric potential distribution is switched immediately to the separation step, in which Channels 1 and 2 are maintained in an open condition while a separation voltage is applied to Channels 3 and 4. This forces the sample out of the intersection region into the separation channel, as shown in Fig. 3c.

Double-L Injection Method

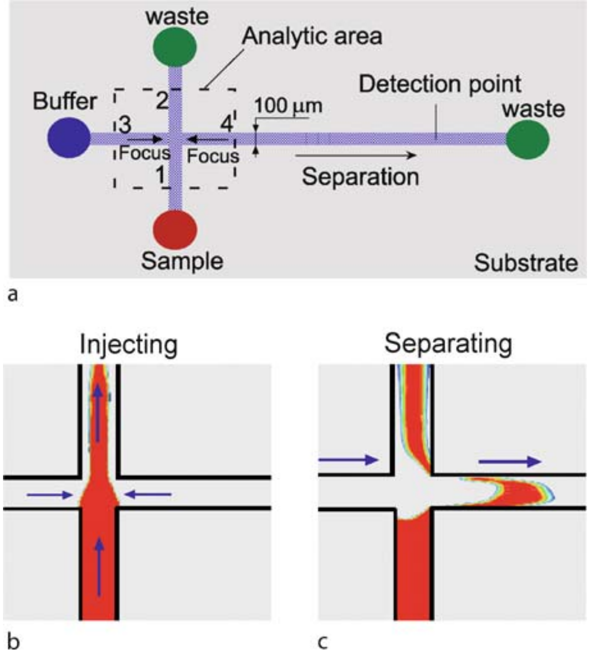
To overcome the problem of flow leakage in the cross-form microchip (Fig. 4a) without resorting to the complex potential control required by the other injection method, a novel double-L injection method has been proposed by Fu et al. [5]. In the injection step, the sample is loaded from Channel 1 to Channel 3 under an applied injection voltage and is diffused into the intersection of Channels 2 and 4 (Fig. 4b). In the separation step, the sample in the intersection region is driven into the separation channel (Channel 4) by a separation voltage applied to Channels 2 and 4 (Fig. 4c). The research demonstrates a clear reduction in the sample leakage into Channel 4 when this double-L injection method is applied. The electric potential control system for the double-L injection method is more straightforward and requires the use of just two control points.

Pinched Injection Method

A pinched injection can be described as an injection technique during which the voltage controls both the injection and the separation [7]. Fig. 5 illustrates the simulated sample plug distributions for the injection and separation procedures in the cross-form microchip (Fig. 5a). Fig. 5b shows the flow of the sample from the inlet channel to the waste channel under the influence of an injection voltage applied to Channels 1 and 2. Meanwhile the chosen electrical field strengths are also applied to Channels 3 and 4 to pinch the sample streams along the waste channel. When the flow reaches the stationary state, the electric potential distribution is switched immediately to the separation step, in which Channels 1 and 2 are maintained in an open con-



Electrokinetic Sample Injection, Figure 4 Double-L injection method in cross-form system, (**a**) schematic diagram of injection system; (**b**) injection step; (**c**) separation step



Electrokinetic Sample Injection, Figure 5 Pinched injection method in cross-form system, (**a**) schematic diagram of injection system; (**b**) injection step; (**c**) separation step

dition while a separation voltage is applied to Channels 3 and 4. This forces the sample out of the intersection region into the separation channel, as shown in Fig. 5c.

For homogeneous buffer and channel properties, material transport into and out of the microchip valve in Fig. 5a can be described as a simple circuit with the following constraint:

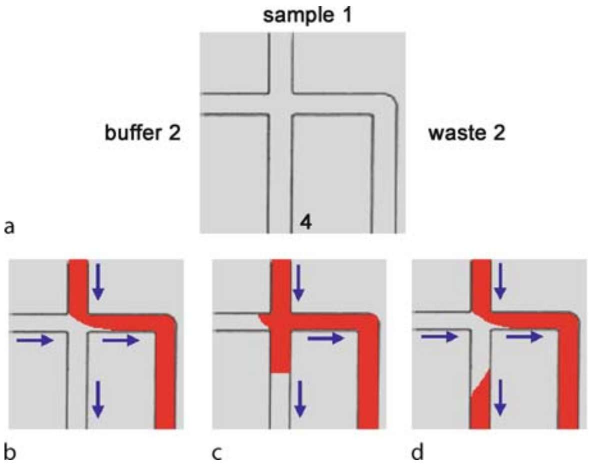
$$E_{\mathrm{w}} = E_{\mathrm{b}} + E_{\mathrm{a}} + E_{\mathrm{s}}$$

where E_{x} is the absolute value of the electric field strength in the buffer (b) Channel 3, sample (s) Channel 1, analysis (a) Channel 4, and sample waste (w) Channel 2.

By adjusting E_{s} relative to E_{b} and E_{a}, the degree of sample confinement in the cross-intersection can be controlled. The electrical field strengths in the buffer and analysis channels should be approximately equal ($E_{\mathrm{b}} \sim E_{\mathrm{a}}$) to achieve a symmetrical sample confinement. The pinching effect can be qualitatively described as weak pinch, medium pinch or strong, depending on the relative magnitude of electrical field strengths $E_{\mathrm{s}} > E_{\mathrm{b}}$, $E_{\mathrm{s}} \sim E_{\mathrm{b}}$ or $E_{\mathrm{s}} < E_{\mathrm{b}}$ respectively.

Gated Injection Method

Initial gated injections [8] also used a T-type configuration. The cross-injection is now widespread. Figure 6 shows the operating sequence of this gated valve. Figure 6a shows a schematic of the microchip used for the gated injection



Electrokinetic Sample Injection, Figure 6 Gated injection method, (**a**) schematic diagram of injection system; (**b**) loading step; (**c**) injection step; (**d**) separation step

method. The sample is transported down the sample Channel 1 through the injection valve into the waste Channel (3) (Fig. 6b). The electric potential applied to the buffer reservoir through the high-voltage relay prevents sample leaking into the analysis channel (4). To load a sample from the sample channel into the analysis channel, the electric potential at the buffer reservoir is removed by opening the high voltage relay for a brief period of time, e. g., 0.4 s in

Fig. 6c. The sample is electrokinetically transported into the analysis channel. To terminate sample flow into the analysis channel, the electric potential at the buffer reservoir is reapplied (Fig. 6d). A small quantity of sample is dispensed into the analysis channel as shown in Fig. 6d. Due to the directionality of the buffer flow, i. e., traveling from left to right as pictured, the rear of the sample plug is triangular in shape but disappears in about one second due to the transverse diffusion within the analysis channel. The asymmetric shape observed at the rear of the sample plug does not hinder high-performance chromatographic separations which employ the gated valve.

For homogeneous buffer and channel properties, material transport in and out of the microchip valve shown in Fig. 6a can be described as a simple circuit with the following constraint:

$$E_\mathrm{b} + E_\mathrm{s} = E_\mathrm{a} + E_\mathrm{w}$$

where E_x is the absolute value of the electric field strength in the buffer (b) Channel 2, sample (s) Channel 1, analysis (a) Channel 4, and waste (w) Channel 3. To prevent the sample from electrokinetically transporting from the cross-intersection into the analysis channel during the sample loading mode

$$E_\mathrm{s} \leqq E_\mathrm{w1} \quad \text{or} \quad E_\mathrm{b} \geqq E_\mathrm{a} \,.$$

The ratio of the sample to waste electric field strength needed to prevent the sample from diffusing into the analysis channel depends on both the transit time of the sample through the cross-intersection and the diffusion coefficient of the sample. Sample to waste electric field strength ratios from 0.4 to 0.75 are obtained empirically for a neutral marker, e. g., rhodamine B. This range allows the sample to pass through the valve from the sample channel to the waste channel without diffusing into the analysis channel.

Key Research Findings

In general, the injections configurations and techniques (including the T-form, the cross-form, the double-T form, gated injection, pinched injection, and double-L injection) described in the above sections are used to load and dispense the sample for bio-analysis. The innate defects of kinetic injection systems are: electrophoretic bias and sample leakage. These effects have to be considered during injection to obtain the higher-resolution detection. Physically, the parameters that affect the quality of the injection are: buffer electroosmotic mobility, sample diffusion coefficient, sample electrophoretic mobility, the difference in conductivity of the solutions, the applied electrical field strength, the channel size, and channel configurations (injector geometry) [1, 10].

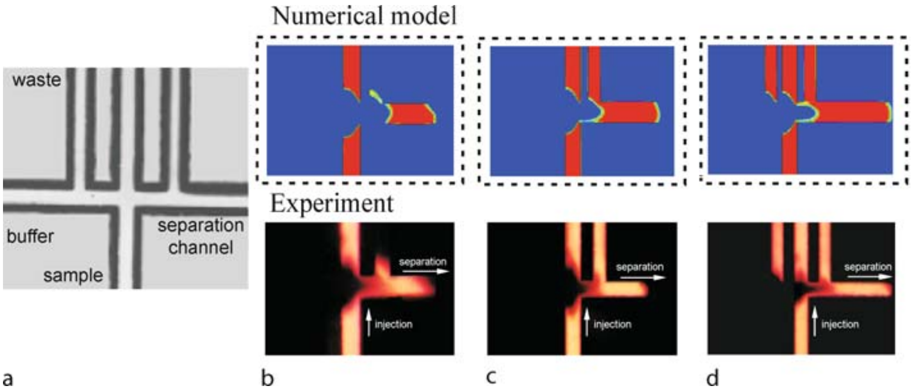
Cross-injection suffers from controlling the sample size and preventing sample leakage, but it is valuable for repeated injections with uninterrupted buffer flow. Jacobson has proposed a pinched injection technique to reduce the sample leakage. A modified pinched injection method with three steps, that minimizes the sample leakage more than the original method has also been proposed [2]. The steps in a three-step pinched injection are: pinched flow from sample reservoir to sample waste reservoir, short flow reversal (retraction into sample reservoir), and dispense sample with buffer from sample channel into analysis channel. The amount that is injected in pinched injection is time independent. Pinched injection does not suffer from controlling the sample size, but it is very limited in the variation of the sample size. The double-L injection technique has been studied in great detail by Fu and his co-workers utilizing experimental and numerical analysis [5]. For this method, sample flow direction is not as in a standard injection across the channel but *around the corner* of the channel cross. The double-L injection is claimed to be very suitable for high-resolution, high-throughput biochemical analytical applications, high precision analysis on a chip, and in many other applications throughout the micrototal analysis systems field.

The gated injector is time dependent and has an electrophoretical sample bias [9]. The performance of this valve is measured by recording temporal profiles at 1 mm downstream of the valve for injection times of 0.2, 0.4, and 0.8 s. The peak maximum does not increase at longer injection times. The peak area reproducibility is better than 0.5% relative standard deviation for 20 injections for each injection time. As with conventional electrokinetic injection schemes, this injection is also biased by the relative electrokinetic mobility of the sample ions. This valve dispenses sample volumes that are linearly proportional to the electrophoretic mobility for which this bias is easily compensated.

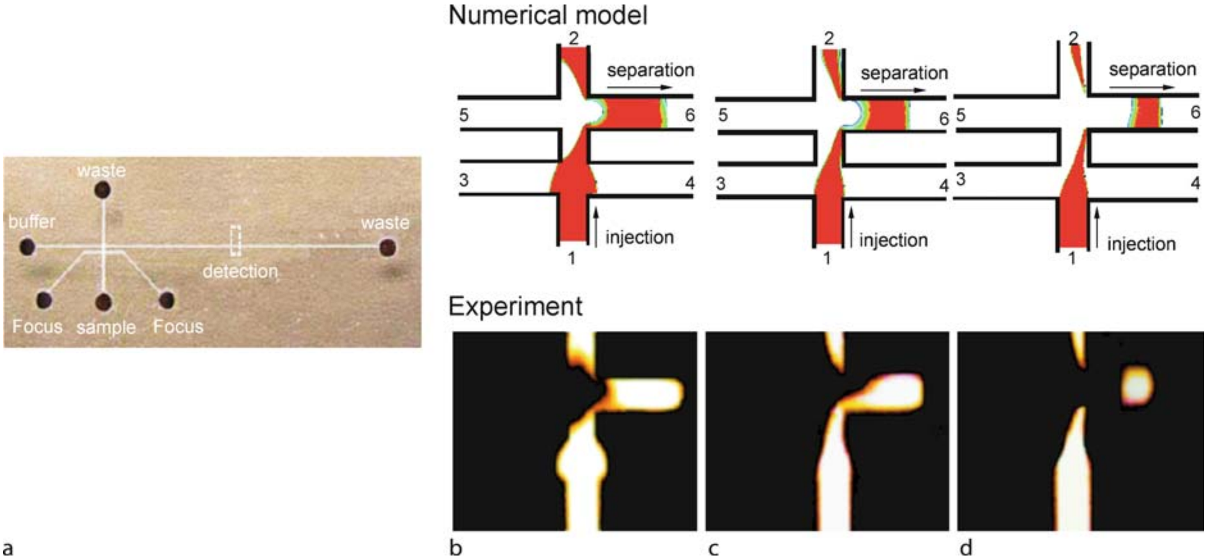
The majority of injection systems are only capable of delivering a fixed-volume sample plug into the analysis channel and are limited in function by their configuration. Fu and his co-workers have proposed the multifunction injection system and a variable-volume-injection system within the microfluidic chip as described below.

Multifunction Injection System

Traditionally, the design of the injection channel has always been in the form of a cross. A limitation of this configuration is that it is only capable of providing discrete, fixed-volume samples. However, some applications require the delivery of different sample volumes to the detection and separation processes. The unique multi-T



Electrokinetic Sample Injection, Figure 7 Multifunction injection system (**a**) schematic diagram of injection system; (**b**) cross form injection method, (**c**) double-T injection method, and (**d**) triple-T injection method



Electrokinetic Sample Injection, Figure 8 Variable-volume-injection system (**a**) microfluidic chip, (**b**) focusing ratios $F/\phi = 1$, (**c**) $F/\phi = 1.4$, and (**d**) $F/\phi = 1.8$

configuration injection system [3] has the ability to simulate the functions of the cross, double-T and triple-T systems through appropriate manipulations of the electric field within its various channels. Figure 7 shows the experimental and numerical simulation results of the proposed multi-T-form injection system.

Variable-Volume-Injection System

A double-cross-injection system, which combines conventional cross-injection systems and the electrokinetic focusing technique on a single microfluidic chip, has been designed and its performance analyzed. Through the appropriate specification of the electric focusing ratio, it has been shown that the proposed system is not only capable of performing the same function as the traditional cross-injection system, but that it is also able to generate sample plugs of different volumes. Finally, the results indicate that the proposed design improves the sample plug distribution in the analysis channel, and thus results in a superior separation detection performance. Figure 8 shows the experimental and simulated results for the double-cross-injection system [4] at focusing ratios of 1, 1.4, and 1.8, respectively.

Future Directions for Research

Quality assurance in micro-CE has yet to be studied in detail. Research focuses on practical applications and the transfer of separation problems to a microdevice. One

problem is the chip-to-chip variation from manufacturing, another the run-to-run performance due to reloading, the cleaning of the channel surfaces, the not perfect electrokinetic injection mode, or that instrumental setups are usually still in the trial state and have only been optimized for one purpose [2].

A problem for all microdevices is the introduction of a sample into the microreservoir or onto the microdevice. Usually the samples are loaded manually onto the device by means of a micropipette or similar tool. This process is not very compatible with an analytical device intended to be ultrafast, with a high sampling rate, and easily applicable in different areas. Methods in which injection and sample loading is done in one step should be developed more intensively in future.

Electrokinetic Sample Introduction

Definition

Electrokinetic sample introduction is performed by using the electroosmotic flow (EOF) in the microchannel as a pump and can be easily controlled by outside high voltages.

Definition

Biological macromolecules are often handled through microfluidic systems, in which these molecules can transport and react. A common driving force behind such microfluidic transport processes is the electrokinetic force, which originates as a consequence of interaction between the electrical double layer potential distribution and the applied electric field. This article discusses some of the important features of the biochemical reactions in such microfluidic systems.

Overview

The development of microfluidic systems enables the integration of miniaturized components for accomplishing biochemical processes or biomedical diagnostics. Performing these procedures in microfluidic systems allows a rapid biochemical analysis to be carried out at a volumetric scale that is several orders of magnitudes below that of conventional practice. Overall, bio-microfluidics provide great promise in improving the sensitivity, specificity and

processing time required, which are the key requirements for advanced biomedical analysis. It needs to be noted in this regard that most of the biological objects of interest, such as DNA, proteins and cells, have characteristic length scales from a few nanometers to micrometers. Electrokinetics are especially effective in such small domains, by taking advantage of the favorable scaling laws. From the implementation point of view as well, the integration of micro- or nanoscale electrodes in fluidic devices is a relatively simple procedure, with the advancement of MEMS fabrication technologies. As a consequence, electrokinetic forces turn out to be ideal for manipulating biological objects and performing fluidic operations in reactive biochemical systems.

Active and Passive Microarrays

In order to appreciate the significance of biochemical reactions in micro total analysis systems, it needs to be appreciated first that different methods, in principle, can be employed to detect eventual abnormalities or illnesses in patients. For viral infections or blood-related pathologies, for example, immunoassays can be performed to determine the nature of organisms that are responsible for disturbing the inherent immunological defensive systems in the living beings. One way of performing this is to use homogeneous systems in which the sample and detection molecules are both in a liquid system. Another way is to employ a heterogeneous system, in which one type of molecule involved is bound to the solid substrate. For genetic ailments, DNA analysis can be performed to figure out whether a patient possesses a mutation in a specific gene. One of the methods to analyze this condition is to perform a gel-phase electrophoretic separation of fragments formed from the DNA under question. Differences in fragment lengths from the patient's DNA and a healthy reference indicate the possibilities of certain genetic ailments. Another method for accomplishing this purpose is to introduce many different known single stranded (ss) DNA sequences, bound together with particles or gels in a reactive microsystem. The DNA sample under investigation can be "hybridized" with these different sequences. By figuring out the specific DNA sequence with which this sample reacts (there is only one complementary sequence with which such selective reaction becomes possible), one can determine the DNA sequence of the unknown sample. A general principle of operation of the heterogeneous assays is to probe molecules that are bound to the solid substrates, in order to detect the target molecules in a given sample. When a liquid sample is brought into contact with the surface-bound probe molecules, target molecules migrate towards the walls by diffusion, and react with the probe (capturing) molecules. A majority of DNA microarray technologies are based on such passive nucleic acid hybridization, i. e., the binding event depends upon diffusion of target DNA molecules to the capture probe DNAs. Unfortunately, the passive DNA hybridization approach may take several hours. This is because of the fact that the target DNAs, with a typical diffusion coefficient of the order of $10^{-7}\,\mathrm{cm^2/s}$ (for oligonucleotides that are 18 base pairs in length, for example), only reach the capture probes via Brownian (random) motion in order to hybridize. Because of this dependency on diffusion transport of target DNA, large amounts of target DNA and long hybridization times are often required to achieve detectable hybridization signals and repeatable results. Accordingly, many researchers have explored alternative methods to make the DNA sensing faster and more sensitive in solutions with low concentrations of target DNAs. One of the earlier alternative methods was to utilize electric fields to accelerate the rate of interaction between capture probes and target DNA molecules, since the DNA strand has multiple negatively charged groups. In diffusion-based transport of DNA, the time (τ) it takes a DNA molecule to travel over a distance x is given as

$$\tau = \frac{x^2}{2D} \tag{1}$$

where D is the diffusion coefficient. In the case of electrophoresis, the time it takes to move a molecule in the electric field (electrophorese) over a distance x is given by

$$\tau = \frac{x}{\mu E} \tag{2}$$

In this case, μ is the electrophoretic mobility and E is the electric field strength. Using typical values for D ($9.943 \times 10^{-7}\,\mathrm{cm^2/s}$) and μ ($15{,}000\,\mathrm{\mu m^2/V-s}$), and under an electric field of $0.004\,\mathrm{V/\mu m}$, it appears that electrophoretic transport may be 150 times faster over a $500\,\mathrm{\mu m}$ distance. Even though the electrophoretic transport method presents a clear hybridization speed advantage, one critical disadvantage is that the sample solution containing the target DNA must be desalted before hybridization in order to establish an appropriate electric field. In a high-salt solution, including most biological buffers, the electric field depth exists only in close proximity to the electrodes because the high concentration of ions nullifies the electric field in the area away from the electrodes. To facilitate rapid movement of DNA by an electric field, a low conductive buffer solution needs to be used. In contrast, in molecular biology, to achieve efficient hybridization, one always works in high-conductivity solutions. Therefore, desalting is not only counterintu-

itive, but also cumbersome. Rather, a more convenient approach can be to combine a DNA microarray with an electrokinetically driven microfluidic platform, in an effort to enhance the mass transport of target DNA to make detection faster and obtain a lower detection limit (LDL) for DNA hybridization. There are several advantages associated with such microfluidic DNA arrays: they enable detection at the lowest possible DNA concentrations, allow for shorter times to achieve this detection because of enhanced mass transport, offer the ability to monitor several samples in parallel by using a multichannel approach, reduce the potential for contamination by relying on an enclosed apparatus, and they hold the overall promise for integration of several functions in one apparatus (μ-TAS). While the case of biochemical reactions involving DNA samples represents a generic example, similar instances do exist for biochemical reactions involving other types of macromolecules as well.

Basic Reaction Kinetics

In order to appreciate the intricacies associated with biochemical reactions in electrohydrodynamic microsystems, it may be instructive to revisit certain basic definitions associated with the chemical kinetics of reactive systems. These basic concepts are briefly elucidated below.

1. Rate of reaction. For a chemical reaction of the form $A + nB \rightarrow mC + D$, the rate of reaction is defined as

$$r = r_D \left(= \frac{\mathrm{d}[D]}{\mathrm{d}t} \right) = \frac{1}{m} r_C \left(= \frac{1}{m} \frac{\mathrm{d}[C]}{\mathrm{d}t} \right)$$
$$= r_A \left(= -\frac{\mathrm{d}[A]}{\mathrm{d}t} \right) = \frac{1}{n} r_B \left(= -\frac{1}{n} \frac{\mathrm{d}[B]}{\mathrm{d}t} \right) .$$

   As such,r is a function of the concentration of individual species, i. e., $r = r([A], [B], [C], [D])$. For most substances, this relationship is empirical in nature and needs to fitted experimentally. The most common form of this functional relationship is $r = k[A]^a [B]^b$, where k, a and b are time-independent coefficients. The parameter k is called the "rate constant", which should not be confused with the thermodynamic definition of "equilibrium constant" of a specified reaction.

2. Order of reaction. If the rate of reaction is described by the above mentioned functional form, the order of reaction is defined as $o = a + b$. It is important to note here that the unit of k depends on the order of the reaction. For example, for a zero-order reaction k is expressed in units of mol/m^3/s, for a first-order reaction k is expressed in units of 1/s and for a second-order reaction k is expressed in units of m^3/mol/s. The rate constant is usually taken to vary with the activation energy (E_a) and temperature (T) by the Arrhenius law, as $k = k_0 \exp(-E_\mathrm{a}/RT)$. From molecular interpretations, the rate constant is the rate of successful collisions between the reacting molecules, the activation energy represents the minimum kinetic energy of the reactant molecules in order to form the products and k_0 corresponds to the rate at which these collisions occur.

3. Adsorption and the Langmuir model. In the case of adsorption of molecules on a solid functionalized surface, there are basically three components in the reaction. There is a free substrate in the buffer fluid (often called the target or analyte), with a concentration of $[S]$. Second, there is a surface concentration of the ligands or capturing sites immobilized on a functionalized surface, with a concentration of $[\Gamma]_0$. Finally, there is a surface concentration of the adsorbed targets (products of the reaction), with a concentration of $[\Gamma]$. The units of $[\Gamma]$ and $[\Gamma]_0$ are in mol/m^2, whereas $[S]$ is expressed in units of mol/m^3. In case of adsorption, the definitions of the reaction rates are somewhat modified from the usual rate constant definitions mentioned above, primarily because of the fact that the immobilization of the substrate S not only depends on the volume concentration at the wall, but also depends on the available sites for adsorption. Accordingly, one can write $-\mathrm{d}[S]/\mathrm{d}t = k_\mathrm{a}([\Gamma]_0 - [\Gamma])[S]_\mathrm{w}$ and $-\mathrm{d}[\Gamma]/\mathrm{d}t = k_\mathrm{d}[\Gamma]$, where k_a and k_d are the adsorption and dissociation rates, respectively. The concentration of Γ is increased by the former and is decreased by the latter, and the net rate of change is given by their balance, i. e.,

$$\frac{\mathrm{d}[\Gamma]}{\mathrm{d}t} = k_\mathrm{a}([\Gamma]_0 - [\Gamma])[S]_\mathrm{w} - k_\mathrm{d}[\Gamma] \tag{3}$$

Equation (3) can be integrated to obtain

$$\frac{[\Gamma]}{[\Gamma]_0} = \frac{k_\mathrm{a}[S]_\mathrm{w}}{k_\mathrm{a}[S]_\mathrm{w} + k_\mathrm{d}} \left[1 - \exp\left(-\left(k_\mathrm{a}[S]_\mathrm{w} + k_\mathrm{d}\right)t\right)\right] \tag{4}$$

Equation (4) represents an exponential growth of $[\Gamma]$ with time, until a saturation (asymptotic) value is reached ($[\Gamma]_\mathrm{a}/[\Gamma]_0 = k_\mathrm{a}[S]_\mathrm{w}/(k_\mathrm{a}[S]_\mathrm{w} + k_\mathrm{d})$ at $t = t_\mathrm{a}$, say). After this occurs, the remaining targets or analytes may be suddenly washed out. In that case, desorption becomes the driving mechanism. With the asymptotic condition as an initial condition for the desorption reaction, the kinetics of desorption is now governed by $-\mathrm{d}[\Gamma]/\mathrm{d}t = k_\mathrm{d}[\Gamma]$, leading to the following time variation of surface concentration:

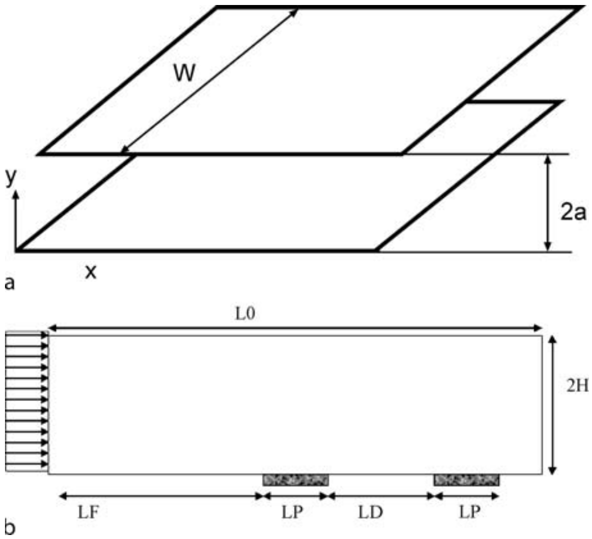
$$\frac{[\Gamma]}{[\Gamma]_\mathrm{a}} = 1 - k_\mathrm{d}(t - t_\mathrm{a}) \tag{5}$$

Basic Methodology

The physicochemical processes associated with the biochemical reactions in the presence of electrokinetic transport are often mathematically described by invoking the governing equations for electric potential distribution and mass, momentum, energy and the species conservation equations. In this article, we shall describe these basic equations by referring to the example of DNA hybridization in electrokinetically driven microchannel flows, which is a problem of immense interest from bio-technological and biomedical perspectives. In fact, hybridization of nucleic acids to their complementary sequences is a fundamental process in molecular biology. It plays a major role in replication, transcription and translation, where specific recognition of nucleic acid sequences by complementary strands is essential for propagation of information content. In practice, microchip-based nucleic acid arrays presently permit the rapid analysis of genetic information by hybridization. Since their introduction, DNA chips have gained wide usage in bioanalytical chemistry, with applications in important areas such as gene identification, genetic expression analysis, DNA sequencing and clinical diagnostics. Many of these devices have been classically based on "passive" microarrays, which suffer from several limitations. First, since all nucleic acids are exposed to the same conditions simultaneously, capture probes must have similar melting temperatures to achieve similar levels of hybridization stringency. This places limitations on the length, GC content and secondary structure of the capture probes. Further, since the rate of hybridization is proportional to the initial concentration of the interrogated solution, high concentrations are required to achieve rapid hybridization. Moreover, due to difficulties associated with control of hybridization conditions, single base discrimination is generally restricted to oligomers of 20 bases or less with centrally placed differences. Overall, the entire phenomenon relies solely on diffusion of probe molecules to the DNA target surface, requiring several hours to achieve efficient hybridization of DNA molecules to capture probes. In an attempt to circumvent the above limitations, "active" microelectronic devices constituted of microchip-based hybridization arrays have recently been proposed, which utilize electric field as an independent parameter to control DNA transport, enhance hybridization and improve stringency of nucleic acid interactions. In typical arrangements utilizing such electrokinetic effects, electrode arrays are covered with a permeation layer with embedded DNA capture probes, in an effort to control the transport of biomolecules and achieve their accumulation and hybridization at desired sites. Such arrays primarily consist of patterned metal electrodes on an insulating substrate, and are contained in a plastic housing equipped with fluidic conduits to manipulate charged biomolecules as well as ions in the fluid sample. It has been effectively realized that electroosmosis, which refers to liquid flow by an applied electric field along electroosmotically charged surfaces, may turn out to be a very suitable method for manipulating liquid flows in such cases in order to transport the biological targets suspended in controlled liquid samples of nanovolumes. Although a number of reports have appeared in the literature to model electrokinetically driven microchannel flows, attempts have rarely been made towards a comprehensive mathematical modeling of transport and accumulation of DNA in a microfluidic channel. Paces et al. [1] were amongst the early groups of researchers to numerically model DNA accumulation and hybridization in the presence of electroosmotic transport of charged species in an electrolyte. Ozkan [2] in a similar study based on finite element methods, investigated the effects of charged species concentration, size, position, type of buffer solution and patterned electrode configuration on the electric field distribution, and hence electrokinetic transport of charged molecules. Kassegne et al. [3], in a more recent study, investigated the transport and accumulation of DNA in active electronic chips, through experimental and numerical modeling. Kinetics of DNA hybridization, however, was not considered in their model. In fact, compared to numerous experimental investigations, relatively few attempts have been made in the literature to develop fundamental models of DNA hybridization. Chan et al. [4] developed one of the more frequently cited solid-phase hybridization kinetics models, based on the receptor–ligand model developed by Axelrod and Wang [5], with a proposition that hybridization can occur either by direct hybridization from the bulk phase or hybridization after an initial nonspecific adsorption step followed by subsequent surface diffusion to the probe. Based on this approach, Zeng et al. [6] proposed a dynamic model combining these two basic mechanisms. Following an alternative approach, Sadana and Ramakrishnan [7] used fractal kinetics for pertinent hybridization data analysis. Erickson et al. [8] came up with a comprehensive model of dynamic solid-phase oligonucleotide hybridization kinetics, based on an approach which accounted for both the direct hybridization from the bulk phase and hybridization after an initial nonspecific adsorption stage. However, investigations regarding influences of electrosmotic flow mechanisms on DNA hybridization characteristics were beyond the scope of their study. Das et al. [9] have recently extended the DNA hybridization model developed by Erickson et al. [8] to include combined effects of electrokinetic and pressure-driven transport. In their study, a comprehensive mathe-

matical model was developed, quantifying the pertinent momentum, heat and species transfer rates. Influences of bulk and surface properties on the velocity field were critically examined, which in turn dictate the nature of thermosolutal transport, and hence the DNA concentration fields, in accordance with specific and nonspecific hybridization mechanisms. Joule heating and viscous dissipation effects were also incorporated, which can cause a perceptible temperature rise, and accordingly affect various flow parameters as well as the rate constants for the hybridization.

The fundamental analysis executed by Das et al. [9] deals with the microfluidic transport through a parallel plate microchannel of height $2a$ and width w, with $w \gg 2a$ (see Fig. 1a). The length of the channel is taken to be L0. Two capturing DNA probes are assumed to be attached to the bottom wall, each spanning over a length of LP (see Fig. 1b). A potential gradient is applied along the axis of the channel, which provides the necessary driving force for electroosmotic flow. Under these conditions, an electric double layer (EDL) forms near the liquid–wall interface. This EDL interacts with the externally applied electrical field. For example, positively charged ions of EDL are attracted towards the cathode and repelled by the anode, resulting in a net body force that tends to induce bulk motion of ionized fluid in the direction of the electric field. When this voltage is applied to a buffer solution with a finite thermal conductivity, the resulting current also induces an internal heat generation, often referred to as Joule heating. The thermal and fluid flow field, thus established within the channel, is responsible for the macromolecular transport, which has to be understood thoroughly to get a complete picture of the hybridization model. For mathematical modeling of the problem mentioned as above, the following major assumptions are made:



Electrokinetic Transport with Biochemical Reactions, Figure 1 (**a**) schematic diagram depicting the problem domain. (**b**) A schematic diagram depicting the probe arrangements at channel walls

1. The temperature, velocity and concentration fields are unsteady and two-dimensional.
2. The effect of pH change on the ensuing chemical reactions due to hydrogen and hydroxyl ions is neglected.
3. The effect of charges carried by the DNA species on the electric field is neglected.
4. The effect of permeation layer on the DNA transport and accumulation and electric field distribution is neglected.

The governing transport equations, under these circumstances, can be described as follows.

Continuity equation:

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \boldsymbol{V}) = 0 \tag{6}$$

X-momentum equation:

$$\frac{\partial}{\partial t}(\rho u) + \nabla \cdot (\rho \boldsymbol{V} u) = -\frac{\partial p}{\partial x} + \nabla \cdot (\mu \nabla u) + b_{\mathrm{x}} \tag{7}$$

where b_{x} is the body force term per unit volume in the x-direction, given as: $b_{\mathrm{x}} = -\rho_{\mathrm{e}}(\partial\phi/\partial x)$, where ρ_{e} is the net electric charge density and ϕ is the potential distribution due to an externally imposed electric field.

Y-momentum equation:

$$\frac{\partial}{\partial t}(\rho v) + \nabla \cdot (\rho \boldsymbol{V} v) = -\frac{\partial p}{\partial y} + \nabla \cdot (\mu \nabla v) + b_{\mathrm{y}} \tag{8}$$

where b_{y} is the body force term per unit volume in the y-direction, given as: $b_{\mathrm{y}} = -\rho_{\mathrm{e}}(\partial\phi/\partial y)$. In both Eq. (7) and (8), the dynamic viscosity, μ, is a function of temperature, given as

$$\mu = 2.761 \times 10^{-6} \exp\left(\frac{1713}{T}\right) \tag{9}$$

where T is in K and μ is in Pa s. It can be noted here that the distribution of ϕ needs to be solved from the Laplace equation, as a consequence of an externally imposed electrical potential gradient. The corresponding governing differential equation is

$$\nabla \cdot (\sigma \nabla \phi) = 0 \tag{10}$$

where σ is the electrical conductivity of the solution. Further, distribution of the net electric charge density, ρ_{e}, appearing in the momentum conservation equations is to

be ascertained by solving the Poisson–Boltzmann equation for surface potential distribution as

$$\nabla \cdot (\varepsilon \nabla \psi) = -\frac{\rho_e}{\varepsilon_0} \tag{11}$$

where ψ denotes the EDL potential, ε_0 is the permittivity of free space and ε is the dielectric constant of the electrolyte which is a function of temperature, given as

$$\varepsilon = 305.7 \exp\left(-\frac{T}{219}\right) \tag{12}$$

where T is in Kelvin. In Eq. (11), ρ_e is described as

$$\rho_e = -2 n_0 e z \sinh\left(\frac{e z \psi}{k_B T}\right) \tag{13}$$

where n_0 is the ion number density, e is the electronic charge, z is the valence, k_B is the Boltzmann constant and T is the absolute temperature. To depict the relationship between the net electric charge density and Debye length, we express n_0 as a function of the Debye length, λ, given as

$$n_0 = \frac{\varepsilon k_B T}{8\pi e^2 z^2 \lambda^2} \tag{14}$$

Energy conservation equation:

$$\frac{\partial}{\partial t}(\rho C_P T) + \nabla \cdot (\rho C_P \boldsymbol{V} T) = \nabla.(k \nabla T) + \varphi + \dot{q} \tag{15}$$

where k is the thermal conductivity of the electrolyte solution, which is a function of temperature, given as

$$k = 0.6 + 2.5 \times 10^{-5} T \tag{16}$$

where T is in K and k is in $\mathrm{W/(m^2K)}$. In Eq. (15), φ is the heat generation due to viscous dissipation, given as

$$\varphi = 2\mu \left[\left(\frac{\partial u}{\partial x}\right)^2 + \left(\frac{\partial v}{\partial y}\right)^2\right] + \mu \left(\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x}\right)^2 \tag{17}$$

Further, $\dot{q}$ is the heat generation due to Joule heating, which, according to Ohm's law, can be given as

$$\dot{q} = \frac{I^2}{\sigma} \tag{18}$$

It can be noted here that the electrical current density includes two parts: one is due to the applied electric field imposed on the conducting solution ($\sigma \boldsymbol{E}$), and the other is due to the net charge density moving with the fluid flow ($\rho_e \boldsymbol{V}$). Therefore, the electrical current density, I, can expressed as

$$\boldsymbol{I} = \rho_e \boldsymbol{V} + \sigma \boldsymbol{E} \tag{19}$$

Using Eq. (18) and (19) one can obtain the heat generation due to Joule heating as

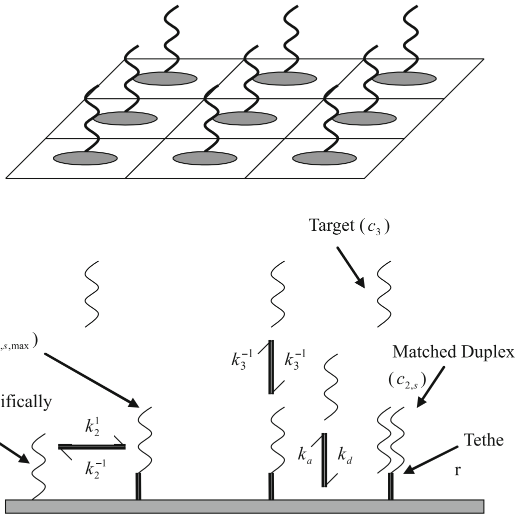
$$\dot{q} = \frac{(\rho_e \boldsymbol{V} + \sigma \boldsymbol{E}) \cdot (\rho_e \boldsymbol{V} + \sigma \boldsymbol{E})}{\sigma} \tag{20}$$

Species conservation equation:

$$\frac{\partial (\rho c_i)}{\partial t} + \nabla \cdot (\rho \boldsymbol{V} c_i) = \nabla \cdot (\rho D_n \nabla c_i) + \mu_{os} z_i F \nabla \cdot (\rho c_i \nabla \phi) + \rho R_i \tag{21}$$

where c_i is the concentration of the ith species in the solution, μ_{os} is the electroosmotic mobility of the concerned species, z_i is the valence of the ith species and F is Faraday's constant. In Eq. (21), D_n is a generalized diffusion coefficient, which is the liquid-phase diffusion coefficient (D_3) in the bulk fluid and surface-phase diffusion coefficient (D_2) at the nonspecific adsorption sites. The term R_i is a generation/source term, details of which will be described subsequently.

The above model of species (DNA) transport is coupled with two basic mechanisms of hybridization (see Fig. 2), namely direct (specific) hybridization from the bulk phase



Electrokinetic Transport with Biochemical Reactions, Figure 2
A schematic diagram depicting the dual mechanism of DNA hybridization

to the surface-bound probes or by indirect (nonspecific) hybridization in which the target is initially nonspecifically adsorbed on the surface and then diffuses along the surface before reaching an available target probe molecule. In recent times, much research has been dedicated to demonstrate how the above reduction of dimensionality (RD) enhances the overall capture rate. In general, when a partner in a biomolecular reaction is immobilized on a surface, the rate of capture would depend on events in the bulk (3D) as well as on the surface (2D), and on the relative ratio of solute diffusion to the intrinsic reaction rate. However, hybridization that occurs in the interphase between a solid and solution is anticipated to demonstrate kinetics that is different from that observed in the bulk solution. It has been suggested in the literature [4] that nonselective adsorption of single-stranded oligonucleotide, followed by surface diffusion (2D diffusion coefficients) to immobilized probes can enhance hybridization rates in contrast to direct hybridization in the solution. This suggestion is based on a reduction of dimensionality of diffusion from a 3D to a 2D phenomenon. A generally accepted mechanistic description of the hybridization reaction between a homogeneously suspended probe DNA and an immobilized target DNA strand postulates that [5] in the first phase, the probe DNA strand diffuses towards the target strand. During the subsequent collision, a so-called nucleation site, involving the formation of the first short stretch of base pairing containing at least three contiguous bases, is formed. In the following phase, either a stable base pair is formed during a rapid "zippering" reaction, or, in case of a mismatch, the nucleation site loses its stability, and the probe strand detaches and prepares for another attempt, either with the same, or with a different target strand. With the basic binding step occurring very rapidly, the overall slowness of hybridization has either to be attributed to a large number of successive attempts which are needed before a successful collision occurs and/or the fact that the supply of unbound probe DNA strand occurs too slowly. Exact theories in this regard, however, are yet to be well established.

Regarding the interactions between bulk- and surface-phase kinetics mentioned above, Eq. (21) needs to be coupled with appropriate boundary conditions depicting specific and nonspecific hybridization, as applied to all reacting surfaces. In the present formulation, incorporation of these boundary conditions is effected by formulating the source term R_i in Eq. (21) such that $R_i = 0$ for the bulk phase. However, for the reactive bottom wall (where the capturing probes are attached):

$$R_i = -\left(\frac{\partial c_{2,\mathrm{s}}}{\partial t} + \frac{\partial c_{2,\mathrm{ns}}}{\partial t}\right) \tag{22}$$

where $c_{2,\mathrm{s}}$ and $c_{2,\mathrm{ns}}$ are the surface-phase concentration of specifically and nonspecifically adsorbed target molecules, respectively. Along the non-reacting surface, the above term reduces to a zero flux boundary condition, in effect. The terms involved in Eq. (22) can further be expressed as a set of coupled 2D kinetic equations as

$$\begin{aligned}\frac{\partial c_{2,\mathrm{s}}}{\partial t} &= \left[k_3^1 c_{3,\mathrm{m}}(c_{2,\mathrm{s,max}} - c_{2,\mathrm{s}}) - k_3^{-1} c_{2,\mathrm{s}}\right] \\ &\quad + \left[k_2^1 c_{2,\mathrm{ns}}(c_{2,\mathrm{s,max}} - c_{2,\mathrm{s}}) - k_2^{-1} c_{2,\mathrm{s}}\right]\end{aligned} \tag{23}$$

and

$$\begin{aligned}\frac{\partial c_{2,\mathrm{ns}}}{\partial t} &= \left[k_\mathrm{a} c_{3,\mathrm{m}}(c_{2,\mathrm{ns,max}} - c_{2,\mathrm{ns}}) - k_\mathrm{d} c_{2,\mathrm{ns}}\right] \\ &\quad - \left[k_2^1 c_{2,\mathrm{ns}}(c_{2,\mathrm{s,max}} - c_{2,\mathrm{s}}) - k_2^{-1} c_{2,\mathrm{s}}\right]\end{aligned} \tag{24}$$

where $c_{2,\mathrm{s,max}}$ is the maximum concentration of the hybridized targets (equivalent to the local concentration of the surface-bound probes available for hybridization), $c_{2,\mathrm{ns,max}}$ is the maximum concentration of the nonspecifically adsorbed molecules, $c_{3,\mathrm{m}}$ is the bulk-phase concentration of the targets in surface film, k_3^1 is the kinetic association constant for direct hybridization (from solution phase), k_3^{-1} is the kinetic dissociation constant for direct hybridization (from solution phase), k_2^1 is the kinetic association constant for indirect hybridization of the nonspecifically adsorbed targets (from surface phase), $k_2^{-1}$is the kinetic dissociation constant for indirect hybridization of the nonspecifically adsorbed targets (from surface phase), k_a is the kinetic association constant for nonspecific adsorption of the targets to the surface and k_d is the kinetic dissociation constant for nonspecific adsorption of the targets to the surface. Physically, Eq. (23) describes that the rate of change in surface concentration of hybridized species is a combination of the rate of change of targets getting hybridized directly from the bulk phase and the rate of targets getting hybridized after an initial nonspecific adsorption. Equation (24) implies that the rate of change in surface concentration of nonspecifically adsorbed targets is increased by the rate of adsorption from the bulk phase, but is decreased by the rate at which the nonspecifically adsorbed targets become hybridized.

Determination of the kinetic constants appearing in Eq. (23) and (24) needs microscopic and statistical theories of collision to be essentially invoked. A physical basis of this lies in the fact that pure diffusion, with its fractal-like path, necessarily leads to an infinitely high collision rate for the situation represented here, manifested by a non-zero average solute concentration immediately

in contact with each target. To account for finite reaction rates with non-zero local concentration in a diffusion-based framework, one must assume that the reaction probability per collision is diminishingly small, which may be a major deviation from the reality. The other approach, which is described here, recognizes that the molecules follow a Brownian motion path rather than a pure diffusion one, which yields a finite number of collisions from a finite solute concentration near the target probe. In Brownian motion, molecular velocity has a finite persistence length, since the instantaneous momentum of the molecule can be transferred to the solvent only at a finite rate of solvent velocity. Hence, the Brownian motion persistence length plays a central role in determining both reaction kinetic rates and reduction of dimensionality enhancement. Following fundamental postulates of statistical physics and the work of Axlerod and Wang [5], it can be postulated that the reaction rate of direct hybridization (R_3) can be obtained as a product of bulk-phase flux of target molecules colliding with the surface (F_3), probability of collision location being a probe site (P_p), probability that the probe is available for hybridization (P_a) and probability that the collision will result in successful hybridization (P_r). All these effects can be combined to obtain the following equation for rate of reaction [8]:

$$R_3 = k_3^1 C_{3,\mathrm{m}} \left(C_{2,\mathrm{ns,max}} - C_{2,\mathrm{s}}\right) \tag{25}$$

where $k_3^1 = 3D_3 N_\mathrm{v} \pi R_\mathrm{p}^2 \chi_3 / 2S_3$. In Eq. (20), N_v is the Avogadro number, R_p is the radius of probe site, χ_3 is the probability that 3D collision will result in a successful hybridization and S_3 is the frequency of collision in 3D. A similar approach can be followed to determine the rate of reaction for nonspecifically adsorbed target as

$$R_2 = k_2^1 C_{2,\mathrm{ns}} \left(C_{2,\mathrm{s,max}} - C_{2,\mathrm{s}}\right) \tag{26}$$

where $k_2^1 = 8D_2 N_\mathrm{v} R_\mathrm{p} \chi_2 / S_2$. In Eq. (21), D_2, χ_2 and S_2 are similar to D_3, χ_3 and S_3, except for the fact that the earlier group represents a 2D collision behavior.

Although Eq. (25) and (26) are fundamental in nature, the reaction probability, χ_n, is rather uncertain. Instead, a classical Wetmur–Davidson relationship [9] may be used to estimate the rate of hybridization for bulk-phase targets in the surface film as

$$k_3^1 = 3.5 \times 10^5 \frac{l^{0.5}}{N} \tag{27}$$

where N is the complexity of the target sequence and l is the number of nucleotide units. In general, complexity of the sequence is taken as the total number of non-repeating sequences in a DNA strand. In the absence of any steric interference, in which the bulk molecules are able to move freely within the surface film, the above is likely to be valid in an approximate sense. In cases of denser probe spacings or a large quantity of nonspecifically adsorbed targets, Eq. (27), however, is likely to overestimate the pertinent kinetic constant.

With the above estimation of k_3^1, k_2^1 can be obtained by dividing Eq. (25) by (26), and assuming that $\chi_2 = \chi_3$, $S_2 = S_3$, as

$$k_2^1 = k_3^1 \left(\frac{16}{3\pi}\right)\left(\frac{D_2}{D_3}\right)\left(\frac{1}{R_\mathrm{p}}\right) \tag{28}$$

The reverse kinetic constant may be obtained by appealing to thermodynamic stability requirements of the dissociation kinetics representing the solid-phase hybridization reaction. Thermodynamic stability of the target probe complex is governed by Gibbs free energy of binding as

$$\frac{k^1}{k^{-1}} = \exp\left(\frac{-\Delta G}{RT}\right) \tag{29}$$

where $\Delta G = \Delta H - T\Delta S$, ΔH being the binding enthalpy and ΔS being the binding entropy. For bulk-phase hybridization, a nearest-neighbor model [9] can be used to calculate ΔG for any complementary or single-base-pair mismatched duplex. For heterogeneous hybridization, however, the thermodynamic stability condition deviates from the above classical result, as the probe density is increased. Consequently, the above approximation is somewhat accurate in the limit of low probe density, with an underlying assumption that other surface effects are not thermodynamically important. Although some other thermodynamic models have been proposed in this respect [9], these are not comprehensive in terms of a complete theoretical development. Hence, one may utilize Eq. (29), with incorporation of an Arrhenius type of formulation for k^1 and k^{-1} as

$$k^1(T) = k_0^1 \exp\left[-\frac{E_\mathrm{a}}{R}\left(\frac{1}{T} - \frac{1}{T_0}\right)\right] \tag{30a}$$

$$k^{-1}(T) = k_0^{-1} \exp\left[-\frac{E_\mathrm{d}}{R}\left(\frac{1}{T} - \frac{1}{T_0}\right)\right] \tag{30b}$$

where k_0^1 and k_0^{-1} are values of k^1 and k^{-1} at T_0 (T_0 is 25°C below melting temperature of DNA). Further, using $E_\mathrm{a} - E_\mathrm{d} = \Delta H$, k^{-1} can be estimated from the above, on estimation of either E_a or E_d (both of which are situation specific). Now, since

$$k^{-1} = k_2^{-1} + k_3^{-1} \tag{31}$$

separate equations are required to estimate individual rate constants k_2^{-1} and k_3^{-1}. To achieve this goal, we assume that at steady state an independent equilibrium exists between directly hybridized probes and targets of bulk solution, as well as between indirectly hybridized probes and nonspecifically adsorbed target molecules. With incorporation of these into Eq. (23), it follows that

$$\left[k_3^1 c_{3,\mathrm{m}}(c_{2,\mathrm{s,max}} - c_{2,\mathrm{s,eq}}) - k_3^{-1} c_{2,\mathrm{s,eq}}\right] = 0 \qquad (32)$$

$$\left[k_2^1 c_{2,\mathrm{ns}}(c_{2,\mathrm{s,max}} - c_{2,\mathrm{s,eq}}) - k_2^{-1} c_{2,\mathrm{s,eq}}\right] = 0 \qquad (33)$$

where the subscript "eq" represents an equilibrium state. Equations (31)–(33) can be simultaneously solved to yield k_2^{-1}, k_3^{-1} and $C_{2\mathrm{s,eq}}$, to be used for the numerical simulations.

Regarding nonspecific adsorption kinetics, one may note that

$$\frac{k_\mathrm{a}}{k_\mathrm{d}} = \frac{C_{2,\mathrm{n,eq}}}{C_{3,\mathrm{m,eq}}\left(C_{2,\mathrm{ns,max}} - C_{2,\mathrm{ns,eq}}\right)} \qquad (34)$$

The unknown terms appearing on the right-hand side of Eq. (34), however, are yet to be theoretically determined. Therefore, one may use the experimental outcomes of Chan et al. [10, 14] to estimate $C_{2,\mathrm{ns,eq}}$, $C_{3,\mathrm{m,eq}}$ and k_d for various types of glass substrates. The term $C_{2,\mathrm{ns,max}}$ can be estimated by noting that because of a prior presence of surface probes (captured by specific hybridization) on the target area, a full monolayer of targets cannot be adsorbed there, leading to an effective radius of adsorbed target, R_t. Accordingly

$$C_{2,\mathrm{ns,max}} = \frac{1 - \pi R_\mathrm{p}^2 N_\mathrm{v} C_{2,\mathrm{s,max}}}{N_\mathrm{v} \pi R_\mathrm{t}^2} \qquad (35)$$

With the estimates mentioned above, k_a can be obtained from Eq. (34), leading to a complete determination of kinetic constants appearing in the source term of Eq. (21).

The governing conservation equations developed here lead to a well-posed system of partial differential equations, on specification of the appropriate boundary conditions. It can be noted here that boundary conditions corresponding to DNA hybridization are already incorporated through specification of the source term R_i (Eq. (21)) for control volumes adjacent to the channel–fluid interface, and need not be duplicated in prescription of boundary conditions. Other pertinent boundary conditions are summarized in Tab. 1.

Key Research Findings

In order to obtain significant insights regarding temporal variations of DNA concentration (hybridized targets, $c_{2,\mathrm{s}}$) at the probes as a function of prevailing flow conditions, one may refer to Fig. 3. Figure 3, in essence, shows an initial slow rate of increase of $c_{2,\mathrm{s}}$, followed by a comparatively higher hybridization rate that eventually approaches a saturation state with respect to time. It is observed that during initial transients, the concentrations of hybridized targets, for each of the cases investigated, remain somewhat close to each other. However, at later instants of time, as the system approaches a meta-stable state, concentration values corresponding to different situations investigated here start differing widely from each other. For a pure electroosmotic flow, the steady value of $c_{2,\mathrm{s}}$ is found to be somewhat less than that corresponding to a mixed flow occurring under a favorable pressure gradient, but turns out to be significantly greater than that observed for a mixed flow occurring under an adverse pressure gradient. This variation can be explained by arguing that for pure electroosmotic flows, the bulk concentration, and hence the film concentration ($c_{3,\mathrm{m}}$), is less as compared to that established in the presence of a favorable pressure gradient, but more than that established in the presence of an adverse pressure gradient. This, in turn, ensures the corresponding variations in $c_{2,\mathrm{s}}$ values, in an

Electrokinetic Transport with Biochemical Reactions, Figure 3 Variation of concentration of hybridized targets with time, at probe location 1, for all cases. The pressure gradients taken for the computations are as follows: $\partial p/\partial x = -10^5\,Pa/m$ (favorable) and $\partial p/\partial x = 10^5\,Pa/m$ (adverse)

analogous fashion. It has also been earlier demonstrated that the rate of the hybridization reaction can be significantly increased due to a nonspecific adsorption of the single-stranded DNA on the surface, and a subsequent two-dimensional diffusion towards surface-bound complementary probe molecules, as compared to the sole effect of three-dimensional hybridization from the bulk [5]. Hence, the initial slowness of hybridization can be explained considering the "lag time" between nonspecific adsorption and consequent hybridization to the probe, mediated by two-dimensional diffusion. During this time, three-dimensional hybridization reaction predominates. However, once the lag phase is over, the rate of hybridization reaction increases at a faster pace, due to a coupled effect of the two types of mechanisms, and saturation reaction kinetics are eventually achieved when all the single-stranded probe molecules become hybridized with target complementary oligonucleotides. Regarding the specific impact of pressure gradients on DNA hybridization, it is revealed that steeper temporal gradients in concentration can be achieved with favorable pressure gradients, especially during early stages of hybridization. On the other hand, imposition of an adverse pressure gradient of similar magnitude may not be consequential enough to retard the hybridization rates drastically. This may be attributed to the fact that although such an adverse pressure gradient decelerates the flow locally, it also ensures that the target DNAs have a greater exposure time with the complementary capture probes, with an enhanced probability of hybridization. For the adverse pressure gradients reported here, these two counteracting effects almost nullify each other, leading to relatively insignificant impacts on the resultant hybridization behavior.

It is important to note here that the numerical computations necessary to come up with the theoretical predictions mentioned above are somewhat involved in nature, primarily because of the strongly interconnected and complicated features of mass, momentum and species transport characterizing the entire sequence of events. Under certain restricted conditions, however, approximate analytical solutions can also be obtained, depicting the interactions between an imposed electroosmotic flow field and the transient DNA hybridization occurring in a microchannel. Such models can turn out to be of immense scientific appeal, in terms of having a quantitative capability of directly capturing the influences of various consequential parameters (such as fluid flow) on DNA hybridization rates, through development of close-formed expressions, without demanding more involved numerical simulations, in many cases (for details, see the analytical solutions of Das et al. [11]).

Other than the DNA hybridization systems mentioned above, mass-transfer systems based on electrokinetic phenomena have shown practical potential for becoming powerful separation methods in other biotechnological and pharmaceutical applications as well. Grimes and Liapis [12] obtained the concentration profiles of charged species in packed chromatographic columns, as the adsorbate adsorbs onto negatively charged fixed sites on the surface of the nonporous particles. Their studies revealed that highly resolved adsorption fronts and large amounts of adsorbate in the adsorbed phase, for a given column length, can be obtained if (1) the ratio of the electroosmotic velocity of the mobile liquid phase at the column entrance to the electrophoretic velocity of the anion is nearly -1, (2) the ratio of the mobility of the cation to the mobility of the analyte is not very large and (3) the concentration of the analyte relative to that of the cation is increased.

Future Directions for Research

Some of the recent findings on reactive systems with electrokinetic transport have revealed certain interesting propositions, which can be potentially exploited to obtain enhanced rates of biomacromolecular transport and hybridization in microfluidic arrangements. For example, Das and Chakraborty [13], in a recent study, have theoretically established a novel proposition that the rate of macromolecular adsorption can be augmented with application of transverse electric fields across patterned walls of a microfluidic channel. In their study, an approximate fully developed velocity profile was derived, which was subse-

quently utilized to solve the species conservation equation pertaining to a combined advection–diffusion transport. Closed-form solutions for the concentration field were subsequently obtained, consistent with the typical second-order kinetics of macromolecular adsorption. It was suggested that the transverse electric field and pattern angles can be regulated as independent parameters to maximize the rate of macromolecular adsorption, under the prevailing conditions. The following major conclusions could be drawn from their study:

1. Benefits of transverse electric fields cannot be effectively realized if the channel surfaces are not patterned, which is primarily attributable to the excess equivalent pressure gradient that cannot be exploited without surface patterning.
2. For moderate values of axial potential gradient, increase in orders of magnitude of transverse potential gradients can augment the rate of macromolecular adsorption significantly. However, a large value of the axial potential gradient may virtually suppress any contributions from an enhanced transverse electric field, and can dictate the adsorption rate by itself alone. Nevertheless, such extreme situations might be rather undesirable, because of adverse effects of Joule heating and subsequent macromolecular degradation on account of high electrical field strength. Hence, in place of a strong axial electric field, a combination of moderate values of axial and transverse electric fields can turn out to be a better proposition for the practical purpose of enhancement of macromolecular transport and adsorption rates.
3. The beneficial effects of transverse electric fields in terms of augmenting the rate of macromolecular adsorption can be best exploited for pattern angles to the tune of 45°. While acute angles turn out to be advantageous in this respect, in general, obtuse angles effectively slow down the rate of macromolecular transport by inducing an equivalent "adverse" pressure gradient that retards the rate of macromolecular transport.
4. In practice, a judicious combination of transverse electric fields and surface patterning effects can be employed, to augment the rate of macromolecular adsorption, without incurring any adverse implications of Joule heating and consequent macromolecular degradation on account of axial electric fields of too high a strength.

Based on the above-mentioned theoretical findings, future efforts, indeed, can be directed to design and fabricate biomicrofluidic devices that can achieve much faster rates of reaction and hybridization, as compared to the maximum limit currently being permitted by the state-of-the-art electrokinetic arrangements.

Definition

In this article, two-phase flow refers to two immiscible fluids or liquid–solid flow. When two immiscible fluids or liquid–solid (particle) co-flow in a microchannel under an applied electric field, an interface forms separating the two phases. This is known as electrokinetic two-phase flow.

Overview

Most surfaces acquire a finite charge density when in contact with an aqueous solution. The effect of any charged surface in an aqueous (electrolyte) solution will be to influence the distribution of nearby ions in the solution and lead to the formation of a region close to the charged surface in which there is an excess of counter-ions over co-ions to neutralize the surface charge. This high capacitance charged region of ions close to the liquid–solid interface is known as an electric double layer (EDL) [1]. An obvious difference between the two-phase interface and the liquid–wall interface is that the interface between the two phases is not stationary. The external electric intensity interacts with the free charge at the interface (liquid–liquid, liquid–particle) to generate a surface force. This surface force is important and has to be taken into account in two-phase electroosmotic flow. In this article, the fundamental aspects of liquid–liquid electroosmotic flow and liquid–particle electrophoretic flow considering the free charge at the interface are studied to investigate the characteristics of such two-phase flow systems.

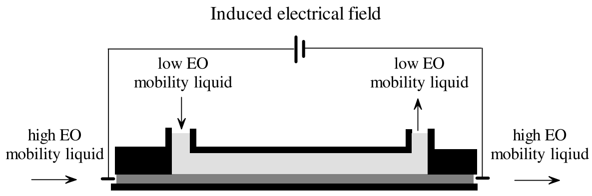
Basic Methodology

Liquid–Liquid Electroosmotic Flow

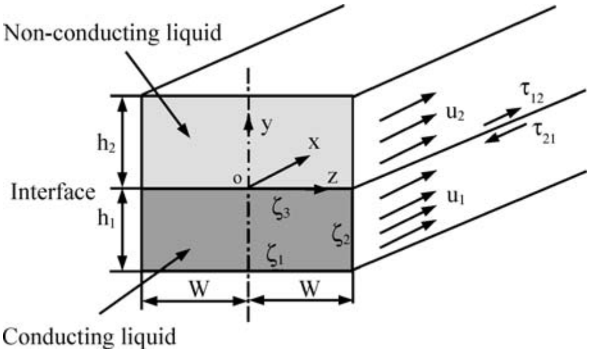
One major drawback of conventional electroosmosis is the requirement of aqueous solutions as the working fluid. Non-aqueous liquids such as organic solvents do not form an EDL layer at channel walls due to the very low conductivity. As such, non-aqueous liquids cannot be pumped by the conventional electroosmotic pumps. In order to drive non-conducting liquids, Brask et al. [2] and Gao et al. [3, 4] proposed the use of a conducting liquid as the driving mechanism to drag another non-conducting liquid. Figure 1 shows a schematic of two immiscible liquids, a conducting liquid and a non-conducting liquid, co-flowing in a rectangular microchannel. When an electric field is applied across the conducting liquid, an electroosmotic force will be generated in the conducting liquid. The flow of the two liquids depends on the viscosity ratio, the strength of the applied electric field, the electroosmotic characteristics of the conducting liquid and the interfacial phenomena between the two liquids. In this way, the non-conducting liquid is delivered by electroosmosis.

Theoretical Flow Models

Consider a two-liquid system, in which one is a conducting liquid containing ionic charges in contact with a charged



Electrokinetic Two-Phase Flows, Figure 1 Schematic of two-liquid electroosmotic flow



Electrokinetic Two-Phase Flows, Figure 2 Schematic of the coordinate system

smooth solid wall and the other is a non-conducting liquid. It is assumed that the two liquids are immiscible. A planar interface is assumed. To analyze this system, a Cartesian orthogonal coordinate system (x, y, z) is used where the origin point, O, is the intersection of the interface and the symmetric line as shown in Fig. 2. The heights of the conducting liquid and the non-conducting liquid are denoted as h_1 and h_2, respectively. Half of the width of the channel is denoted by w. When the flow is fully developed, at position $\boldsymbol{r}$, the velocities of two liquids, u_1 or u_2, along the channel are independent of the x-coordinate. The subscripts 1 and 2 denote the conducting liquid and the non-conducting liquid, respectively.

As a result of surface phenomena, electric double layers (EDLs) form at the liquid–liquid interface and the wall surfaces that are in contacted with the conducting liquid. For a more general situation, the bottom wall and the side walls may be made of different materials. We specify that the zeta potential at the bottom wall is ζ_1 and at the side walls is ζ_2; the zeta potential at the liquid–liquid interface is ζ_3. The electric potential in the conducting liquid due to a charged channel wall is taken as ψ and the net volume charge density in the conducting liquid as ρ_q. The length scale and velocity scale of the flow are taken as L and V, respectively. The independent variable $\boldsymbol{r}$ and dependent variables u, ψ and ρ_q are expressed in terms of the corresponding dimensionless quantities (shown with an overbar) by

$$\begin{aligned} \boldsymbol{r} &= L\bar{\boldsymbol{r}} \\ u &= V\bar{u} \\ \psi &= k_B T\bar{\psi}/(z_0 e) \\ \rho_q &= 2n_0 z_0 e\bar{\rho}_q \end{aligned} \tag{1}$$

where k_B is Boltzmann's constant, T is the absolute temperature, z_0 is the valence of the ions, e is the elementary charge and n_0 is the reference value of the ion concentration. Due to symmetry, only half of the cross-section of the rectangular channel is considered. At the mid-plane $z = 0$, a symmetric condition, $\partial\psi/\partial z = 0$ is held.

Electrical Double Layer Potential in the Conducting Liquid

It is assumed that the electric charge density is not affected by the external electric field due to the thin EDLs and small fluid velocity; therefore the charge convection can be ignored and the electric field equation and the fluid flow equation are decoupled. Based on the assumption of local thermodynamic equilibrium, for small zeta potential, the electric potential due to the charged wall is described by the linear Poisson–Boltzmann equation which can be written in terms of dimensionless variables as

$$\frac{\partial^2\bar{\psi}}{\partial\bar{z}^2} + \frac{\partial^2\bar{\psi}}{\partial\bar{y}^2} = K^2\bar{\psi} \tag{2}$$

where $K = L\kappa$ is the ratio of the length scale L to the characteristic double layer thickness $1/\kappa$. Here κ is the Debye–Hückel parameter, $\kappa = \left(2z_0^2 e^2 n_0/\varepsilon k_B T\right)^{1/2}$, which is referred to the characteristic thickness of the EDL. ε is the relative permittivity of the conducting liquid. The solution to the Poisson–Boltzmann equation is obtained as

$$\begin{aligned} &\bar{\psi}(\bar{y},\bar{z}) = \\ &\sum_{j=1}^{\infty} \frac{4(-1)^{j+1}[\bar{\zeta}_1 \sinh(B_j\bar{y}) + \bar{\zeta}_3 \sinh(B_j\overline{h_1} - B_j\bar{y})]\cos(\lambda_j\bar{z})}{(2j-1)\pi \sinh(B_j\bar{h}_1)} \\ &+ \sum_{p=1}^{\infty} \frac{2\bar{\zeta}_2\left[1+(-1)^{p+1}\right]\cosh(A_p\bar{z})}{p\pi\cosh(A_p\bar{w})} \sin\left(\frac{p\pi}{\bar{h}_1}\bar{y}\right) \end{aligned} \tag{3}$$

where

$$B_j = \sqrt{K^2 + \frac{(2j-1)^2\pi^2}{4\bar{w}^2}}$$

$$\lambda_j = \frac{(2j-1)\pi}{2\bar{w}}$$

$$A_p = \sqrt{K^2 + \frac{p^2\pi^2}{\bar{h}_1^2}}$$

From electrostatics, the normal component of the gradient of the electric potential, ψ, jumps by an amount propor-

tional to the surface charge density, ρ_q^s, that is

$$\rho_q^s = -\varepsilon \frac{\partial \psi}{\partial y} \tag{4}$$

It is assumed that the gradient of electric potential in the non-conducting liquid vanishes. Using the reference surface charge density as $(\varepsilon k_B T)/(z_0 eL)$, one obtains the dimensionless surface charge density at the liquid–liquid interface as

$$\overline{\rho_q^s} = \sum_{j=0}^{\infty} \frac{4(-1)^{j+1} B_j}{(2j-1)\pi} \left[\frac{\bar{\zeta}_3}{\tanh(B_j \bar{h}_1)} - \frac{\bar{\zeta}_1}{\sinh(B_j \bar{h}_1)} \right] \cdot \cos(\lambda_j \bar{z}) - \sum_{p=1}^{\infty} \frac{2\bar{\zeta}_2 \left[(-1)^{p+1} - 1 \right] \cosh(A_p \bar{z})}{\bar{h}_1 \cosh(A_p \bar{w})} \tag{5}$$

It should be mentioned that the surface charge at the interface, ρ_q^s, is opposite in sign to the volumetric net charge in the EDL region at the vicinity of the interface. Once the electric potential distribution is known, the volumetric net charge density can be obtained through the relationship

$$\bar{\rho}_q = -\bar{\psi} \tag{6}$$

This volumetric net charge density, Eq. (6), and the interface surface charge density, Eq. (5), are required to determine the electrostatic force caused by the presence of zeta potential. The bulk electrostatic force is considered as an additional body force acting on the conducting liquid to modify the conventional Navier–Stokes equation. The non-conducting liquid is dragged by the viscous forces from the conducting liquid and the external electrostatic force due to the surface charge density at the liquid–liquid interface.

Momentum Equation of Liquid–Liquid Flow

We now consider a transient, fully developed, laminar, liquid–liquid stratified electroosmotic flow through a rectangular channel as illustrated in Fig. 2. For electroosmotic flow in an open-ended channel, it is assumed that there is no pressure gradient along the microchannel.

EDLs form in the conducting liquid, and the momentum equations of the two liquids reduce to

$$\frac{\partial \bar{u}_1}{\partial \bar{t}} = \frac{1}{\text{Re}} \left(\frac{\partial^2 \bar{u}_1}{\partial \bar{z}^2} + \frac{\partial^2 \bar{u}_1}{\partial \bar{y}^2} \right) + G_x \bar{\rho}_q \quad \text{(for the conducting liquid)} \tag{7}$$

and

$$\bar{\rho}_2 \frac{\partial \bar{u}_2}{\partial \bar{t}} = \beta \frac{1}{\text{Re}} \left(\frac{\partial^2 \bar{u}_2}{\partial \bar{z}^2} + \frac{\partial^2 \bar{u}_2}{\partial \bar{y}^2} \right) \quad \text{(for the non-conducting liquid)} \tag{8}$$

where G_x is a parameter given as $G_x = (2z_0 e n_0 L E_x)/(\rho V^2)$, in which ρ is the liquid density and E_x the external electric field along the x-direction. The second term of the right-hand side of Eq. (7) represents the electric body force term, which is caused by the action of the applied electrical field on the volumetric net charge density in the EDLs of the conducting liquid, where $\beta = \mu_2/\mu_1$ is the dynamic viscosity ratio.

At the liquid–liquid interface ($y = 0$), due to the presence of the surface charge, shear stress is not continuous at the interface. The matching conditions are the continuities of velocity and the shear stress balance, which jumps abruptly at the interface.

$$\begin{cases} \bar{u}_1 = \bar{u}_2 \\ \frac{\partial \bar{u}_1}{\partial \bar{y}} = \beta \frac{\partial \bar{u}_2}{\partial \bar{y}} - \bar{M} \bar{\rho}_q^s \end{cases} \tag{9}$$

where $M = (\varepsilon k_B T E x) / (z_0 e V \mu)$.

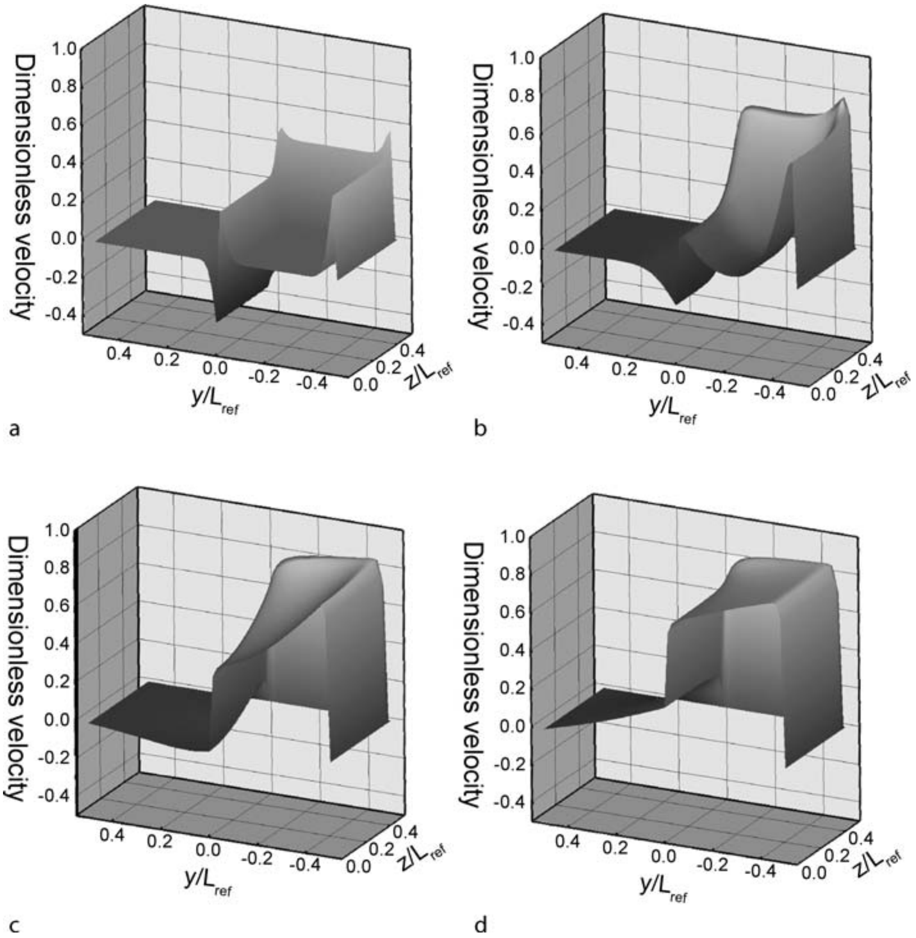
The term $\bar{M} \bar{\rho}_q^s$ accounts for the surface force exerted on the interface due to the interface surface charge. Laplace transform method is applied to solve Eqs. (7) and (8) with the boundary conditions. The analytical solution is presented in [4].

Key Research Findings

Liquid–Liquid Electroosmotic Flow

In the analysis, an aqueous binary electrolyte, KCl, with univalent charge is used as the conducting liquid. The dimensions of the microchannel are 40 μm in width and 40 μm in height. We choose $h_1 = h_2 = 20$ μm and $\zeta_1 = \zeta_2 = -25$ mV. The concentration of the conducting liquid is 10^{-6} M, and hence $K = 130$ ($1/\kappa = 307$ nm). The kinematic and dynamic viscosity ratios are $\alpha = 1.5$ and $\beta = 1$, respectively.

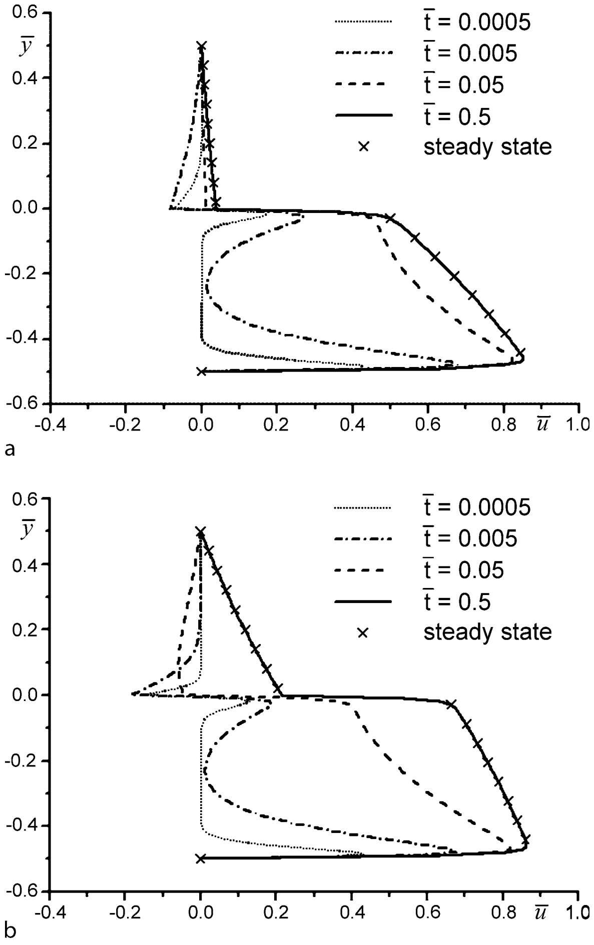
Figure 3 shows the 3D time evolutions of the velocity profiles for the liquid–liquid electroosmotic flow. EDLs form at the liquid–liquid interface and the wall surfaces that are in contacted with the conducting liquid. The interface zeta potential $\zeta_3 = 0.5\zeta_1$ is assumed. It can be seen that upon the application of the electric field, the flow is activated within the EDLs of the conducting liquid and at the liquid–liquid interface. In the conducting liquid, EDLs at the liquid–wall and liquid–liquid interfaces drive the flow



Electrokinetic Two-Phase Flows, Figure 3 Developing process for two-liquid electroosmotic flow: (**a**) $\bar{t} = 0.0005$, (**b**) $\bar{t} = 0.005$, (**c**) $\bar{t} = 0.05$, (**d**) $\bar{t} = 0.5$ ($K = 130$, $\alpha = 1.5$, $\beta = 1$, $\bar{\zeta}_1 = \bar{\zeta}_2 = 2\bar{\zeta}_3 = 0.97$)

in the positive x-direction. As the interface zeta potential ζ_3 is negative, the surface force at the interface drives the interface in the negative x-direction. The surface charge density at the liquid–liquid interface is directly related to ζ_3 as shown by Eq. (5). A surface force is generated due to the interaction between the surface charge density and the externally applied electric field as shown by the matching condition Eq. (9). During the transient period, the flow field near the interface region is significantly influenced by the surface force. As time elapses, the negative velocity reduces as the EDLs exert hydrodynamic shear stress on the adjacent liquid; the liquid flow outside the EDLs may be considered as 'passive' flow caused by the shear viscous forces. The flow characteristics of liquid–liquid electroosmotic flow depend on the coupling effects between the two liquids, which involve the electrokinetic driving forces in the conducting liquid and the interface phenomena. The interface phenomena include the interface surface force and the interfacial shear stress between the two liquids.

To investigate the effect of viscosity ratio between the two liquids, different values of β are chosen. Figure 4a and b show the dimensionless velocity profiles at the symmetric line when $\beta = 1$ and 10, respectively. The velocity profile of the non-conducting fluid is very much like Couette flow as the non-conducting liquid is dragged by the conducting liquid through the interfacial shear stress. As $\beta = \mu_2/\mu_1$, a smaller value of β corresponds to a lower flow resistance of the non-conducting fluid. The results show that when $\beta = 1$ the non-conducting fluid can be dragged relatively easily by the conducting liquid as compared to when $\beta = 10$. Figure 5 shows the dimensionless velocity profiles in the absence of the interface zeta potential ($\zeta_3 = 0$). Upon the application of the electric field, the flow is activated within the EDL at the liquid–wall interface in the conducting liquid. As there is no opposite sur-



Electrokinetic Two-Phase Flows, Figure 4 Dimensionless transient two-liquid velocity at the symmetric line: (**a**) $K = 130$, $\alpha = 1.5$, $\beta = 1$, $\zeta_3 = 0.5\zeta_1$; (**b**) $K = 130$, $\alpha = 0.15$, $\beta = 10$, $\zeta_3 = 0.5\zeta_1$

face force exerted on the interface, the non-conducting liquid is delivered by electroosmosis of the conducting liquid, through the hydrodynamic viscous forces at the interface.

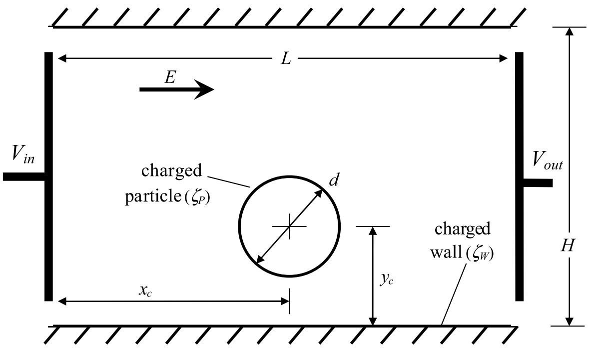
Liquid–Particle Electrophoretic Flow

Electrophoresis is the motion of a charged particle relative to the surrounding liquid due to an imposed external electric field [5]. Its applications include but are not limited to characterization and manipulation of organic and inorganic particles. In particular, electrophoresis has been applied to a variety of analytical separation problems involving nucleic acids, proteins and drugs.

For electrophoresis on various Lab-on-a-Chip platforms, the particles are of sizes comparable to the microchannel in which they flow. As such, particle–particle and particle–wall interactions are no longer negligible. Therefore, the electric field, the flow field and the particle motion are strongly coupled together.

Analytical solutions for some simplified situations have been obtained [6, 7]. For more complicated problems, numerical models have to be employed. For this purpose, a fixed-grid finite volume method is presented for electrophoresis of a particle. It is based on a previously developed fluid–particle flow model [8].

Figure 6 shows a rigid particle suspended in a fluid in a microchannel. The fluid is an aqueous electrolyte solution. Both the particle and the walls of the microchannel are non-conducting and uniformly charged with zeta potentials of ζ_P and ζ_W, respectively. When an electric field is applied along the microchannel, the fluid is electroosmotically driven into motion. At the same time, the particle undergoes electrophoresis. The particle is sufficiently large such that momentum is exchanged between the particle and the flowing fluid. As a result, the particle affects the fluid flow significantly and vice versa resulting



Electrokinetic Two-Phase Flows, Figure 6 Schematic of the electrophoresis of a charged particle in a microchannel

in a transient process where the motion of the particle, the flow field and the electric field are strongly coupled.

Particle Motion The particle location and orientation are determined from the motion of the particle. For a two-dimensional situation, the motion of the particle is characterized by its centroid location $\boldsymbol{x}_{\mathrm{P}}$ and orientation θ_{P}. The translational and rotational motions of the particle are governed respectively by

$$m\frac{\mathrm{d}^2\boldsymbol{x}_{\mathrm{P}}}{\mathrm{d}t^2} = \boldsymbol{F} + \boldsymbol{G} \tag{10}$$

and

$$I\frac{\mathrm{d}^2\theta_{\mathrm{P}}}{\mathrm{d}t^2}\hat{k} = \boldsymbol{T} \tag{11}$$

with $\boldsymbol{x}_{\mathrm{P}}$, $\mathrm{d}\boldsymbol{x}_{\mathrm{P}}/\mathrm{d}t$, θ_{P} and $\mathrm{d}\theta_{\mathrm{P}}/\mathrm{d}t$ known at $t = 0$. Parameters m, I, $\boldsymbol{F}$, $\boldsymbol{G}$ and $\boldsymbol{T}$ are the mass, moment inertia, resultant surface force, body forces and the induced torque on the particle, respectively.

Fluid Motion In this article, an unsteady incompressible laminar flow is considered. The continuity and the momentum equations are given by

$$\nabla \cdot \boldsymbol{u} = 0 \tag{12}$$

$$\frac{\partial(\rho\boldsymbol{u})}{\partial t} + \nabla\cdot(\rho\boldsymbol{u}\boldsymbol{u}) = -\nabla p + \nabla\cdot\left[\mu\left(\nabla\boldsymbol{u} + \nabla\boldsymbol{u}^T\right)\right] + \boldsymbol{g} \tag{13}$$

where $\boldsymbol{u}$, $\boldsymbol{g}$, p, ρ and μ are the velocity vector, body force per unit mass, pressure, density and viscosity, respectively. For a thin EDL with the electric field developing instantly, the electrical potential φ is governed by the Gauss law

$$\nabla\cdot(\varepsilon_{\mathrm{e}}\nabla\varphi) = 0 \tag{14}$$

where ε_{e} is the electrical permittivity. The ionic concentration is uniform and therefore the local volume charge density is zero.

Boundary Conditions For a thin EDL at the walls, the Helmholtz–Smoluchowski slip velocity is imposed:

$$\boldsymbol{u} = \frac{\varepsilon_{\mathrm{e}}\zeta_{\mathrm{W}}}{\mu}\left(\bar{\bar{I}} - \hat{N}_{\mathrm{W}}\hat{N}_{\mathrm{W}}\right)\cdot\nabla\varphi \tag{15}$$

where ζ_{W} and $\hat{N}_{\mathrm{W}}$ are the zeta potential and unit normal of the charged walls.

The velocity at the particle surface is set to

$$\boldsymbol{u} = \frac{\mathrm{d}\boldsymbol{x}_{\mathrm{P}}}{\mathrm{d}t} + \frac{\mathrm{d}\theta_{\mathrm{P}}}{\mathrm{d}t}\hat{k}\times(\boldsymbol{x} - \boldsymbol{x}_{\mathrm{P}}) + \frac{\varepsilon_{\mathrm{e}}\zeta_{\mathrm{P}}}{\mu}\left(\bar{\bar{I}} - \hat{N}_{\mathrm{S}}\hat{N}_{\mathrm{S}}\right)\cdot\nabla\varphi \tag{16}$$

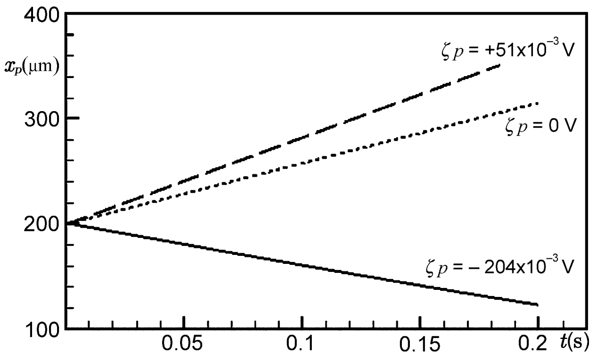
where $\boldsymbol{x}$ and $\hat{N}_{\mathrm{S}}$ are the position vectors of the surface of the particle and the unit outer normal of the particle, respectively. The first and second terms on the right-hand side represent the translational and the rotational motions, respectively. The third term represents the Helmholtz–Smoluchowski slip velocity due to the presence of an EDL around the particle.

Liquid–Solid Electrophoretic Flow

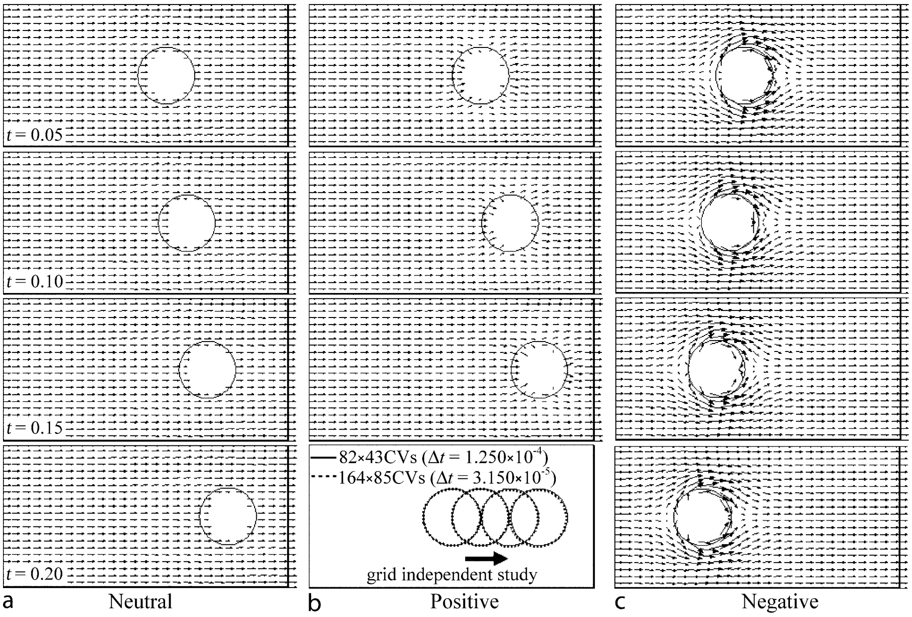
Electrophoretic Motion of a Particle

In Fig. 6, the particle is subjected to an electrical field parallel to the x-axis. The length and height of the microchannel are set to $L = 400\,\mu\mathrm{m}$ and $H = 200\,\mu\mathrm{m}$, respectively. A circular particle of density $\rho_{\mathrm{P}} = 8960\,\mathrm{kgm}^{-3}$ and diameter $d = 80\,\mu\mathrm{m}$ is initially suspended at $(x_{\mathrm{c}}, y_{\mathrm{c}}) = (200, 100)$. Solutions are obtained for neutral ($\zeta_{\mathrm{P}} = 0$), positively charged ($\zeta_{\mathrm{P}} = +51\times10^{-3}\,\mathrm{V}$) and negatively charged ($\zeta_{\mathrm{P}} = -204\times10^{-3}\,\mathrm{V}$) particles. The zeta potential of the wall is set to $\zeta_{\mathrm{W}} = -102\times10^{-3}\,\mathrm{V}$.

Thin EDLs form at both the particle and the wall surfaces. The formation of EDLs at the surfaces sets the fluid in motion and consequently drives the particle. As the particle is located at the center of the microchannel, it experiences neither vertical translation nor rotation. Fig. 7 shows the instantaneous location of the particles with different zeta potentials. The translational velocity U of the particle is given by the gradient of the graph. For all cases, the gra-



Electrokinetic Two-Phase Flows, Figure 7 Instantaneous location of particles with different zeta potentials



Electrokinetic Two-Phase Flows, Figure 8 Flow field around neutral, positively and negatively charged particles

dient is constant. This implies that the particles accelerate in a very short time to a constant velocity and move with that constant velocity thereafter. This is not unexpected as the inertia force is negligible in such a small-scale channel. The induced electroosmotic flow is in the positive x-direction. A neutral particle thus flows in the positive x-direction. Figure 8a shows the velocity field around the neutral particle at $t = 0.05$, 0.10, 0.15 and 0.20 s. No distortion of the velocity field is observed. This indicates that the particle flows with the same velocity as the fluid.

When the particle is charged, an additional electrophoretic flow field is induced around the particle. It pushes a positively charged particle to flow in the positive x-direction. With both electroosmotic and electrophoretic effects acting in the same direction, the particle flows with a higher velocity as implied by a larger gradient in Fig. 7. The velocity field around the positively charged particle is shown in Fig. 8b. Since the particle is flowing faster than the fluid, a low-pressure region is created at the trailing edge. Fluid is drawn into this region. On the other hand, a high-pressure region is created at the leading edge, pushing the fluid to move forward.

For the negatively charged particle, the electrophoretic effect tends to drive it in the negative x-direction. As the particle is highly negatively charged, the electrophoretic effect is strong enough to overcome the electroosmotic effect. As a result, the particle is driven to move in the negative x-direction creating regions of high velocity between the particle and the walls (Fig. 8c).

Future Directions for Research

The computational results demonstrate that the liquid–liquid electroosmotic pumping concept is feasible for relatively low interface zeta potentials and viscosity ratios. The time evolution of the velocity profile provides a detailed insight of the flow characteristic. It is recommended that detailed experiments to be carried to validate the model.

Modeling of electrophoresis of a particle in microchannel is presented. It is of interest to extend the model to a three-dimensional flow and to the case with a conducting particle.

Electromechanical Coupling

Definition

A quantity that describes the amount of energy transferred from electrical to mechanical forms, or vice versa, in a mechanism capable of making the energy transformation, namely, piezoelectric materials or electromagnetic solenoids. Often refers to a specific value between 0 and 1, where 1 represents a complete transformation of all energy from one form to the other via the mechanism.

Electric paper-like display

Definition

Conventional paper is a sheet made of cellulose pulp bearing writing or printing. It is characterized by it being thin, lightweight, flexible, shatterproof, sunlight readable. Electronic paper can be defined as a digital media with paper-like attributes and can alter its display properties when a voltage is applied on and off. That is why it has been called a paper-like electronic display.

Overview of Electronic Paper

A television using a cathode ray tube (CRT) installed in homes for almost a century has been rapidly replaced by flat panel displays such as the liquid crystal display (LCD) panel and plasma display panel (PDP). Along with the development of the telecommunications technology, a small flat panel display of portable electronic devices especially supplies a convenient interface to its user.

Since an LCD needs a backlight and a PDP uses a plasma source, power consumption is usually high. To increase power saving without a backlight, new reflective displays with bi-stability have been introduced into electronic paper, because bi-stable displays can keep an image for some period of time even if the power is turned off. Bi-stability enables the displays to have a long battery life when rapid updates of the image are not necessary. Flexibility is another important attribute to electronic paper. The glass used in conventional displays is substituted for a plastic film that is much thinner and more lightweight. These two remarkable characteristics cause the electronic paper to have a feature of paper [1]. Another outstanding advantage is sunlight viewability. This is an important characteristic for electronic paper to compete with LCDs. Examples of electronic paper suggested by industrial companies, as shown in Fig. 1, are (a) a weather forecast, (b) a flag or cloth, (c) a credit card, (d) a cell phone, and so on.

The goal of electronic paper is to make a display that works like paper under various viewing conditions [1]. The interesting point is that there is no typical driving mechanism in electronic paper unlike in LCDs and PDPs. Many investigators have done remarkable work with diverse approaches: electrophoresis [2], liquid crystals [3], fluids [4], and micro-electro-mechanical systems (MEMS) [5]. The development status of several approaches up to the present, mainly from industry, are shown in Table 1, where the key factors compared are driving voltage, contrast ratio, response time and reflectivity.

Electronic paper based on particle technology has the longest history and has four distinct driving methods, as shown in Table 1. The common main principle is to use electrophoresis to display black or white when a voltage is applied on and off. Electrically charged particles suspended in oil can be included in a tiny capsule (E-ink), microcup (SiPiX) and a twisting ball (Xerox). Air is used as a fluid medium in the QR-LPD type by Bridgestone. This driving mechanism has advantages of mass production and bi-stability. However, the response time is long and high voltage is required. Therefore, it cannot be usefully applied to video-speed electronic paper. Color filters are also necessary to display color.

Kent Display is a pioneer of cholesteric liquid crystal displays (ChLCDs) in which the director of the liquid crystal twists around a helical axis [3]. The remarkable property is that the cholesteric material reflects light of certain

wavelengths depending on the pitch over which the director rotates. When an electric field is applied, the material can be switched into either one of two stable states, planar or focal conic. The planar and focal conic states are reflective mode and transparent mode, respectively. In order to display color, it does not require color filters; however, a stacking process is necessary and results in a thick module. Like particle-based electronic paper, it is also difficult to play video-rate displays due to a long switching speed.

Electrowetting-driven electronic paper was first introduced by Philips research laboratories [4], where colored oils act as a switcher under the influence of an electric field. This type is focused on increasing the response time for a video-speed electronic paper. The attractive points are low driving voltage and high reflectivity. Recently, the Steckl group at the University of Cincinnati has developed a light-wave coupled display using light emitting diodes [6].

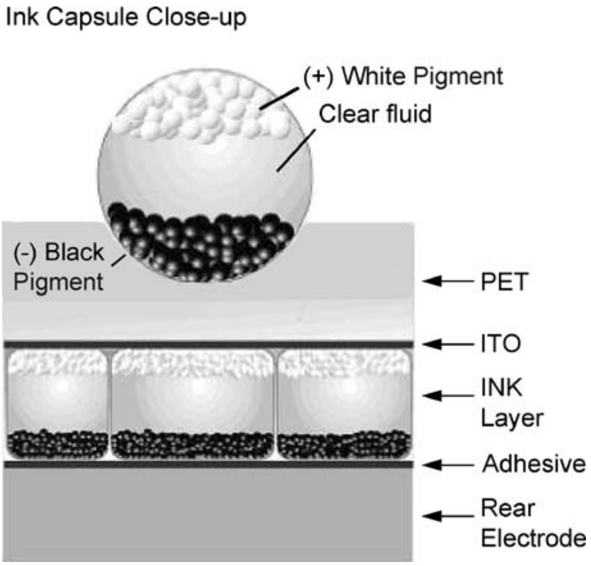
The iMod type based on biomimetics reflects light using the principle of a photonic crystal, imitating butterfly wings or peacock feathers [5]. The periodic microstructure inside wings or feathers causes light to interfere with itself. The driving cell fabricated by MEMS is composed of a glass substrate with thin films and a reflective membrane, where an air gap between the thin-film stack and the membrane is controlled by a voltage. This approach has a strong advantage of power saving and response time, while the disadvantage is inflexibility due to the glass substrate.

Issues of fluid dynamics in electronic paper are in switching mechanisms and in fabrication processes such as coating, encapsulation and dispersion. For example, charged particles' switching time depends on electrophoretic mobility, given electric fields and cell gap. The contact line motion of oils is also a dominant process for electrowetting-based electronic paper. From the viewpoint of process, encapsulation is required for electrophoretic imaging film of E-ink and for cholesteric liquid crystals of Kent Display. The significant process to give flexibility to electronic paper is the process to coat or print display materials (such as encapsulated particles or cholesteric liquid crystals) or cells on a flexible substrate. In this article, these problems are discussed in the following section from the point of view of driving principles and fabrication processes for electronic paper.

Key Research Findings

Electrophoresis-Based Electronic Paper

Electrophoretic displays based on particles suspended in oil have been investigated for commercial use since the 1970s. E-ink Corporation has used the principle of electrophoresis to develop a microencapsulated electrophoretic imaging film, where charged pigment particles are contained in a colored or transparent fluid and switched under an electric field [2]. The main advantages of microcapsules are to prevent particles from migrating in a lateral direction and to give a tight packing between microcapsules. The former and the latter contribute to block a failure mode and to increase high optical contrast, respectively. The well-known cross-sectional view of the microencapsulated electrophoretic imaging film is presented in Fig. 2 [7]. To achieve the display image of white or black, white or black pigments are shifted by applied voltages on the back plane that can be flexible or solid.



Electronic Paper, Figure 2 Physical configuration of a microencapsulated electrophoretic imaging film of E-ink. Figure from [7]

The transport of particles in electrophoretic image displays was simulated with an assumption of a normal distribution of particles, where charged pigments and charged inverse micelles through flocculation of surfactant molecules are assumed to have the same distribution [8]. Simulation results can be used to optimize the electrical and optical properties through physical parameters. For example, the switching time, t_{switch}, can be simply estimated as the ratio of the cell gap, h, to the average velocity, $v_{average}$:

$$t_{switch} \approx \frac{h}{v_{average}} = \frac{h^2}{\mu V_2 (1-\psi)}, \tag{1}$$

where

$$\psi = \frac{hN}{V_2 \varepsilon} \sqrt{\frac{4\pi Q V_1}{cst}}. \tag{2}$$

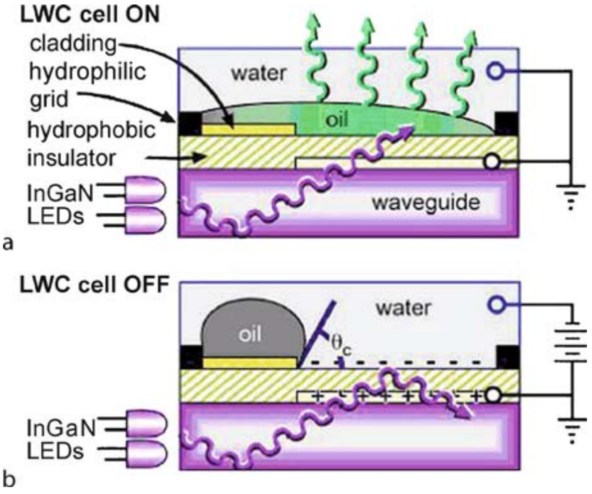
Here, V_2 is the applied voltage, V_1 is the voltage applied in the previous half period, μ is the mobility, N is the total amount of particles, ε is the dielectric constant, Q is the charge of the particles and cst is an unknown constant which has units of meters. When ψ is negligible, the main contributions of the switching time are the cell gap and the electrophoretic mobility of particles, because the applied voltage has a restriction corresponding to available electronics. Since the electrophoretic mobility is inversely proportional to viscosity of the surrounding fluid and proportional to the charge of the particles, a fast switching time can be obtained by small cell gap, a high particle charge and low fluid viscosity. ψ is the parameter to explain the effect of internal field screening due to diffusion of particles [8]. When the charge of particles increases or high V_1 is applied, the internal field screening becomes stronger in a way that the switching time increases. The internal field screening is also an important factor to obtain a fast switching speed.

Recently, the theory of dielectrophoresis was applied to explain the microscopic physics of the movement of pigments in electrophoretic image displays and to prove the discrepancies between theory and measurement [9]. Dielectrophoresis is induced by the interaction of the electric field and the induced dipole, and is used to describe the behavior of polarizable particles in a locally non-uniform electric field. For example, the phenomenon of the delay time can be explained by the principle of dielectrophoresis. In electrophoresis, when the backplane voltage is switched, the particles on the electrode have to move instantaneously under a given electric field. However, the particles need a removal time which results in a delay time in the switching process. The time constant to obtain an induced dipole from a particle at rest is derived by Schwarz's formula [10] and used to compute the dielectrophoretic force at its steady-state value. The force and the velocity fields under a non-uniform electric field due to the presence of pigments also help to estimate realistic values for physical properties.

Electrowetting-Based Electronic Paper

The technology using the principle of electrowetting enables one to manipulate rapid motion of a liquid on a micrometer scale and results in many applications such as liquid lenses for miniature cameras [10], an actuator on lap-on-a-chip and reflective displays [4]. The dynamics of droplet transport and wetting have been studied by many researchers [11] and a detailed explanation can be found in the literature. Reflective displays using the principle of electrowetting were first shown by Hayes and Feenstra [4], where a fast response time is a strong advantage to realize a video-speed electronic paper. Colored oils switched by the applied voltage are utilized as a color filter in LCD displays and give high brightness. The motion of liquid inside a pixel was studied as a function of oil film thickness, pixel size and oil viscosity to determine the electro-optical performance, where the white area percentage defined by the ratio of the area uncovered by oil is compared as a function of the above parameters [12].

Recently, the emissive display of electrowetting-driven electronic paper has been developed by Heikenfeld and Steckl [6], where a non-polar oil acts as a switcher of a light valve under the influence of a given electric field. The pixel luminance for LCD displays depends on the backlight, while this novel fluorescent display has $\sim 10-40$ times higher theoretical luminous efficiency than conventional LCD displays and the maximum luminance values for red, green and blue emission are 950, 5530 and 530 $\mathrm{cd/m^2}$, respectively. The core device is driven by light wave coupling and is composed of three components: a UV light storage plate (refractive index of ~ 1.5), a light wave coupling region and oils including lumophores for colors, as shown in Fig. 3. Violet light using LEDs is used as a light source to reduce optical absorption losses and not to decrease photo-degraded organic fluorescent oils. The lumophores in the oils are organic materials that emit visible light when violet light is excited. In the 'ON' state in Fig. 3a, the oil covers over the hydrophobic layer and visible light is emitted through lumophores, where the cladding layer reflects the violet light back into the UV storage plate due to a refractive index less than 1.3. In the 'OFF' state, the polar water repels the oil film due to the applied electric field and the



Electronic Paper, Figure 3 Light wave coupling display based on electrowetting. Figure from [6]

oils move on the hydrophobic cladding layer, where the violet light reflects over all the surface of the water (refractive index ~ 1.3) and the cladding layer due to low refractive index.

Cholesteric Liquid Crystal-Based Electronic Paper

Cholesteric liquid crystal (ChLC)-driven electronic paper has been investigated mainly by Kent Display [2]. Since ChLCs are chiral molecules, the particular color of light depends on the pitch denoted as P, where the pitch is the distance along the helical axis for ChLC to twist 360° and is determined by the amount and type of chiral additive within the liquid crystal mixture. ChLCDs are driven by switching the different textures of the ChLC electrically [1, 3], as shown in Fig. 4.

The ChLC has two stable states of planar and focal conic at zero field condition. In the planar state in Fig. 4a, the helical axis is arranged perpendicular to the cell substrate, and incident light is reflected backward due to the Bragg reflection. The reflection band is a narrow range of wavelengths and its bandwidth is defined as $\lambda_0 = (n_e - n_0)P$, where n_e and n_0 are the ordinary and extraordinary refractive index, respectively. In the focal conic state in Fig. 4b, the direction of the helical axis is randomly distributed within the cell in a way that Bragg reflection does not happen. Then, incident light is diffracted or scattered depending on the size of the helical pitch; the focal conic state is transparent to all wavelengths. When the absorption layer is coated on the bottom, the light in the focal conic state is absorbed. The ChLC in the homeotropic state, as show in Fig. 4c, relaxes to either the planar state or the focal conic state, depending on the magnitude of applied voltage. The ChLC can achieve the focal conic state when a low-voltage pulse is applied to the electrode on the substrate, and the planar state can be achieved when the power is removed from the homeotropic state. There exists a critical voltage, V_C, over which the focal conic state is transformed to the homeotropic state:

$$V_C = \frac{\pi^2 d}{P}\sqrt{\frac{K_{22}}{\varepsilon_0 \Delta\varepsilon}}, \tag{3}$$

where d is the thickness of cell gap, K_{22} is the twist elastic constant and $\Delta\varepsilon$ is the dielectric anisotropy of the ChLC [13].

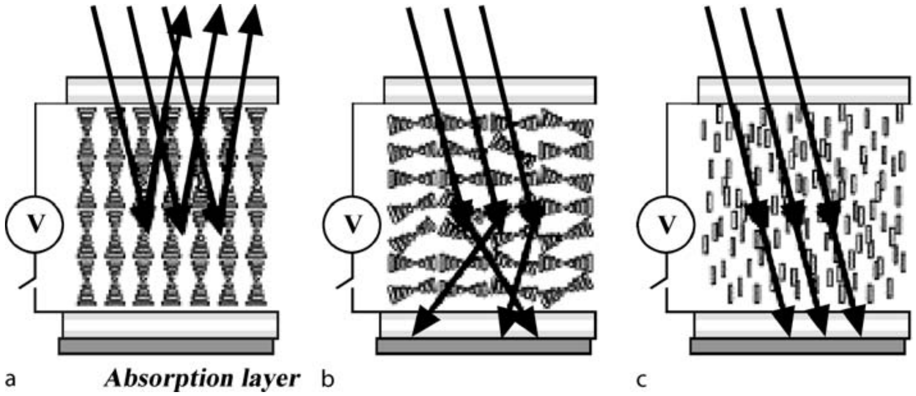
When liquid crystals are encapsulated in a polymer-dispersed matrix, many different configurations of the droplets occur, depending on droplet morphology, surface anchoring, and applied fields [13]. In the case of spherical liquid crystals, when long helical axes of the droplets are perpendicular to the droplet wall, the radial and axial configurations occur, where the axial configuration has weak surface anchoring and results in a line defect along the equator of the droplet, while the radial configuration has strong surface anchoring and has a point defect in the center of the droplet. When tangential anchoring of the liquid crystal molecules is applied on the droplet wall, the bipolar configuration is obtained and two point defects at the poles are created.

Since liquid crystals have long thin molecules, the dynamics of liquid crystals is affected by the elastic and viscous response to an external stress induced by an electric field. One of the significant non-Newtonian flow behaviors is caused by coupling between the director field of liquid crystal and the imposed velocity field. Recently, the Lattice–Boltzmann method was used to investigate permeative flows in ChLCs [14], where the Beris–Edwards equations of motion for a cholesteric liquid crystal were considered. The viscosity of a ChLC can be changed enormously according as to whether the helical axis is pinned at the wall or not. In the case of free boundary condition, liquid crystal molecules can drift freely along the flow direction and viscosity increase is small. However, if the helical axis is anchored, viscosity increases greatly due to energy dissipation that is caused by anchoring effects at the wall. The computation result showed that a double twisted director pattern is observed when the strong flow field is imposed.

Fabrication Process

The method to manufacture cost-effective displays is to use proper processes for mass production or on a large scale. One example is a roll-to-roll process which needs a flexible substrate to be coated or printed display materials. Here, an important issue is to provide a monolayer of display materials. In order to supply this monolayer, a variety of methods have been tried for encapsulated cholesteric liquid crystals by Kent Display, microencapsulated electrophoretic display films by E-ink Corporation, and microcup shapes by SiPiX. In the case of the first and second types, encapsulation processes are a significant step.

The encapsulation process for ChLC is mainly attributed to its transport and optical properties [15]. Firstly, since viscosity of pure ChLC is close to that of water, its fluidity prevents ChLC from being coated on flexible substrates. Secondly, when a cholesteric liquid crystal is pressed, the flow generated inside makes the displayed image erase. Therefore, droplet dispersions by encapsulation act as a protector for its bi-stability and optical properties. The additional advantage is that encapsulated cholesteric liquid crystals are self-sealing; the materials confined to the droplets cannot flow through an interface of the droplets.



Electronic Paper, Figure 4 Different textures of the cholesteric liquid crystal: (**a**) planar state, (**b**) focal conic state and (**c**) homeotropic state. Figure from [15]

Encapsulating materials that have better adhesion to flexible substrates are used to maintain the cell thickness. The droplet morphology after encapsulation is also important. When droplets smaller than about 2 – 3 μm are used, different refractive indices between the droplets or the droplet and the encapsulating material result in light scattering; by using a smaller size of droplets, more light can be scattered. Then, a droplets size of as large as 30 – 50 μm is normally used. As the size of droplets decreases, the droplet shape tends to spherical due to surface tension. However, the spherical shape makes the planar texture unstable and decreases reflective brightness and contrast. A flattened or ellipsoidal droplet morphology is preferred to achieve the desired domain texture [16].

There are two classic approaches for encapsulation: emulsification [17] and phase separation [18]. The main difference between the two methods depends on how to make and process encapsulated droplets. In the emulsification method, water is used as a solvent to dissolve a polymer and to form a viscous solution, and cholesteric liquid crystals are mixed with the aqueous solution. By a shearing device like a propeller blade, small droplets of micrometer scale are formed and finally emulsified. The resulting emulsion is then printed on a plastic film and dried by evaporation of water. The disadvantage of this method is the broad size distribution of the droplets. In the phase separation method, cholesteric liquid crystals are homogeneously mixed with a prepolymer solution such as monomers or oligomers. Similarly, the mixture is then coated on a flexible substrate and phase separation to form droplets occurs by polymerization, cooling or solvent evaporation. This approach gives a narrow size distribution; however manufacture on a large scale is difficult. Recently, Stephenson [19] has proposed the limited coalescence process, where inorganic colloidal particles are used to stabilize dispersed droplets. This method makes it possible to investigate the effect of droplet size on optical performance. The novel approach by colloidal self-assembly has been demonstrated for a cost-effective single substrate approach [20], where a close-packed monolayer is formed by drying-assisted self-assembly.

Encapsulated liquid crystal droplets of non-spherical shapes show better electro-optical properties than those of spherical shapes [16]. The flattened droplets can be obtained by stretching a composite thermoplastic film in a solvent-induced or thermally induced phase separation method, where the mean aspect ratio is enhanced by local heat stress. In the photopolymerization-induced phase separation, droplets are elongated by a shear force during curing of the polymer binder and the final shape is reached by a cured polymer, if the plastic film thickness is larger than the initial size of the droplets. Electric field can be also applied to droplet deformation during phase separation in the direction either parallel or perpendicular to the field. At the negative dielectric permittivity of liquid crystals, the droplets are elongated in the main cell plane.

Future Directions for Research

The main advantages of electronic paper are lower fabrication costs and low power consumption compared to conventional displays. Thus, plastic printed electronics have been mainly investigated for low cost as well as flexibility. For instance, Plastic Logic Corporation has created flexible active matrix backplanes for rollable electronic paper. New battery technology like printable batteries is also required to give the attribute of flexibility to electronic paper. However, most of all, the stability of driving modes on electronic paper is significant to realize sufficient electrical and optical properties.

Definition

Electroosmotic flow is the bulk liquid motion that results when an externally applied electric field interacts with the

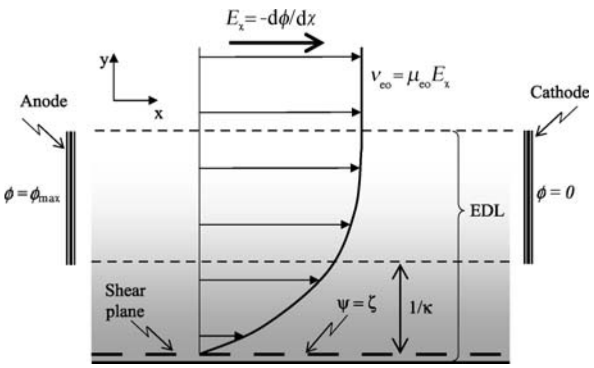
net surplus of charged ions in the diffuse part of an electrical double layer. The term electroosmotic flow and electroosmosis are generally used interchangeably in the context of micro- and nanofluidics. Alternating current electroosmosis in which bulk flow is generated using creative application of AC electric fields is covered under a separate title.

Overview

The discovery that externally applied electric fields could be used to generate bulk liquid motion is generally credited to Reuss who, in 1809, reported the observation of water migration through porous clay under such an influence. Since then a number of prominent scientists and engineers have left their mark on the field (see the text by Dukhin and Deryaguin [1] for a complete historical perspective) and it has become a critical technology in a variety of fields ranging from integrated micro- and nanofluidic systems to environmental decontamination and remediation. In this article we will begin by providing a brief conceptual overview of direct current electroosmotic flow focusing on the former of these applications. This will be followed by a detailed review of the relevant fluid mechanics and electrostatics culminating in a brief review of some of current research directions and a few key recent technological advancements. For more detailed information on electroosmotic flow and electrokinetics in general it is suggested that readers consult one of a variety texts on the subject, each of which approaches the topic from a slightly different point of view: transport and hydrodynamics [2], colloidal systems [3], and surface and interfacial phenomena [4].

An electrical double layer (EDL) is a very thin region of non-zero net charge density near a two phase interface (for the cases of interest here, typically a solid-liquid interface). It is generally the result of adsorption or desorption of charged species from the surface and the resulting rearrangement of the local free ions in solution so as to maintain overall electro-neutrality. As shown in Fig. 1, the diffuse region of the EDL (indicated by the grey shading) decays roughly exponentially into the bulk solution with a depth characterized by the inverse of the Debye–Hückel parameter ($1/\kappa$). The penetration depth of the diffuse EDL can vary from a few 10 s of nanometers to over a micrometer, depending on the ionic strength of the bulk phase solution.

When an electric field is applied perpendicular to the decay of the EDL (or equivalently parallel with the surface), the surplus of either positive or negative ions results in a net body force on the fluid proportional to the local net charge density. The resulting velocity profile consist of a region



Electroosmotic Flow (DC), Figure 1

of very high shear rate near the surface where the velocity increases from zero at the shear plane to its bulk phase velocity (v_{eo} in Fig. 1) at the edge of the EDL. The proportionality between v_{eo} and the strength of the electric field, E_x, is given by the electroosmotic mobility, μ_{eo}, which is a function of both surface and solution phase properties. Unlike pressure driven flow, uniform electroosmotic flow exhibits a flat or "plug flow" velocity profile outside the double layer region.

The popularity of electroosmotic flow as a primary transport mechanism in microfluidic devices is largely the result of the simplicity of its implementation and the uniqueness of this velocity profile. In the classic example, the near flat velocity profile serves to minimize sample dispersion in capillary electrophoresis systems thereby facilitating highly efficient analytical separations. As will be discussed in further detail in the "Key Research Findings" section, since electroosmotic flow is a surface driven phenomena, v_{eo} is largely independent of channel size (outside the limit of double layer overlap). Thus it tends to be more suitable for operation of nanofluidic devices than traditional transport mechanisms. Additionally, the ability to perform precise, picoliter scale fluidic handling simply through the manipulation of externally applied voltages significantly simplifies device operation. The development and growing acceptance of new pressure driven architectures, such as multilayer soft-lithography, however has reduced the prominence of this final advantage.

The most significant disadvantages associated with the use of electroosmotic flow tend to be related to the relatively high applied potentials that are required to generate significant flow velocities. Generally μ_{eo} tends to be on the order of 10^{-8} m^2/Vs (though significant variability exists). As a consequence a potential of 1000 V applied over a 10 cm channel is required to reach the relatively meager flow rate of 100 μm/s. While the technical difficulties in generating potentials of this scale in portable and autonomous

devices are relatively minor (given the availability of relatively low cost, high efficiency DC to HVDC converters) this does tend to place an upper limit on the speed at which many manipulations can be performed. The use of these relatively high potentials also results in conditions of significant ohmic energy conversion generally referred to as joule heating. This effect can result in temperature variations within a channel network leading to: significant variations in local viscosity, uneven thermal conditions for chemical reactions, and potentially culminating in localized in-channel boiling. These high electric fields also cause difficulty when transporting living organisms since internal elements tend to exhibit different mobilities (and thus they migrate at different speeds) which can lead to significant damage to the target. Perhaps the most significant disadvantages associated with electroosmotic flow are that: it is only compatible with a limited class of fluids (specifically low ionic concentration, aqueous solutions), it exhibits extreme sensitivity to surface conditions (reflected in the electroosmotic mobility) and it cannot be used with semiconductive substrates such as silicon (as it requires a highly insulating substrate to confine the electric field to the fluidic channel).

Basic Methodology

Flow Field

Incompressible fluid flow is governed by the Navier–Stokes (momentum), Eq. (1), and continuity equations, Eq. (2), shown below,

$$\rho\left(\frac{\partial \boldsymbol{v}}{\partial t} + \boldsymbol{v}\cdot\nabla\boldsymbol{v}\right) = -\nabla p + \eta\nabla^2\boldsymbol{v} - \rho_e\nabla\Phi \tag{1}$$

$$\nabla\cdot\boldsymbol{v} = 0 \tag{2}$$

where $\boldsymbol{v}$, t, p, η and ρ are velocity, time, pressure, viscosity and density respectively. The assumption of incompressibility is not globally applicable to all microfluidic systems however most electroosmotic flows of interest tend to involve a single phase liquid and thus we can make this assumption without loss of generality. For the purposes of this discussion we also assume a constant viscosity solution, which is significantly more restrictive due to the importance of joule heating as mentioned above. This limits us to systems comprising of either high thermal conductivity substrates (which can reject internally generated heat from the flow system rapidly) or low applied electric field strengths (where joule heating is minimal). The final term in Eq. (1) represents the electroosmotic body force and is equivalent to the product of the net charge density in the double layer, ρ_e, multiplied by the gradient of the total potential, Φ.

The relatively small channel dimensions and flow velocities in micro and nanofluidics limits the flow to the strongly laminar, low Reynolds number, Re, regime ($\mathrm{Re} = \rho L v_{eo}/\eta$ where L is the hydraulic diameter). In the systems of interest here the Re tends to vary from negligibly small to a practical maximum of approximately Re $= 0.1$. As a result the transient and convective terms (those on the left-hand side of Eq. (1)) tend to be negligibly small and thus are typically ignored in order to further simplify the formulation. Removing the transient term from the formulation implies that the system reaches a steady state instantaneously. This tends also to be broadly applicable so long as the other quantities of interest (e. g. species transport) and variations in applied potential occur on longer timescales, which they typically do.

As is apparent from Eq. (1) evaluation of the momentum equation requires a description of the net charge density, ρ_e, and the total electrical potential, Φ. The latter of these comprises of the summation of the electrical double layer, ψ, and the applied electric potential, ϕ, as per Eq. (3),

$$\Phi = \phi + \psi \tag{3}$$

The decoupling of these two terms is contingent on a number of assumptions as detailed in [5]. The relatively high ionic strength buffers used in most Lab-on-Chip applications typically yield very thin double layers and thus this decoupling is very often valid within a reasonable degree of error.

Electrical Double Layer – General Formulation

The EDL potential and the net charge density are related via the Poisson equation,

$$\nabla\cdot(\varepsilon_w\varepsilon_0\nabla\psi) + \rho_e = 0 \tag{4}$$

where ε_0 and ε_w are the dielectric permittivity of a vacuum ($\varepsilon_0 = 8.854\times10^{-12}$ C/Vm) and the local relative dielectric permittivity (or dielectric constant) of the liquid respectively. The ionic species concentration field within the double layer is given in its most general form by the Nernst-Planck conservation equation,

$$\nabla\cdot\left(-D_i\nabla n_i - \frac{D_i z_i e}{k_b T} n_i\nabla\psi + n_i\boldsymbol{v}\right) = 0 \tag{5}$$

where D_i, z_i and n_i are the diffusion coefficient, valence and number density of the ith species and e (e $= 1.602\times10^{-19}$ C), k_B ($k_B = 1.380\times10^{-23}$ J/K) and T are the elemental charge, Boltzmann constant and temperature

respectively. These two equations (Eq. (4) and Eq. (5)) are coupled by the definition of the net charge density given by,

$$\rho_e = \sum_i z_i e n_i \tag{6}$$

Equations (4) and (6) are coupled to the flow field by the convective (3rd) term in Eq. (5) and as such they must, in principal, all be solved simultaneously. As with many of the cases mentioned above this tends to significantly complicate the mathematical system without adding significantly to the model at this stage. An additional complication results from the fact that according to Eq. (6), all charged species must be accounted for in order to accurately determine the net charge density. This tends to be exceedingly difficult particularly when one wishes to examine the multispecies buffers which are commonly used in most actual Lab-on-Chip devices. Thus it is common to implement a two species model based on the most highly concentrated ions (dominant) in the buffer solution and to ignore the rest.

Electrical Double Layer – Simplified Formulation

By making the above simplifications and assuming that the EDL only varies strongly in the direction normal to the surface, we can simplify Eq. (5) by imposing a no flux condition into the surface yielding,

$$\frac{1}{n_i}\frac{\mathrm{d}n_i}{\mathrm{d}y} + \frac{z_i e}{k_B T}\frac{\mathrm{d}\psi}{\mathrm{d}y} = 0 \tag{7}$$

Integrating Eq. (7) assuming a point exists where the bulk concentration of the electrolyte is equal to n_0 and $\psi = 0$ yields the Boltzmann distribution given by Eq. (8),

$$n_i = n_0 \exp\left(\frac{-z_i e\psi}{k_B T}\right) \tag{8}$$

Assuming a two species, symmetric electrolyte (as described above) we can combine the 1D version of Eq. (4) with the definition of net charge density, Eq. (6) and the above Boltzmann distribution to obtain,

$$\varepsilon_w \varepsilon_0 \frac{\mathrm{d}^2\psi}{\mathrm{d}y^2} - \left(\frac{2\,|z|\,en_0}{k_B T}\right)\sinh\left(\frac{|z|\,e\psi}{k_B T}\right) = 0, \tag{9}$$

which is commonly referred to as the Poisson–Boltzmann distribution for a symmetric electrolyte. While analytical solutions do exist to Eq. (9) (see [3]) it is common to perform one further simplification and linearize the second term in the equation to obtain the Debye–Hückel approximation,

$$\frac{\mathrm{d}^2\psi}{\mathrm{d}y^2} - \kappa^2\psi = 0 \tag{10}$$

where κ is the Debye–Hückel parameter and is given by $\kappa = (2z^2e^2n_0/\varepsilon_w\varepsilon_0 k_B T)^{1/2}$. As shown in Fig. 1, $1/\kappa$ is characteristic of the double layer thickness. Depending on the value of n_0 this thickness can vary from close to 1 μm down to a few 10 s of nanometers at high ionic concentration consistent with the buffers used in most Lab-on-Chip applications.

Though subject to the limitations discussed above one can capture the majority of the influence of the double layer on the flow field in uniform systems by solving Eq. (10), subject to a $\psi = \zeta$ boundary condition at the shear plane (as shown in Fig. 1) and an assumption that $\psi \to 0$ as $y \to \infty$. For the 1D case this yields,

$$\psi(y) = \zeta e^{-\kappa y} \tag{11}$$

which can then be substituted into Eqs. (6) and (8) to compute the net charge density field. Though this linearization of the Poisson–Boltzmann equations does introduce some error at higher ζ-potentials, in most microfluidic systems this tends to be reasonably minor. This formulation also ignores convective and electrical effects on the EDL distribution as well as the potential for overlap between opposing double layers. While not commonly encountered in microscale fluidics, these effects can be very significant in many nanofluidic systems.

The major drawback of using such a formulation is that information regarding the convective and electrical effects on the double layer field and the resulting influence on the flow structure are lost and thus there is an inherent assumption that ρ_e varies on spatial scales much smaller than that of the flow system (see comments on nanofluidics below).

Applied Electrical Potential

The electric potential is most generally governed by the conservation of current condition as below,

$$\nabla \cdot j = 0 \tag{12}$$

where j is the current flux. The current flux can be obtained by summation of the flux of each individual species multiplied by the valence and elemental charge yielding,

$$\nabla \cdot \left(\sum_i z_i e\left[-D_i\nabla n_i - \frac{D_i z_i e}{k_B T} n_i \nabla\phi + n_i \boldsymbol{v}\right]\right) = 0 \tag{13}$$

which is derived by combining Eq. (5) and (6) above (here we consider the conservation or charge as opposed to the conservation of individual species and the conditions of zero flux at the boundaries do not apply at the anode and cathode). For electroosmotic flow in Lab-on-Chip systems, the conduction current (2nd term) tends to be much larger than the other terms and thus the 1st and 3rd terms in Eq. (13) can be ignored.

$$\nabla \cdot (\lambda \nabla \phi) = 0 \tag{14}$$

where λ is the bulk solution conductivity. Note that Eq. (14) also assumes that any additional conduction through the double layer region (due to the higher ionic concentration) is negligible. In practice the bulk conductivity is usually measured directly however it can in principal be calculated from a summation of the constituent ionic species,

$$\lambda = \sum_i \frac{D_i z_i^2 e^2 n_{i,0}}{k_B T} \tag{15}$$

where $n_{i,o}$ is the bulk concentration of the ith species. While there are many examples of non-uniform conductivity solutions in on-chip processes in most cases it is assumed to be constant everywhere. In that case λ can be removed from the above formulation leaving a simple Laplacian to describe the applied potential,

$$\nabla^2 \phi = 0 \tag{16}$$

In most cases it is proper to assume that the channel walls are perfectly insulating, thus a zero gradient (insulation) boundary condition is applied at those points.

Simplifications and Analytical Solutions

Helmholtz–Smoluchowski Equation

The most common simplification encountered in electroosmotic flow analysis is the “Helmholtz–Smoluchowski” approximation. To derive this we begin by eliminating the non-linear and transient terms in Eq. (1) as described above and assume that the pressure gradient, ∇p, is zero everywhere. The latter of these assumptions is generally valid for pure electroosmotic flow (no applied pressure) with uniform surface (ζ-potential) and solution (viscosity and conductivity) properties. We also replace $-\nabla\Phi$ with the local applied electric field strength E_x, and use Poisson’s Equation (Eq. (4)) to express the net charge density in terms of the double layer potential, ψ. This yields,

$$\eta \frac{d^2 v_x}{dy^2} - \varepsilon_w \varepsilon_0 \frac{d^2 \psi}{dy^2} E_x = 0 \tag{17}$$

We integrate this equation with respect to y twice and apply the condition that as $y \to \infty$, both $dv_x/dy = 0$ and $d\psi/dy = 0$, and that at $y = 0$ (i. e. the shear plane), $\psi = \zeta$. Following this procedure and considering the region outside the double layer $\psi = 0$) yields,

$$v_x = v_{eo} = -\frac{\varepsilon_w \varepsilon_0 \zeta}{\eta} E_x \tag{18}$$

which is commonly referred to as the Helmholtz–Smoluchowski equation and is descriptive of a plug flow velocity profile. Commonly the terms which precede E_x in Eq. (18) are expressed as single linear proportionality coefficient between v_{eo} and E_x referred to as the electroosmotic mobility, $\mu_{eo} = (-\varepsilon_w \varepsilon_0 \zeta/\eta)$.

The essential criticism of Eq. (18) is that it provides us with absolutely no information regarding the flow field within the double layer. We can capture this information by incorporating the Debye–Hückel solution, Eq. (11), into Eq. (17) above which yields,

$$v_x(y) = \mu_{eo} E_x \left(1 - e^{-\kappa y}\right) \tag{19}$$

After application of a no slip boundary condition at $y = 0$ and $dv_x/dy \to 0$ as $y \to \infty$. As can be seen from Eq. (19), v_x varies exponentially from zero at the shear plane eventually reaching its steady state value of v_{eo} at the edge of the double layer. In situations where the linear approximation are not accurate (typically when the ζ-potential is very high) Eq. (19) can be further generalized by incorporating a non-linear Poisson–Boltzmann distribution. This however typically involves the use of a numerical technique to find a solution.

Extension to 2D and 3D Systems

In the majority of microfluidic cases where $1/\kappa$ is much smaller than the channel height the Helmholtz–Smoluchowski equation provides a reasonable estimate of the flow velocity at the edge of the double layer field. As such when modelling two and three dimensional flow systems it is common to apply this equation as a “slip” boundary condition on the bulk flow field. Since beyond the double layer by definition $\rho_e = 0$, the flow equation reduces to (assuming pure electroosmotic flow) to a simple Laplacian,

$$\nabla^2 v = 0 \tag{20}$$

which can be very easily solved numerically for complex geometries. Once of the great advantages of this formulation is that exhibits the same mathematical properties as the electric potential equation and thus good qualitative information on flow rates in complex channel networks

can be described analytically with relatively simple circuit models.

If we relax the condition of uniform surface properties (which occurs quite commonly in microsystems either by design or as a result of system fouling) local pressures are induced in order to maintain continuity. In such a case Eqs. (1) and (2) reduce to the Stokes flow equations as shown below,

$$\eta \nabla^2 v - \nabla p = 0 \quad (21)$$

$$\nabla \cdot v = 0 \quad (22)$$

In this case the variation in the surface properties is also expressed through the slip boundary condition. A numerical technique is typically required to capture a solution however nearly all commercial CFD packages provide this functionality. The advantage of the above system is of course that it allows one to describe 2D and 3D velocity fields in microfluidic devices which commonly have channel lengths on the order of several centimetres without having to worry about resolving the solution on the spatial scale of the double layer (which can be seven orders of magnitude smaller).

Nanofluidic Systems with Overlapped Double Layers

Nearly all the analytical derivations above have explicitly assumed that the system is sufficiently large that there exists a region far away from the surface where the double layer vanishes and both ρ_e and ψ go to zero. In nanofluidic systems however the channel height, h, is commonly on the same spatial order as the double layer thickness (i. e. $1/\kappa$) and as such the above approximation is no longer valid and the accuracy of these models are compromised. Fortunately this situation also occurs in problems of colloid stability and thus the theory for such problems has also been well developed [4].

Put simply the extension to overlapped double layer models involves the replacement of the vanishing double layer condition with that of either symmetry at the channel midplane (for a half domain solution) or the additional specification of the ζ-potential at the opposite surface. For the former of these it can be shown that the solution to Eq. (10) becomes,

$$\psi(y) = \zeta \frac{\cosh(\kappa |h/2 - y|)}{\cosh(\kappa h/2)} \quad (23)$$

Under conditions of double layer overlap the Helmholtz–Smoluchowski approximation looses meaning since the velocity profile never reaches a constant velocity "plug flow" velocity. We can however still compute a reasonable approximation to the average velocity through the channel, $v_{eo,odl}$, via Eq. (24),

$$v_{eo,odl} = v_{eo}\left(1 - \frac{\tanh(\kappa h/2)}{\kappa h/2}\right) \quad (24)$$

where v_{eo} is the Helmholtz–Smoluchowski velocity (for details on the derivation see Hunter [3]). In the limit of not large double layer overlap (typically cited as $\kappa h/2 > 3$) the correction term in Eq. (24) reduces to $\approx 1 - 2/\kappa h$.

E

Key Research Findings

The major application of DC electroosmotic flow in micro- and nano-fluidics continues to be as a general transport mechanism in Lab-on-Chip type devices. Specific applications along these lines are too numerous to mention here and thus interested readers should consult any one of a number of recent review articles (e. g. Erickson et al. [6]) for more details. Rather we provide a brief overview of a select number of key research findings with regards to "non-traditional" emerging technologies involving electroosmotic effects for micro- and nanosystems.

High Pressure Electroosmotic Pumps

A number of groups have recently developed high pressure electroosmotic pumps which, briefly speaking, operate on the principal that impeding or stopping the flow upstream of an electroosmotic cell induces a backpressure on the system. It can be relatively easily shown that the maximum obtainable pressure in such a system (occurring at no net flow rate) is given by,

$$\Delta P_{max} = \left|\frac{8\varepsilon_w \varepsilon_0 \zeta}{a^2}\right| \Delta\phi \quad (25)$$

where a is the pore or channel radius (in the limit of no double layer overlap). Using such systems very high pressures have been demonstrated (on the order of a 100 kPa per applied Volt) and work continues in developing cell materials and fluid systems which tend to increase the value of the proportionality term in Eq. (25) while avoiding overlapped double layer effects. Such devices are expected to find application in on-chip chromatography and electronics cooling (See Reichmuth et al. [7] for system examples).

Electroosmotic Control over Surface Phase Binding Stability

One of the well known but not well exploited characteristics of electroosmotic flow are the exceptionally high rates of shear at the surface. While a series of models exist for

electroosmotic transport in the presence "hairy" double layers, little is known about how these high rates of shear will affect probe orientation and the subsequent kinetics in surface phase binding reactions. Recently Erickson et al. [8] demonstrated the ability to discriminate single nucleotide polymorphisms in microfluidic architectures using a combination of these shear rates with electrophoretic and joule heating effects.

Electroosmotic/Electrokinetic Energy Conversion

Though more commonly associated with an analogous electrokinetic effect referred to as the streaming potential (whereby an externally induced flow is used to convect ions from the double layer to a downstream reservoir where they collect and form a steady state electric potential difference across the channel), electroosmotic effects are of critical importance in some of the recent work in electrokinetic energy conversion. The concepts behind using electroosmotic flow for mechanical energy (as in the electrokinetic pumps discussed above) and the analogous use of mechanically pumped flow for direct electrical energy conversion (via the streaming potential discussed above) have been developed for years. The emergence of new electroosmotic cell materials (similar to those described for the high pressure pumps above) along with the more global interest in developing new energy conversion devices has lead to some renewed interest in this field (see Yang et al. [9] and Daiguji et al. [10] for some recent works). Eventual application of such devices is likely to be relatively limited as predicted optimal efficiencies tend to be less than 1%.

Future Directions for Research

Although the basic fluid dynamics and transport issues in microscale systems are reasonably well described there have been a number of significant recent theoretical and experimental advancements in the study of electroosmotic flow. The majority of the models described generally assume uniformity of surface and solution properties and thus much of the recent work has involved investigating systems where uniform ζ-potential, solution conductivity and/or viscosity can no longer be assumed. This has led to the discovery of a number of new effects such as electrokinetic instabilities. Non-linear "induced charge" electroosmotic flows, though originally described years ago in the colloidal literature, have also been of interest in microscale systems.

Electroosmotic flow (and more broadly electrokinetics) is uniquely positioned to become the primary transport mechanism in nanofluidic devices and other confined nanosystems. As is well known the average velocity of a traditional pressure driven flow scales with the square of the channel height whereas an electroosmotic flow velocity varies much more weakly (as indicated by Eq. (24)) and then only in the limit of double layer overlap. At the same time the greater surface area to volume ratio of the systems leads to better rejection of joule heat from the flow enabling the application of much higher potentials. While much of the continuum based theory applicable to electroosmotic flows in nanochannels is reasonably well developed, greater availability of computing power has enabled the development of MD type simulation which enable more precise probing of the flow field. Modifications to existing theories which capture other relevant effects, such as ion size excluded volume effects, are also likely to be of increasing importance. From an experimental point of view the broader availability of nanofabrication facilities has enabled a much more systematic experimental study of electroosmotic flow in nanoscale systems.

Synonyms

Electroosmotic flow over non-uniform surfaces

Definition

Electroosmotic flow is the bulk liquid motion that results when an externally applied electric field interacts with the net surplus of charged ions in the diffuse part of an electrical double layer (EDL). In the presence of non-uniform or heterogeneous ζ-potential, the net charge density in the EDL changes locally resulting in an irregular body force applied to the flow field and ultimately in a non-uniform flow field. Better understanding of this effect can lead to enhanced binding rates for surface phase reactions (through enhanced transport to the surface) and better mixing in microfluidic systems.

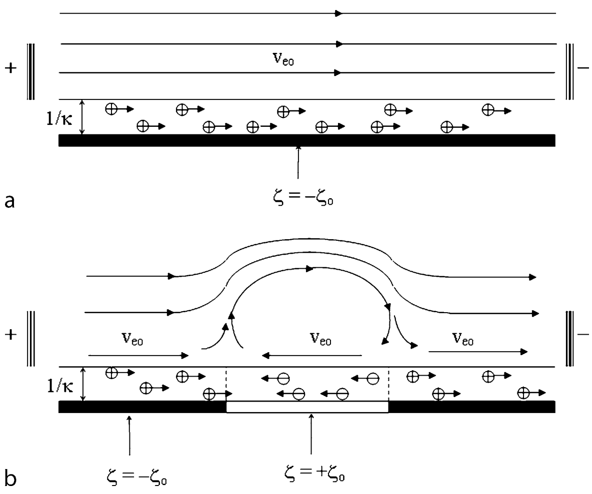
Overview

Transport over heterogeneous surfaces arises in a variety of electrokinetic characterization and micro-/nanofluidics based applications. With respect to the former of these the streaming potential technique has been used to monitor the dynamic or static adsorption of proteins (e. g. Norde and Rouwendal [1]) and colloidal particles (e. g. Zembala and Adamczyk [2]) onto a vast array of surfaces. In these systems the surface's electrokinetic properties are altered by introducing a heterogeneous region which has a different ζ-potential than the original surface. The introduction of this heterogeneous region induces a change in the surface's average ζ-potential, which is monitored via a streaming potential measurement, and dynamically related back to the degree of surface coverage. The presence of this streaming potential necessarily induces an electroosmotic flow in the direction opposite to the main pressure driven flow and thus it becomes important to understand the coupling of these two flow effects and how their presences affects the spatial distribution of counter ions in the double layer field in order to better relate global streaming potential measurements to local adsorption phenomena.

For the latter of these, electroosmotic flow has evolved into likely the most popular transport mechanism for integrated microfluidic devices, largely the result of the simplicity of its implementation and the uniqueness of its flat *plug-flow* like velocity profile (for more details see ► electroosmotic flow). While the majority of modeling and transport studies are done assuming uniformity of the surface ζ-potential, there exists a large number of applications where such an assumption become invalid. As an example, microfluidics based biosensors often involve selective capture of a solution phase target onto a surface phase probe (see Erickson et al. [3]). Probe patches are typically arranged in a periodic fashion and in general do not have the same electrokinetic properties of the homogeneous surface. Such systems are particularly interesting since the spatial scale of the non-uniformity exists both on the patch size (which affects the global velocity field) and the probe size (which affects the local flow and transport fields around the probe). Active and passive manipulation of the surface ζ-potential field has also proven successful at addressing mixing problems in microscale systems (as will be further demonstrated below) and for providing local control over ion and molecular transport in nanoscale systems (see Karnik et al. [4]).

Pioneering analytical studies examining these effects were conducted by Ajdari (e. g. [5]), Anderson (e. g. [6]) and Ghosal [7]). Anderson's work (which precedes the other two) was one of the first to look at the effects of surface non-uniformity on the electrophoretic motion of particles. In Ajdari's works it was predicted that the presence of surface heterogeneity could result in regions of electroosmotically induced bulk flow circulation, referred to as *tumbling* regions which was later observed experimentally. Ghosal presented an elegant lubrication theory approach to the solution of electroosmotic flow accounting for changes in both channel size and surface charge.

The mechanism for inducing electroosmotic flow is well described in the article on that subject within this encyclopedia, so here we only provide a brief qualitative explanation. As mentioned in that article, an electrical double layer (EDL) is a very thin region of non-zero net charge density near a two phase interface. The diffuse region of the EDL



Electroosmotic Flow over Heterogeneous Surfaces, Figure 1 Electroosmotic flow near the double layer region for (**a**) a homogeneous surface ($\zeta = -|\zeta_0|$) and (**b**) a homogeneous surface with a heterogeneous patch ($\zeta = +|\zeta_0|$). Over the heterogeneous patch, the excess cations are attracted to the positive electrode resulting in an electroosmotic flow in the opposite direction to that over the homogeneous regions with an excess anion concentration. Arrows represent streamlines and $1/\kappa$ refers to the characteristic thickness of the electrical double layer

decays roughly exponentially into the bulk solution over a distance of 10 nm to as much as a few 100 nm and comprises bulk charge density of opposite polarity to that of the surface charge to maintain overall electrical neutrality. When an electric field is applied perpendicular to the surface, the surplus of either positive or negative ions results in a net body force on the fluid proportional to the local net charge density. For the homogeneous case (Fig. 1a) the electroosmotic body force applied to the liquid continua within the double layer is equivalent at each point along the flow axis and results in a constant bulk liquid velocity at the edge of the diffuse double layer, v_{eo}, which can be described by,

$$v_{eo} = -\frac{\varepsilon_w \varepsilon_o \zeta}{\eta} \boldsymbol{E} = \mu_{eo} \boldsymbol{E} \tag{1}$$

where μ_{eo} is the electroosmotic mobility, ε_w is the electrical permittivity of the solution, η is the viscosity and $\boldsymbol{E}$ is the applied electric field strength.

The same relation holds true for the heterogeneous surface except the ζ-potential (and by extension therefore μ_{eo}) is no longer constant across the domain of interest. As will be detailed below, when the change in ζ from the mean value is relatively small the result is a local slowing or quickening of the velocity near the surface which in turn results in an induced pressure driven flow to maintain overall continuity. The major consequence of this induced flow is that the superimposed parabolic velocity profile can lead to anomalous transport affects (namely sample dispersion) which tend to negate many of the advantages associated with electroosmotic plug flow. In the extreme case where the local ζ-potential is opposite sign to that of the mean surface, the electroosmotic body force now acts in the opposite direction to that in the homogeneous regions. This results in the formation of circulation zones which, as shown in Fig. 1b, extend into the bulk flow field.

A variety of analytical and numerical models have been proposed recently to investigate electrokinetic effects over heterogeneous surfaces. In general however these models can be separated into either slip flow approaches, whereby the electroosmotic contribution to the flow field is accounted for through the application of a slip velocity condition at the edge of the double layer, and the more comprehensive Nernst–Planck–Poisson–Navier–Stokes simulations in which the effects of the flow and electrical fields on the double layer distribution are also captured. In the following section we will introduce both of these approaches and some of our experimental work demonstrating surface heterogeneity enhanced mixing in electrokinetic systems. As mentioned above, the theory of electroosmotic flow has already been described in detail in the article by that name and thus here we focus on extensions to that theory as applicable to flow over heterogeneous surfaces. Some of the experimental aspects of our work will also be discussed.

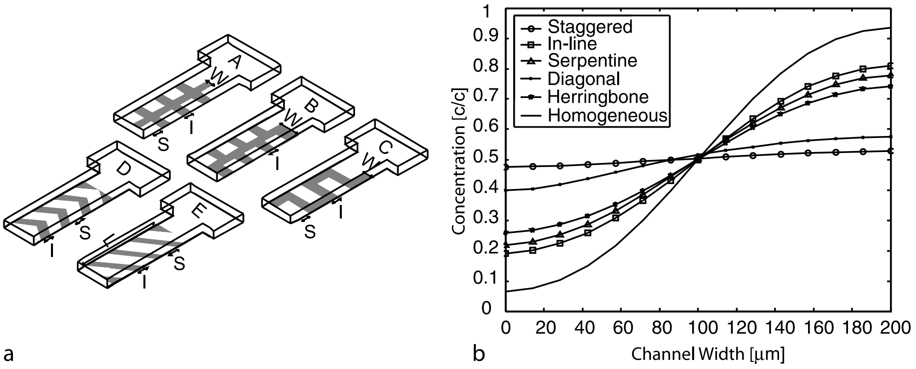
Basic Methodology

Enhanced Species Mixing in Electroosmotic Flow due to the Presence of Non-Uniform Electrokinetic Surface Properties

Most microfluidic systems, particularly electroosmotically driven ones, are limited to the low Reynolds number regime and thus species mixing is largely diffusion dominated (as opposed to convection dominated at higher Reynolds numbers). Consequently, mixing tends to be slow and occur over relatively long distances and times. In the first section of this article we will describe how surface heterogeneity can enhance species mixing. The work described here is based on articles by Erickson and Li [8] and Biddiss, Erickson and Li [9].

Numerical Simulations

As our model system, we consider the mixing of equal portions of two buffer solutions, one of which contains a concentration, c_0, of a species of interest in a T-mixer type channel geometry (see Fig. 2a), 200 μm in width and 8 μm in depth. In general the introduction of surface heterogeneity induces flow in all three coordinate directions, thus necessitating the use of a full 3D numerical simulation. The length of the mixing channel used in our simulations



Electroosmotic Flow over Heterogeneous Surfaces, Figure 2 (**a**) Surface charge patterning configurations with a mixing region length *L* consistent for all configurations, a patch length *l*, a patch width *w*, and patch spacing *s* for (A) In-line pattern (B) Staggered pattern (C) Serpentine pattern (D) Herringbone pattern and (E) Diagonal pattern. (**b**) Numerically simulated concentration profiles across the channel width for the staggered pattern subsequent to the mixing region for an applied potential of 280 V/cm

was dictated by that required to obtain a uniform concentration (i. e. a fully mixed state) at the outflow boundary. Depending on the simulation conditions this required L_{mix} to be on the order of 200 times the channel width. This is an example of a case where we are primarily interested in steady state, bulk phase fluid flow and species transport. As such we have no specific interest the double layer field and thus the electroosmotic slip condition approach to model the flow field (see the "Simplifications and Analytical Solutions" section of the ▶electroosmotic flow). In systems such as that of interest here, species transport is accomplished by 3 mechanisms: diffusion, electrophoresis, and convection. In the most general case the superposition of these three mechanisms results in the following conservation equation

$$\frac{\partial c_i}{\partial t} = \nabla \cdot \left(D_i \nabla c_i + \mu_{\text{ep},i} c_i E - c_i v \right) + R_i \,, \tag{2a}$$

where c_i and D_i is the local concentration and diffusion coefficient of the ith species, μ_{ep} is the electrophoretic mobility ($\mu_{\text{ep}} = D_i z_i e / k_b T$) and R_i is a bulk phase reaction term. In this case we are primarily concerned with the steady state mixing profile and will not consider any bulk or surface phase reactions. Additionally here we only track a single species and drop the i notation. As such Eq. (2a) reduces to,

$$D \nabla^2 c + \mu_{\text{ep}} E \nabla c - v \nabla c = 0 \,. \tag{2b}$$

Details of the solution algorithm used here are available in Erickson and Li [8].

In general the strength of the relatively simple technique outlined above is that it allows one to relatively rapidly numerically prototype the system and perform a broad range of simulations in order to optimize the system.

In this article we focus on characterizing the pattern of surface charge heterogeneity and its effect on mixing enhancement. For the purposes of this article we define mixing efficiency as,

$$\varepsilon(y) = \left(1 - \frac{\int_0^W |c_i - c_\infty| \, \mathrm{d}x}{\int_0^W |c_0 - c_\infty| \, \mathrm{d}x} \right) \times 100\% \,, \tag{3}$$

where c_0 and c_∞ are the concentration profiles at the inlet to the mixer and after an infinitively long mixing profile respectively.

Figure 2 shows the results of these simulations for five different heterogeneous surface patterns (shown in Fig. 2a) expressed at the concentration profile downstream from the mixing region. For each configuration, the patch length and spacing parameters were selected to maintain a constant ratio of heterogeneous to homogeneous surface areas over a channel length of 1.8 mm. As can be seen in Fig. 2b, which shows the concentration profile downstream of the surface patterns, the non-symmetrical patterns, namely the staggered and the diagonal, generated better mixing distributions in comparison to the symmetrical herringbone and in-line arrangements. With a theoretical mixing efficiency of 96%, the staggered configuration provided the greatest degree of mixing, out-performing the diagonal, the herringbone and the serpentine configurations by 8%, 31% and 36% respectively. In comparison with the homogenous case, the staggered configuration provided a 61% increase in mixing efficiency.

Heterogeneous Surface Modification and Characterization

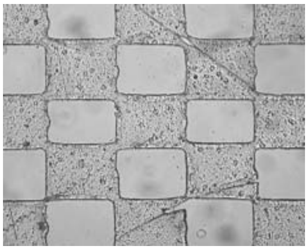
As mentioned above heterogeneous surface occur in a number of different micro- and nanofluidic applications,

here we describe a simple technique, developed as part of the Biddiss et al. [9] study, to create arbitrary surface charge patterns similar to those shown in Fig. 2a. Using rapid prototyping/soft lithography techniques [10] a PDMS master featuring a channel configuration corresponding with the pattern of heterogeneities to be examined, was created and was reversibly sealed to a glass slide. A negative pressure was applied to the downstream end of the system such and the PDMS master was flushed sequentially with 0.1 M sodium hydroxide for 2 min, deionized water for 4 min, and 5% Polybrene solution for 2 min, resulting in selective regions of positive surface charge while leaving the majority of the glass slide with its native negative charge. All fluid was then removed from the channel and the system was left exposed to air for 40 min before a second flush was done with water for 20 min. Following this second flush the channel was again evacuated and the system left exposed to air for 24 h prior to use. Following this the location of the surface pattern was land-marked and the PDMS master was removed from the glass slide. Figure 3 below shows an optical image of the surface after patterning.

To characterize the electroosmotic mobility of the Polybrene surfaces we performed a series of experiments using the well established current monitoring technique. In all our experiments a 25 mM sodium carbonate/bicarbonate run buffer with pH 9.0 was used. Details of the experimental technique can be found in Sze et al. [11]. Briefly however, to begin the buffer solution was diluted to 95% of its original concentration and introduced into a PDMS channel sealed to a glass surface which had undergone the polybrene surface treatment described above. After infusing the channel, the solution in the upstream reservoir was replaced with a second buffer concentrated at 105% of the final 25 mM solutions. An electric field was then applied across the channel and the current load monitored as a function of time. As the high conductivity buffer replaced the low conductivity buffer in the solution the current was observed to rise, eventually reaching a stable plateau once the original solution had been completely replaced. Given the applied voltage, the length of the channel and the time required for complete displacement the electroosmotic mobility, μ_{eo}, of the surface could be extracted using Eq. (4) below,

$$\mu_{\text{eo}} = \frac{\Delta V L^2}{\Delta t}\,, \tag{4}$$

where ΔV, Δt and L are the applied voltage, recorded time and channel length respectively. Given that the mobility of the untreated (in this case PDMS) surfaces is known the average μ_{eo} from Eq. (4) can be related to the local μ_{eo} of the polybrene treated surface through a surface area weighted averaging technique. Using this method the mobility of the polybrene surface was measured as $2.3 \times 10^{-4}\ \text{cm}^2/\text{Vs}$ (corresponding to a ζ-potential of $+33$ mV).



Electroosmotic Flow over Heterogeneous Surfaces, Figure 3 Optical image of polybrene patches on a surface

Experimental Validation and Characterization

To experimentally validate our system, a T-shaped microchannel with the same geometry as that used in our numerical simulations was fabricated in PDMS (also using soft lithography) and then permanently sealed to the glass slide such that the patterned surface heterogeneities were appropriately positioned within the mixing channel. For our experiments we used the optimized micromixer consisting of 6 offset staggered patches (Fig. 2a, pattern B) spanning 1.8 mm downstream and offset 10 μm from the channel centerline with a width of 90 μm and a length of 300 μm. Mixing experiments were conducted at applied voltage potentials ranging between 70 V/cm and 555 V/cm as corresponded to Reynolds numbers of 0.08 and 0.7 and Péclet numbers of 190 and 1500. As can be seen in Fig. 4, experimental results compared well with numerical simulations with images of the steady state flow for the homogenous and heterogeneous cases exhibiting near identical flow characteristics and circulation at 280 V/cm. Qualitatively, experimental visualization of a staggered configuration of heterogeneities exhibited the formation of highly unsymmetrical concentration gradients indicative of flow constriction and localized circulation in the patterned region. Bulk flow was forced to follow a significantly narrower and more intricate route thereby increasing the rate of diffusion by means of local concentration gradients. Convective mechanisms were also introduced by local flow circulation which transported a portion of the mixed downstream flow upstream. Additionally, sharp, lengthwise gradients absent in the homogeneous case resulted in an additional diffusive direction and enhanced mixing.

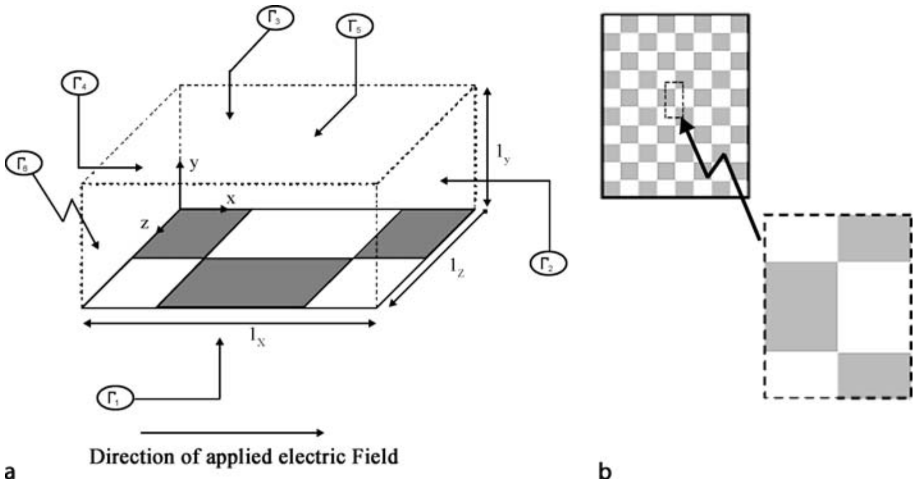
Comprehensive Nernst–Planck–Poisson–Navier–Stokes Simulation of Flows over Heterogeneous Surfaces

The modelling technique discussed above represent a relatively simple formulation which enables us to very rapidly (i. e. requiring minimal computational resources) simulate complex 2D and 3D electrokinetic flows and subsequent species transport. The ultimate limitation is that while the influence of the double layer on the bulk flow field can be reasonably well determined, the coupled effect of the flow and applied electrical fields on the double layer structure is ignored. As outlined in our recent review article [12] in many cases this represents a reasonable simplification given the ultimate goals of the simulation (which may simply be device numerical prototyping). Perhaps the most important reason for developing models which go beyond this level of understanding relate to the extreme conditions which exist within the double layer (for electroosmosis surface shear rates can be as high as 10^5 1/s) and how these conditions effect surface bound molecules. As an example we have recently demonstrated that by controlling the coupling of the shear, electrical and thermal energies within the double layer, sufficiently precise energy can be applied to specifically bound DNA so as to denature targets which contain single base pair mismatches, while those which are fully complementary remain bound [13].

Towards this end we have begun to investigate the flow in such systems using a variant of our finite element code. The numerical model used here is based on a simultaneous solution to the Nernst–Planck, Poisson and Navier–Stokes equations, which also allows us to shed the Poisson–Boltzmann double layer distribution assumption and to adopt a more general approach. The details of the analytical model and numerical solution method are described in detail in Erickson and Li [14]. Rather than focus on the technique here will present results for electroosmotically driven flow through a slit microchannel (i. e. a channel formed between two parallel plates) exhibiting the periodically repeating heterogeneous surface pattern shown in Fig. 5. To minimize the size of the solution domain it has been assumed that the heterogeneous surface pattern is symmetric about the channel mid-plane, resulting in the computational domain also shown in Fig. 5. As a result of these two simplifications, the inflow and outflow boundaries surfaces 2 and 4 represent periodic boundaries on the computational domain, while surface 3 at the channel mid-plane represents a symmetry boundary. From Fig. 5 it can be seen that in all cases the surface pattern is symmetric about surfaces 5 and 6 and thus these surfaces also represent symmetry boundaries.

For our simulations we will consider $l_x = 50\,\mu$m, $l_y = l_z = 25\,\mu$m computational domain (see Fig. 5) containing a 10^{-5} M KCl solution, an applied driving voltage of 500 V/cm and a surface charge density of $\sigma_{\text{homo}} = -4\times10^{-4}$ C/m^2. This represents a slightly different computational approach to that above in that now we enforce a Neumann boundary condition to the Poisson equation ($\sigma = \varepsilon_w \varepsilon_o \partial\psi/\partial n$, where n is the surface normal) The simulations revealed three distinct flow patterns, depending on the degree of surface heterogeneity, each of which is shown in Fig. 6. The contours in these figures represent the magnitude of the velocity perpendicular to the direction of the applied electric field ($v^2 = v_y^2 + v_z^2$) scaled by the maximum velocity in a homogeneous channel, which in this case is 1.7 mm/s.

At low degrees of surface heterogeneity ($\sigma_{\text{hetero}} \leqslant -2\times 10^{-4}$ C/m^2) the streamline pattern shown in Fig. 6a was obtained. As can be seen a net counter-clockwise flow perpendicular to the applied electric field is present at the first transition plane (i. e. at the initial discontinuity in the heterogeneous surface pattern) and a clockwise flow at the second transition plane. This flow circulation is a pressure induced effect that arises as a result of the transition from the higher local fluid velocity (particularly in the double layer) over the homogeneous surface on the right hand side at the entrance, to the left hand side after the first transition plane (and vice versa at the second transition plane). To satisfy continuity then there must be a net flow from



Electroosmotic Flow over Heterogeneous Surfaces, Figure 5 (**a**) Domain for periodically repeating computational cell (**b**) Patchwise surface periodicity pattern

right to left at this point, which in this case takes the form of the circulation discussed above. The relatively straight streamlines parallel with the applied electric field indicate that at this level the heterogeneity is too weak to significantly disrupt the main flow.

While a similar circulation pattern at the transition planes was observed as the degree of surface heterogeneity was increased into the intermediate range (-2×10^{-4} C/m$^2 \leqslant \sigma_{\text{hetero}} \leqslant +2\times10^{-4}$ C/m^2) it is apparent from the darker contours shown in Fig. 6b that the strength of the flow perpendicular to the applied electric field is significantly stronger reaching nearly 50% of the velocity in the homogeneous channel. Unlike in the previous case it is now apparent that the streamlines parallel with the applied electric field are significantly distorted due to the much slower or even oppositely directed velocity over the heterogeneous patch. At even higher degrees of heterogeneity ($+2\times10^{-4}$ C/m$^2 \leqslant \sigma_{\text{hetero}} \leqslant +4\times10^{-4}$ C/m^2) a third flow structure is observed in which a dominant circulatory flow pattern exists along all three coordinate axes, as shown in Fig. 6c. This results in a negligible, or even nonexistent, bulk flow in the direction of the applied electric field (which is to be expected since the average surface charge density for these cases is very near zero). As indicated by the contour plots, the velocity perpendicular to the flow axis has again increased in magnitude, reaching a maximum at the edge of the double layer near the symmetry planes at the location where a step change in the surface charge density has been imposed.

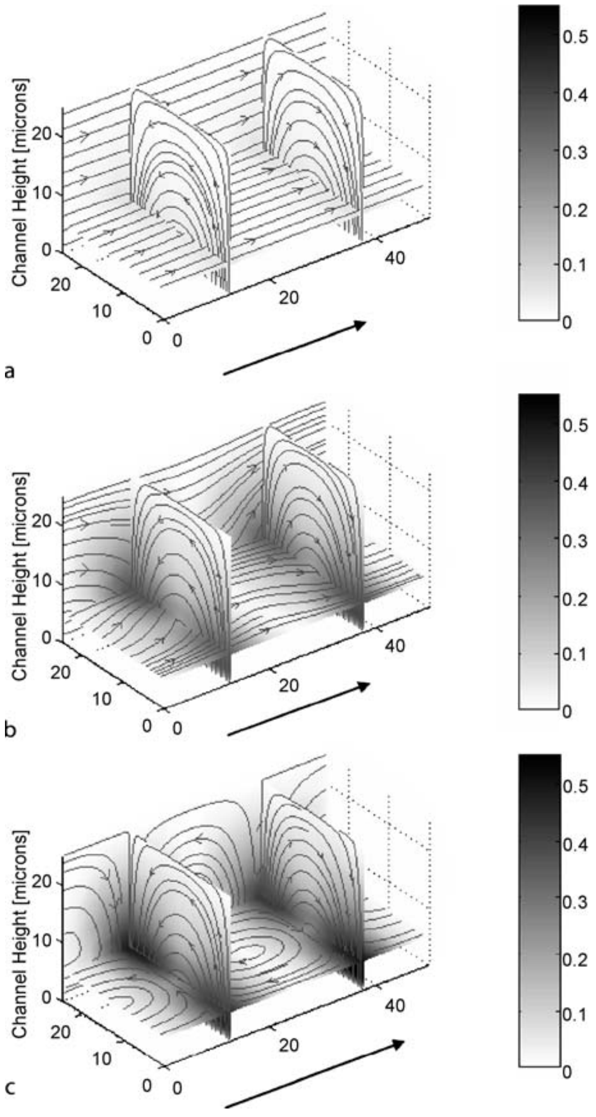
Key Research Findings

The above article (and cited works within) have focused on the modeling electroosmotic flow and transport over surfaces with non-homogeneous electrokinetic properties. The presence of periodically repeating heterogeneous patches is shown to induce distinct flow structures depending on the relative difference between the surface charge density of the homogeneous and heterogeneous regions. Small differences in the charge density are shown to induce fluid motion perpendicular to the applied electric field however the bulk flow remains largely unaffected. As the degree of heterogeneity is increased the streamlines in the direction of the applied electric field become significantly distorted. When oppositely charged surfaces are encountered a strong circulatory flow regime is observed which we have demonstrated both numerically and experimentally can be used to enhance mixing in electrokinetic systems.

Although we have focused here on periodic variations in surface charge patters, analogous works exists for non-uniform topographies intended to mimic electroosmotic flow over rough surfaces (see [15]). In the latter of these cases the general result is that the influence of the roughness extends into the bulk flow roughly on the same height scale as that of the roughness itself and thus tends not to have as dramatic of an effect as an irregular ζ-potential does.

Future Directions for Research

Electroosmotic flows over irregular surfaces can be modeled extremely well using the continuum based approaches described above, down to length scales of a few 10 s of nanometers. As such these models are likely to be very efficient at predicting both average and local flow structure down to scales of this order. In the above we mentioned that the initial motivation for investigating these



Electroosmotic Flow over Heterogeneous Surfaces, Figure 6 Electroosmotic flow streamlines over a patchwise heterogeneous surface pattern with $\sigma_{homo} = -4 \times 10^{-4}$ C/m^2 and (**a**) $\sigma_{hetero} = -2 \times 10^{-4}$ C/m^2 (**b**) $\sigma_{hetero} = +2 \times 10^{-4}$ C/m^2 (**c**) $\sigma_{hetero} = +4 \times 10^{-4}$ C/m^2. systems was our interest in electroosmotic flow and transport over DNA microarrays. In such systems the heterogeneity exists on two lengths scales, namely the patch (or spot) size and the probe size. Modeling the interaction of the flow, electrical and transport fields and their interaction with compliant structures such as immobilized DNA represents a significantly more challenging problem than those addressed here. It is not clear if simple continuum based modeling may be able to provide a reasonable approximation to such a system (whereby the DNA is treated as a compliant beam for example) or if more advanced atomistic simulation may be required.

Definition

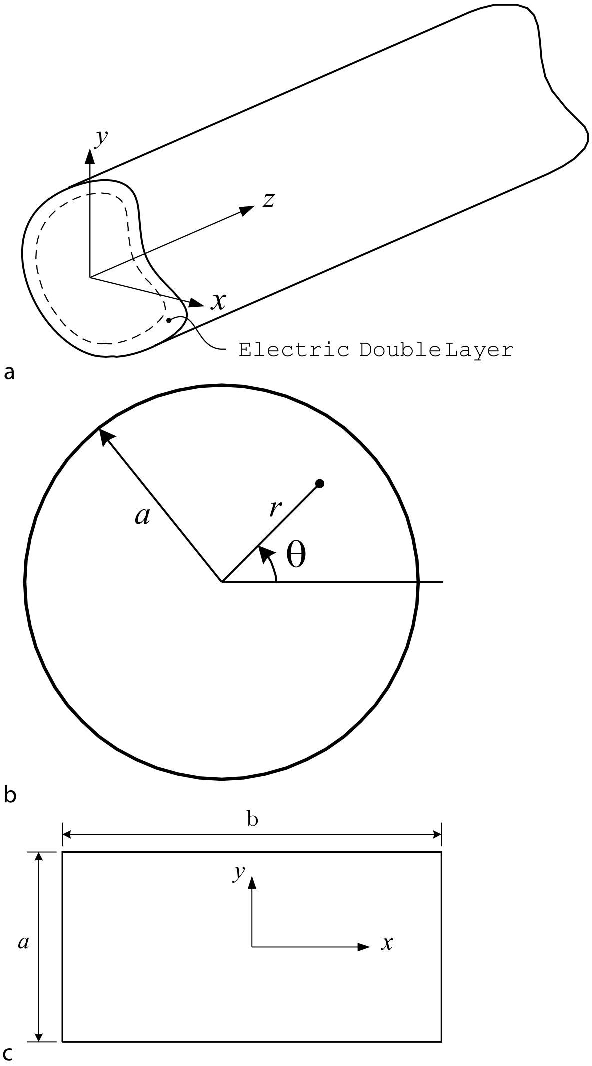
A pump whose working principle is electroosmosis.

Chemical and Physical Principles

Electroosmotic Pump Through a Single Channel

We consider a micro- or nanochannel having a uniform cross-section as shown in Fig. 1a. When the channel is in contact with an electrolyte, its surface is charged with usually negative ions. The counter-ions in the liquid are then attracted onto the surface while the co-ions are repelled away from the wall. The thin layer near the surface where the counter-ions are thus highly concentrated is called the electric double layer (EDL). The amount of accumulation of the counter-ions in the EDL is determined in such a way that the electric potential difference induced between the wall surface and the bulk equals the zeta potential, which is an intrinsic property of the interface. When an external electric field is applied along the channel, it exerts the Coulomb force to the ions thereby driving the fluid flow. This kind of fluid motion is called electroosmosis (e. g. [1]), the working principle of the electroosmotic pump.
The electric potential ϕ within the channel induced by the unbalanced distribution of the ions in the EDL is determined from the Poisson equation:

$$\nabla^2\phi = -\frac{\rho_e}{\varepsilon\varepsilon_0} \tag{1}$$



Electroosmotic Pump, Figure 1 Coordinates for analysis of the electroosmotic flow inside a single capillary with a uniform cross-sectional shape. (**a**) Perspective view of an arbitrary shape of cross-section; (**b**) circular section; (**c**) rectangular section

where $\nabla^2 = \partial^2/\partial x^2 + \partial^2/\partial y^2$ is the 2D Laplacian, (x, y) denotes the coordinates on the cross-sectional plane of the channel (Fig. 1a), ρ_e the net charge density (net charge per unit volume), ε the dielectric constant of the solution and ε_0 the permittivity of the vacuum. For symmetric ions, the charge density is given by

$$\rho_e = ze(n_+ - n_-) \tag{2}$$

Here z is the valence of the ions, e the proton charge and $n_\pm$ the number concentration (ion number per unit volume) of the cations and anions, respectively. Assuming the equilibrium Boltzmann distribution for the ion concentra-

tion, we can relate the number concentration to the potential as follows:

$$n_{\pm} = n_{\infty} \exp(\mp ze\phi / k_{\mathrm{b}}T)$$

where n_{∞} is the concentration of each ion in the bulk region, k_{b} the Boltzmann constant and T the temperature. Then Eq. (1) becomes

$$\nabla^2 \phi = \frac{2zen_{\infty}}{\varepsilon\varepsilon_0} \sinh(ze\phi / k_{\mathrm{b}}T) \tag{3}$$

Analytic solutions to this equation can be obtained under the assumption of small magnitude of $ze\phi / k_{\mathrm{b}}T$. Then Eq. (3) leads to

$$\nabla^2 \phi = \frac{\phi}{\lambda^2} \tag{4}$$

where

$$\lambda = \sqrt{\frac{\varepsilon\varepsilon_0 k_{\mathrm{b}} T}{(2z^2 e^2 n_{\infty})}} \tag{5}$$

denotes the Debye–Huckel parameter (or Debye length) representative of the EDL thickness. Such simplification is called the Debye–Huckel approximation [1].

The velocity vector $\boldsymbol{u}$ of the fluid flow caused by the nonzero charge density in the EDL is governed by

$$\mu \nabla^2 \boldsymbol{u} = \nabla p - \rho_{\mathrm{e}} \boldsymbol{E} \tag{6}$$

where $\boldsymbol{E}$ is the external electric field vector and μ the dynamic viscosity of the fluid. When the applied pressure gradient ∇p and the applied external electric field $\boldsymbol{E}$ are along the axial direction with uniform magnitudes, $\Delta p / L$ and E, respectively, we can assume a fully developed flow, and the only nonzero velocity component w, i. e. the axial component, can be decomposed into the pressure-driven and the electroosmosis-driven parts: $w(x, y) = w_{\mathrm{p}}(x, y) + w_{\mathrm{eo}}(x, y)$. Here the length of the pump unit is denoted as L and the applied pressure increase as Δp. This pressure increase is considered as the initially given one in solving Eq. (6), but in the actual application of the pump, it plays a role as a source of power like a voltage difference built across an electric battery. We then have

$$w_{\mathrm{p}} = \frac{-a^2}{\mu} \frac{\Delta p}{L} W_{\mathrm{p}}(x, y) \tag{7a}$$

$$w_{\mathrm{eo}} = \frac{-\varepsilon\varepsilon_0 \varsigma E}{\mu} \left(1 - \frac{\phi}{\varsigma}\right) \tag{7b}$$

where $W_{\mathrm{p}}(x, y)$ satisfies the Poisson equation,

$$\nabla^2 W_{\mathrm{p}} = \frac{-1}{a^2} \ . \tag{8}$$

a denotes a suitable length scale, such as radius of a capillary for the circular section (Fig. 1b) and the channel depth for the rectangular section (Fig. 1c) and ς is the zeta potential. Note that the Helmholtz–Smoluchowski formula for the electroosmotic velocity is recovered from Eq. (7b) for the thin EDL limit.

We obtain the flow rate from integration of the axial velocity over the whole cross-sectional area A as follows:

$$Q = -\frac{f_1 A a^2}{8\mu} \frac{\Delta p}{L} - \frac{g_1 A \varepsilon\varepsilon_0 \varsigma E}{\mu} \tag{9}$$

where dimensionless constants f_1 and g_1 are defined as

$$f_1 = \frac{8}{A} \int_A W_{\mathrm{p}}(x, y)\, \mathrm{d}A \tag{10a}$$

$$g_1 = \frac{1}{A} \int_A \left(1 - \frac{\phi}{\varsigma}\right) \mathrm{d}A \tag{10b}$$

The constant f_1 becomes unity for the circular capillary of Fig. 1b, and the constant g_1 approaches unity for any geometry if the EDL thickness λ tends to zero. Maximum flow rate is defined as the one attained when the pressure gradient vanishes or

$$Q_{\max} = \frac{-g_1 A \varepsilon\varepsilon_0 \varsigma E}{\mu} \ . \tag{11}$$

We can see that the maximum flow rate increases with the area of the cross-section as well as the electric field. The maximum pressure difference built between both ends of the pump unit is provided for the case when the flow rate becomes zero, or

$$\Delta p_{\max} = \frac{-8 g_1 \varepsilon\varepsilon_0 \varsigma V}{f_1 a^2} \tag{12}$$

where V is the external potential difference applied across the channel length; $V = EL$. It is seen that the maximum pressure difference increases as the external potential difference increases and also as the capillary size decreases. In terms of $Q_{\max}$ and $\Delta p_{\max}$, the formula for the flow rate can be expressed as follows:

$$Q = Q_{\max} \left[1 - \frac{\Delta p}{\Delta p_{\max}}\right] . \tag{13}$$

The thermal efficiency of the pump is determined from the following equation:

$$\eta = \frac{Q\Delta p}{IV} \tag{14}$$

where I indicates the total current through the electrolyte. The current flux is given as

$$j = \sigma E + \rho_e w \ . \tag{15}$$

Here σ is the conductivity. The first term corresponds to the electromigration (or conduction) effect and the second to the ion advection. We neglect the diffusion effect. The conductivity is related to the mobility β by

$$\sigma = \beta ze(n_+ + n_-) \tag{16a}$$

$$\beta = \frac{Dez}{k_b T} \tag{16b}$$

where D is the ion diffusivity [2]. Then the total current I is obtained by integrating j over the whole cross-section. The result is

$$I = g_2 A\sigma_\infty E + \frac{g_3 a^2 \varepsilon\varepsilon_0 \varsigma}{\mu L}\Delta p + \frac{g_4 a(\varepsilon\varepsilon_0)^2\varsigma^2}{\mu\lambda}E \tag{17}$$

where

$$\sigma_\infty = 2\beta zen_\infty \tag{18a}$$

$$g_2 = \frac{1}{A}\int_A \cosh\phi^* \, \mathrm{d}A \tag{18b}$$

$$g_3 = \frac{1}{\lambda^2\varsigma^*}\int_A W_p \sinh\phi^* \, \mathrm{d}A \tag{18c}$$

$$g_4 = \frac{1}{a\lambda\varsigma^*}\int_A \left(1 - \frac{\phi^*}{\varsigma^*}\right)\sinh\phi^* \, \mathrm{d}A \tag{18d}$$

$$\varsigma^* = \frac{ze\varsigma}{k_b T} \tag{18e}$$

The dimensionless potential ϕ^* has been scaled by the reference potential $k_b T/ze$ like Eq. (18e). Note that the factor $1/\lambda^2\varsigma^*$ in Eq. (18c) and $1/a\lambda\varsigma^*$ in Eq. (18d) are different from $a^2/A\lambda^2\varsigma^*$ used by Min et al. [2]. This factor is chosen in such way that, even for the limit of a thin EDL, the coefficients g_2 and g_3 take an $O(1)$ value. Then the efficiency Eq. (14) becomes

$$\eta = \frac{Q_{\max}\left(1 - \frac{\Delta p}{\Delta p_{\max}}\right)\Delta p}{E\left[g_2 A\sigma_\infty V + \left(\frac{g_3 a^2\varepsilon\varepsilon_0\varsigma}{\mu}\right)\Delta p + \frac{g_4 a(\varepsilon\varepsilon_0)^2\varsigma^2 V}{\mu\lambda}\right]} \tag{19}$$

We can see from this that when the effect of Δp in the denominator is negligible compared with other two terms, the maximum efficiency occurs at $\Delta p = \Delta p_{\max}/2$. Min et al. [2] provided further analysis for the case when Δp in the numerator is considered for a circular capillary. It was shown that the efficiency is increased with decreasing a, but it reaches maximum at around $\lambda = (0.3 \sim 0.4)a$ under the practical range of the zeta potential. For deionized water (10^{-6} M ion concentration), this corresponds to $a = (0.7 \sim 1)\,\mu$m, whereas for 10^{-4} M concentration $a = (0.07 \sim 0.1)\,\mu$m. The efficiency generally depends on ς; for the practical range of ς, it can reach as much as 15%.

For a circular cross-section, Eq. (4) can be written as

$$\frac{\partial}{r\partial r}\left(r\frac{\partial\phi}{\partial r}\right) = \frac{\phi}{\lambda^2} \tag{20}$$

under the assumption of axisymmetric profile for ϕ, where r denotes the radial coordinate (Fig. 1b). Then the solution becomes

$$\phi = \frac{\varsigma I_0(r/\lambda)}{I_0(a/\lambda)} \tag{21}$$

$$\rho_e = -\frac{\varepsilon\varepsilon_0\varsigma I_0(r/\lambda)}{\lambda^2 I_0(a/\lambda)} \tag{22}$$

where I_0 denotes the first kind of the modified Bessel function of zero-order and a the radius of the circle. The normalized axial velocity $W_p(r)$ is determined from Eq. (8) as follows:

$$W_p = \frac{1}{4}\left[1 - \left(\frac{r}{a}\right)^2\right] \ . \tag{23}$$

Further, the constants f_1 and g_1 are evaluated to be

$$f_1 = 1\,, \quad g_1 = 1 - \frac{2\lambda I_1\left(\frac{a}{\lambda}\right)}{aI_0\left(\frac{a}{\lambda}\right)} \ . \tag{24}$$

We assure that g_1 approaches unity in the thin EDL limit as addressed above. No closed-form solutions have been reported as for the constants g_2, g_3 and g_4. Most results reported so far have been given from the numerical integration of Eqs. (18b)–(18d).

For a rectangular cross-section, as shown in Fig. 1c, the solution to Eq. (4) and the subsequently given velocity component were provided in a double-series form by, for example, Li [1], and later in a single series form by Wang et al. [3]. The Helmholtz–Smoluchowski formula for the electroosmosis-driven flow velocity can be given of course

for the thin EDL limit. The series solution for the pressure-driven flow velocity is presented, for example, by Min et al. [2] as follows:

$$W_p = \frac{16}{\pi^3}\sum_{n=1}^{\infty}\frac{(-1)^{n-1}}{(2n-1)^3}\left\{1-\frac{\cosh\left[(2n-1)\frac{\pi x}{a}\right]}{\cosh\left[(2n-1)\frac{\pi b}{2a}\right]}\right\} \times \cos(2n-1)\frac{\pi y}{a} \quad (25)$$

As we can see from this formula, fortunately the series shows a very fast convergence property, and therefore only the leading-order term has been considered by several researchers.

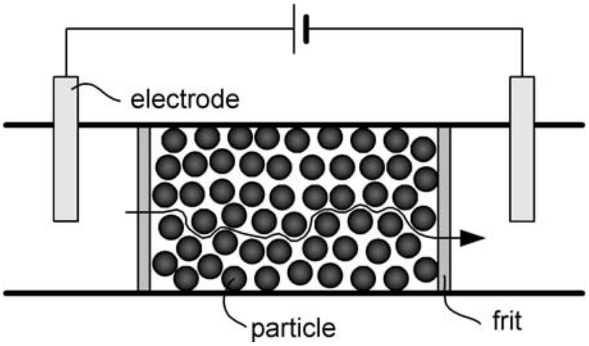
Packed Column Electroosmotic Pump

In many microfluidic applications, e. g. microseparation techniques with chromatographic columns, the required pumping pressure is enormous. A packed-column electroosmotic pump is one of the most favorable alternatives replacing the membrane-displacement pump because it does not require moving parts such as valves and flow control is very easy.

It was shown from Eq. (12) that the maximum pressure difference Δp_{max} can be increased by decreasing the channel size a. However the maximum flow rate decreases when the channel size decreases as seen from Eq. (11). Therefore it is natural to consider using a parallel assembly of narrow capillaries or channels to achieve the high pressure difference as well as the high flow rate. The packed-column electroosmotic pump developed due to this reason is composed of a column packed with solid particles as shown in Fig. 2. The electrolyte completely fills the porous space. So, when the external electric potential difference is applied between both ends of the column (Fig. 2) the counter-ions accumulated in the EDL developed near the surface of particles drive the bulk fluid.

In this case the porous media can be modeled by an array of N capillaries with the inner radius a and an effective length L_e that differs from L_c, the actual length of the column. The effective length L_e can be understood as the averaged path length of the fluid particles traveling from the entrance to the exit of the column as shown in Fig. 2. Then it is required that the volume $A_e L_e$ should be the same as the total volume of the porous space, where $A_e = N\pi a^2$ is the total cross-sectional area of the collection of the capillaries. Then the porosity ψ, defined as the ratio of the volume of the porous space to the total volume of the column, can be given as

$$\psi = \frac{A_e L_e}{A_c L_c} \quad (26)$$



Electroosmotic Pump, Figure 2 Sectional view of a packed-column electroosmotic pump unit. The frit is also composed of a porous medium

where A_c stands for the cross-sectional area of the empty column. The tortuosity τ is defined as

$$\tau = \left(\frac{L_e}{L_c}\right)^2 . \quad (27)$$

Then we can write

$$A_e = \frac{\psi A_c}{\sqrt{\tau}} . \quad (28)$$

Therefore we can derive the formula for the flow rate from Eq. (9) as follows:

$$Q = -\frac{\psi A_c a^2}{8\tau\mu L_c}\Delta p - \frac{\psi g_1 A_c \varepsilon\varepsilon_0\varsigma}{\tau\mu L_c}V \quad (29)$$

where $f_1 = 1$ is applied as shown in Eq. (24). From Eq. (29) we can derive the following:

$$Q_{max} = -\frac{\psi g_1 A_c \varepsilon\varepsilon_0\varsigma V}{\tau\mu L_c} \quad (30a)$$

$$\Delta p_{max} = \frac{-8 g_1 \varepsilon\varepsilon_0\varsigma V}{a^2} . \quad (30b)$$

From the second equation, we can see that the maximum pressure difference is independent of the specific structure of the porous medium, i. e. ψ or τ.

The formula for the efficiency takes the same form as Eq. (19), in which A should be taken as the area of the individual capillary, i. e. $A = \pi a^2$. This implies that the efficiency is independent of the number of capillaries used in modeling the packed column.

The porosity ψ is usually measured from the dry and wet weight of the packed column, the calculation formula being

$$\psi = \frac{\mathrm{wt_{wet}} - \mathrm{wt_{dry}}}{\gamma A_c L_c} \quad (31)$$

where γ denotes the specific weight of the liquid. In order to determine the tortuosity τ we need to measure the resistance of the empty column, $R_{em} = \omega L_c / A_c$, and that of the packed one, $R_{pack} = \omega L_e / A_e$, where ω is the resistivity of the liquid [4]. It can be shown that the ratio of these two quantities becomes

$$\frac{R_{em}}{R_{pack}} = \frac{\psi}{\tau} \ . \quad (32)$$

Since ψ is predetermined from Eq. (31), this can offer τ. Now coupling Eqs (30a) and (30b) we get the formula that gives a as follows:

$$a = \left[\frac{8\tau\mu L_c}{\psi A_c} \frac{Q_{max}}{\Delta p_{max}} \right] \ . \quad (33)$$

This equation implies that to obtain a we need to know the ratio $Q_{max}/\Delta p_{max}$ from a separate experiment.
To demonstrate the calculation procedure, we use the data given by Zeng et al. [4]:

$$L_c = 5.4\,\text{cm}\,,\ D_c = 530\,\mu\text{m (diameter of the column)}\,,$$

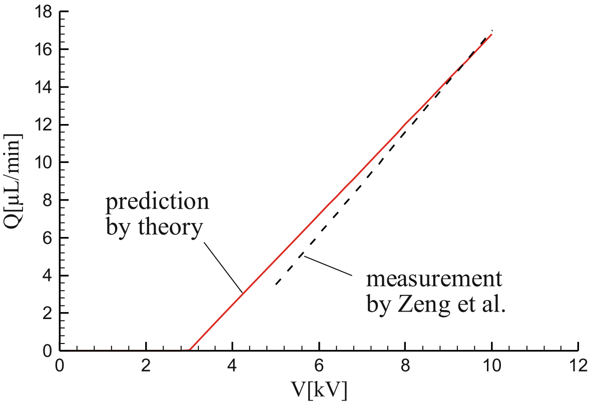
$$\mu = 10^{-3}\,\text{Pa s}\,,\ \varepsilon = 80\,,\ \ \varepsilon_0 = 8.854 \times 10^{-12}\,\frac{\text{C}^2}{\text{Nm}^2}\,,$$

$$n_\infty = 7.5\,\mu\text{M}\,,\ z = 1\,,\ V = 2\,\text{kV}\,.$$

From the measurement of the dry and wet weight of the packed column, the porosity is calculated to be $\psi = 0.37$. They further provided the measurement results of R_{em}/R_{pack}, Q_{max} and Δp_{max} as follows:

$$\frac{R_{em}}{R_{pack}} = 0.24\,,\ Q_{max} = 4.8\,\mu\text{l/min}\,,\ \Delta p_{max} = 23.5\,\text{atm}$$

from which we can get $\tau = 1.54$ by using Eq. (32). Then Eq. (33) gives $a = 523$ nm. The zeta potential ς can be determined from either Eq. (30a) or (30b). However we need to evaluate g_1 from Eq. (24) for this. First λ is calculated from Eq. (5) as $\lambda = 112$ nm, where $T = 298$ K was assumed. Then we can get $a/\lambda = 4.67$, and from Eq. (24) we obtain $g_1 = 0.621$. Now we use either Eq. (30a) or (30b) to predict the zeta potential, the result being $\varsigma = -94.1$ mV; Zeng et al. [4] predicted this as $\varsigma = -95$ mV.
The validity of the formula for the flow rate, i. e. Eq. (29), can be checked from the plot Q versus V (Fig. 8 in [4] given from the experiment at a constant pressure difference, $\Delta p = 35$ atm. We first compute the slope



Electroosmotic Pump, Figure 3 Comparison of the linear relationship between the external potential V and the flow rate Q from the experiment of Zeng et al. [4] and from the theory (Eq. (34))

$(\partial Q/\partial V)_{\Delta p} = 4.00 \times 10^{-14}\,\text{m}^3/\text{sV}$ from Eq. (29). Then the linear dependence of Q on V is expressed by

$$Q = Q_0 + \left(\frac{\partial Q}{\partial V}\right)_{\Delta p} V \quad (34)$$

where $Q_0 = -1.19 \times 10^{-10}\,\text{m}^3/\text{s}$ is calculated from the first term on the right-hand side of Eq. (29) at $\Delta p = 35$ atm. Figure 3 shows a comparison between the experimental result given by Zeng et al. [4] and the theoretical one of Eq. (34). It reveals a fairly good agreement between the two predictions.

Key Research Findings

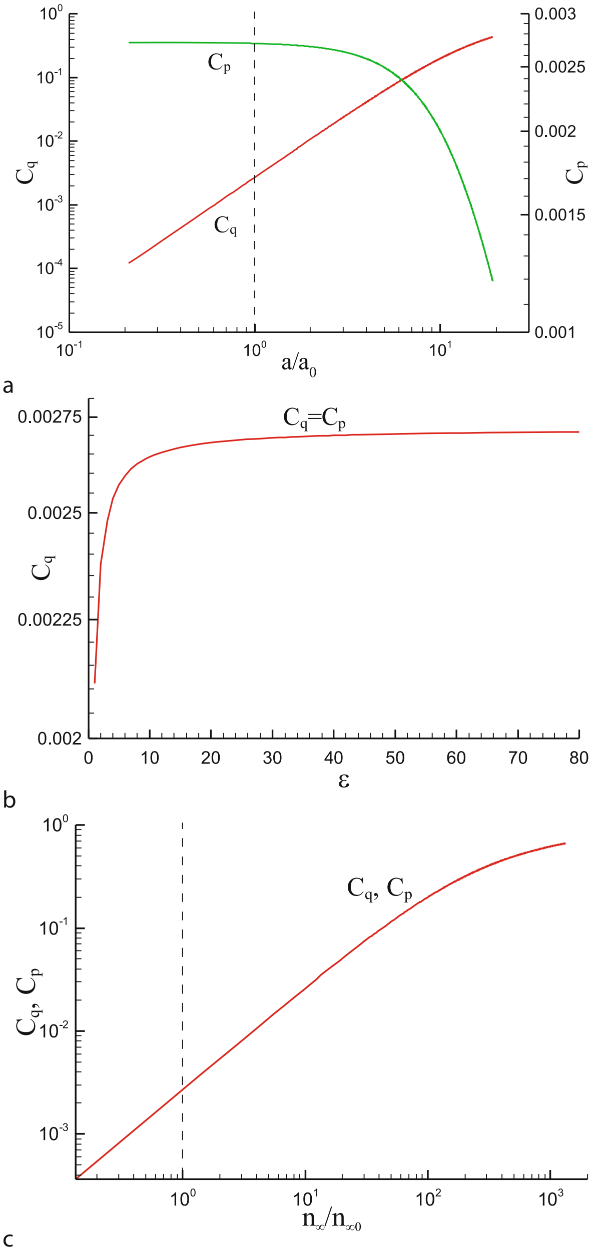
The effect of various parameters on Q_{max}, Δp_{max} and η will be important in the design of an electroosmotic pump. The effect of the parameters ζ, V, A_c, L_c, ψ, μ and τ on Q_{max} and Δp_{max} can be explicitly understood from the followings:

$$\frac{Q_{max}}{\frac{-\psi\varepsilon_w\varepsilon_0 A_c \varsigma V}{\tau\mu L_c}} = g_1\left(\frac{\varepsilon}{\varepsilon_w}\right) \equiv C_q \quad (35a)$$

$$\frac{\Delta p_{max}}{\frac{-8\varsigma V \varepsilon_w \varepsilon_0}{a_0^2}} = \frac{g_1\left(\frac{\varepsilon}{\varepsilon_w}\right)}{\left(\frac{a}{a_0}\right)^2} \equiv C_p = \frac{C_q}{\left(\frac{a}{a_0}\right)^2} \quad (35b)$$

where ε_w denotes the dielectric constant of the water and a_0 is a reference size of the capillary. Note that the right-hand side terms of the above formula are dimensionless. It is seen that Δp_{max} increases linearly with ζ and V, while Q_{max} increases linearly with ζ, V, A_c, ψ, $1/\mu$, $1/\tau$ and $1/L_c$.

The effect of the other parameters, a, ε and n_∞, should be implicitly understood from Eqs. (35a) and (35b) through λ of Eq. (5) and the constant g_1 of Eq. (24). The effect of the capillary size a is first investigated. It can be shown that $g_1 \sim a^2/8\lambda^2$ for small a/λ and $g_1 \to 1$ under the limit $a/\lambda \to \infty$. Therefore the coefficient C_p approaches a constant value for the limit $a/\lambda \to 0$ and tends to be proportional to $1/a^2$ for $a \to \infty$ (thin EDL limit). This implies that packing the column with smaller particles induces a higher pumping force, but use of particles that are too small leads to overlap of the EDL and thus results in a saturated value of $\Delta p_{\max}$ as shown in Fig. 4a, where $a_0 = 523\,\mathrm{nm}$ is chosen. On the other hand, the coefficient C_q shows the same behavior as g_1 as can be seen from Eq. (35a). Thus C_q approaches a constant value for $a \to \infty$ but it is proportional to a^2 for $a \to 0$ because of the EDL overlap effect. Shown in Fig. 4a is the effect of a on C_q. The asymptotic behavior of both coefficients for the high range of a/a_0 is not shown in this plot because such a range is not practically relevant. We can predict from this figure that selecting a particle size slightly larger than the present one, that corresponds to a_0, would result in a significantly higher flow rate but a slightly smaller maximum pressure difference.



Electroosmotic Pump, Figure 4 Effect of the dimensionless capillary radius a/a_0 (**a**), the dielectric constant of the liquid ε (**b**) and the dimensionless bulk concentration $n_\infty/n_{\infty 0}$ (**c**) on the coefficient C_q for the maximum flow rate and C_p for the maximum pressure difference

The effect of the parameter ε on C_q and C_p is shown in Fig. 4b. Since the capillary radius a is selected as $a = a_0$, both C_q and C_p show identical behavior. It is seen that the coefficients approach a constant value for $\varepsilon \to \infty$ and show a linear increase with ε for small ε, both of which can be proved from Eqs (35a) and (35b). The reason that change of ε in the practical range does not significantly affect the coefficients arises from the fact that the pore size a is taken very small. When a larger a is selected, the coefficient curves become flatter over the whole range of ε.

The effect of n_∞ is shown in Fig. 4c. It also shows the same behavior for both coefficients for the reason explained above. In a similar manner to the case for the effect of ε, the coefficients tend to a constant value for large n_∞ and increase linearly with n_∞ for small n_∞. It can be predicted from this plot that a much greater increase of the concentration would produce much higher capacity.

Understanding the effect of the various parameters on the efficiency is not so simple. Min et al. [2] converted Eq. (19) to a dimensionless form for both numerators and denominators as follows:

$$\eta = \frac{(1 - \Delta p^*)\,\Delta p^*}{\alpha_0 + \alpha_1 \Delta p^*} \tag{36}$$

where $\Delta p^* = \Delta p/\Delta p_{\max}$ and

$$\alpha_0 = \left(\frac{g_2}{8g_1^2}\right)\left(\frac{\mu D}{\varepsilon\varepsilon_0 \varsigma^2}\right)\left(\frac{a}{\lambda}\right)^2 + \left(\frac{g_4}{8\pi g_1^2}\right)\left(\frac{a}{\lambda}\right)$$

$$\alpha_1 = -\left(\frac{g_3}{\pi g_1}\right)$$

When the effect of the second term on the denominator is small, the maximum efficiency $\eta_{\max}$ occurs at $\Delta p^* = 1/2$

as addressed previously. Min et al. [2] have thoroughly investigated the effect of the three dimensionless parameters on η_{max} based on Eq. (36). They have demonstrated that η_{max} can be increased by decreasing the viscosity or by increasing the dielectric constant of the liquid. They have also proposed the possibility that efficiencies as high as 15% are possible with careful attention to the channel size and the solution composition.

Examples of Application

It has been shown that the thermal efficiency of the electroosmotic pump is very low. Most of the electric energy put into the electrolyte liquid is dissipated into heat, so called Joule heating. In many cases, the mismatch between the theory and the measurement for the pressure is attributed to the Joule heating [5].

The maximum efficiency achievable through a careful selection of packed materials and electrolyte has been reported by Min et al. [2] to be at most 15%. In contrast, Griffiths and Nilson [6] reported that the likely maximum efficiency for any electroosmotic pump would be about 10% for operation at the condition of maximum work.

Hu and Chao [7] performed two-dimensional numerical simulation on the performance of an electroosmotic pump for planar channels. The model is able to handle the case with the dimensions comparable to the EDL thickness. Also no Debye–Huckle approximation and symmetric conditions are required. But the results show considerable deviation from the experimentally measured ones.

Yao and Santiago [8] provided useful review on the historical background of the development of EO pumps. They considered different molar conductivities for cations (Λ_+) and anions (Λ_-) in calculating the electric current caused by electromigration. They predicted that Λ_+ is almost twice Λ_- for sodium ions.

Kang et al. [9] considered the wall effect surrounding the packed materials. Zeta potentials on the inner surface may not be the same as those of packed spheres, and the porosity is a function of the distance from the wall. The wall effect is more enhanced for larger packed particles.

Yao et al. [10] studied an electroosmotic pump made from porous silicon membranes having straight circular pores. Tortuosity is unity and ψ was measured directly from SEM images of the cross-section. Zeta potential is calculated by using the formula for the ratio Q_{max}/I_{max} and the measured data of Q_{max} and I_{max}. Comparison between theory and experiment is good for the plots Q_{max} versus V and I_{max} versus V. There was considerable deviation for the prediction of Δp_{max} and Yao et al. attributed this discrepancy to the problem in the zeta potential measurement and non-uniform distribution of the pore size. At a lower flow rate, the buffer electrolyte shows variation of PH leading to unstable results.

Definition

Electrophoresis is the motion of charged particles in a fluid under the influence of an electric field.

Chemical and Physical Principles

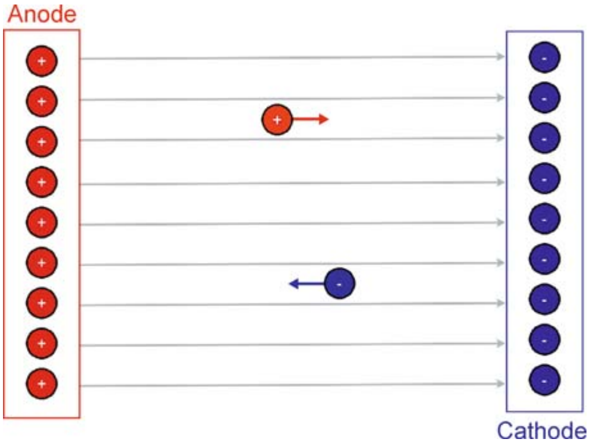
Electrophoresis provides an important method of actuation in microfluidics. Many of the different types of species that need to be transported on a microfluidic device are charged, and electrophoresis thus provides a convenient method for moving them to different locations on a chip. Amongst the most important examples are colloidal particles, such as latex spheres, and biomolecules, such as proteins and DNA. Under certain circumstances, electrophoresis can also be used to separate these particles by zeta potential or size, which is an important part of biological analyses.

Electrophoresis also requires that the fluid entraining these particles be able to conduct electricity. Often, salts are added, yielding an electrolytic solution. The salts disassociate into positively charged ions (▶ cations) and negatively charge ions (▶ anions). The cations are attracted towards the negative electrode (the ▶ cathode) and anions are attracted towards the positive electrode (the ▶ anode). When dealing with biomolecules, the salts are usually weak acids and weak bases. The resulting solution is a buffer, which keeps the solution within a narrow pH range. As the charge and conformation of the biomolecules depend on the solution pH, the buffer composition plays an important role in biological applications of electrophoresis.

Consider first the simple case an isolated, charged ion moving in a uniform electric field, as illustrated in Fig. 1. While this is an overly simplistic picture of electrophoretic motion in solution, it serves to illustrate the general principle. We will consider a more realistic model of electrophoresis in free solution in the following section.

The ion possesses a charge Q, with $Q > 0$ for a cation and $Q < 0$ for an anion. The charge of the ion is given by the number of unpaired electrons or protons, with the elementary electric charge $e = 1.60219 \times 10^{-19}$ C per proton or electron. In this example, the ions in solution are assumed to be so dilute that they do not interact electrostatically. The ion is placed in a uniform electric field of strength E. The field strength is often reported in V/cm, although the proper SI units are V/m. In applications, one would typically apply a potential V between the two electrodes separated by a distance L. In this case, the electric field between them is simply

$$E = \frac{V}{L} \,. \tag{1}$$



Electrophoresis, Figure 1 Electrophoresis of a cation and an anion in a uniform electric field. The anode and cathode are assumed to extend infinitely in the vertical direction to avoid end effects. The positively charged cations move towards the negatively charged cathode, whereas the negatively charged anions move towards the positively charged anode

The electrical force acting on the ion is the product of its charge and the electric field,

$$F_e = QE = \frac{QV}{L} \,. \tag{2}$$

For a nominal electric field of 10 V/cm acting on a monovalent ion (like Na^+), the electrical force would be 1.6×10^{-16} N – very small indeed! However, this force is sufficient to animate the ion because it is balanced by a very small drag force. If the ion is approximated as a spherical particle of radius a moving through a fluid of viscosity η, then the drag coefficient ξ is given by the Stokes drag

$$\xi = 6\pi\eta a \,, \tag{3}$$

and the drag force resisting the motion is

$$F_d = -\xi v \,. \tag{4}$$

By Newton's second law, the sum of the electrical force and the drag force equals zero. As a result, the ion has an electrophoretic velocity

$$v = \frac{QE}{\xi} \,. \tag{5}$$

Keeping the example of Na^+, the ionic radius is $a = 116$ pm. If the electrophoresis is performed in a fluid with a viscosity similar to that of water (which is typically the case), then $\eta = 1\,\text{cP} = 0.001\,\text{Pa s}$, and the resulting drag coefficient is $\xi = 2.18 \times 10^{-12}$ Ns/m. With an electric force of 1.6×10^{-16} N, the sodium ion would thus

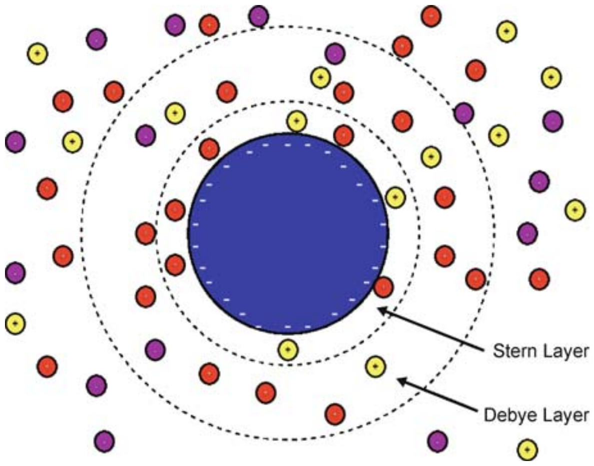
move at a speed of 73 μm/s. Albeit a very slow speed on macroscopic length scales, the ion moves over its own radius over 500,000 times per second.

In general, data are not reported as electrophoretic velocities, but rather as electrophoretic mobilities. The electrophoretic mobility is defined as

$$\mu \equiv \frac{v}{E}\,. \tag{6}$$

If the velocity is a linear response to the electric field, as is the case here, then the electrophoretic mobility is independent of the field. This scaling breaks down in the case of ▶polyelectrolytes [1].

Determining the electrophoretic mobility of polyelectrolytes, such as colloidal particles and flexible polyelectrolyte chains such as DNA, is considerably more complicated because their electrostatics and hydrodynamics differ from the simple charged, spherical ion considered above. Polyelectrolytes are intrinsically uncharged, but contain ionizable groups (for example –OH and –H groups) that will dissociate from the particle when it is placed in solution. As indicated in Fig. 2, these ionizable groups, known as ▶counterions, dissociate from the macroion. The dissociation is not limited by mass action,



Electrophoresis, Figure 2 Polyelectrolytes contain ionizable groups that dissociate from the particle when it is placed in solution. In the figure, the red cations were originally associated with the colloidal particle. The yellow cations and purple anions represent the dissociated salts contained in the buffer solution. Nearby the particle, the counterions are strongly bound by electrostatics and chemical affinity for the colloid, leading to the formation of the Stern layer. The Stern layer is surrounded by a more diffuse layer of charges, known as the Debye layer, where the local density of counterions is governed by a balance between attraction towards the oppositely charged colloid, the repulsion from other counterions, and diffusion

although flexible polyelectrolyte chains do not necessarily completely dissociate due to Manning condensation [2]. Note that the solution can also contain counterions and ▶co-ions of its own (with co-ions having the same charge as the particle), which will normally be the case during electrophoresis in buffers. The overall system is electrically neutral – the number of counterions (red) equals the number of charges on the particle surface, and the number of counterions already in the solution (yellow) equals the number of solution co-ions (purple).

When the counterions dissociate from the particle, diffusion attempts to randomize their locations. However, the counterions are attracted to the particle by electrostatic interactions, which act over long distances. Immediately proximate to the particle is a molecular-sized layer of counterions, called the Stern layer. The counterions in the Stern layer are immobile as a result of their chemical affinity for the particle surface, as well as the very strong electrical attraction at short distances from the charged particle. The Stern layer also includes polar water molecules that are oriented to the surface. A second, larger layer of charges, called the ▶Debye layer, surrounds the Stern layer. These charges are mobile and their location is affected by electrostatic attraction to the sphere, which wants to pull them towards the inner edge of the Debye layer, and diffusion, which tries to randomize their locations. To further complicate the issue, the counterions repel one another, since they have the same charge. Exactly computing the structure of the Debye layer is a challenging task, requiring the solution of the nonlinear Poisson–Boltzmann equation (see ▶Lattice Poisson-Boltzmann Method, Analysis of Electroosmotic Microfluidics), but the characteristic thickness can be obtained from scaling, yielding

$$\kappa^{-1} = \sqrt{\frac{\varepsilon_0 \varepsilon_{\mathrm{b}} k_{\mathrm{B}} T}{2e^2 I}}\,. \tag{7}$$

In the latter, ε_0 is the permittivity of vacuum (8.854×10^{-12} F/m) and ε_{b} is the permittivity of the bulk solution (or the dielectric medium), k_{B} is Boltzmann's constant (1.38×10^{-23} J/K), and T is the temperature in Kelvin. The parameter I is the ionic strength of the medium,

$$I = \frac{1}{2}\sum_i z_i^2 c_i\,, \tag{8}$$

where z_i is the valence of ion i and c_i is its concentration. The ▶Debye length is historically written as an inverse length (i. e. κ has units of m^{-1}). In typical biological buffers, the Debye length is between 1 – 10 nm.

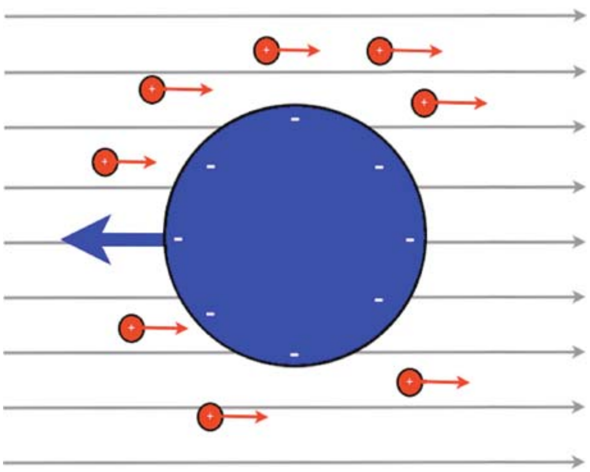
Key Research Findings

Free Solution Electrophoresis

The first key physical phenomenon to consider is the electrophoresis of colloidal particles and polyelectrolytes in free solution. The use of the term free solution here implies two assumptions: the particles are very far from any boundaries and the particles are sufficiently dilute so that they do not interact with one another. Free solution results are generally applicable for electrophoresis in an empty microchannel, provided that the particles are not too large relative to the smallest dimension of the channel. As a rule of thumb, the particle radius (or the radius of gyration, in the case of polyelectrolytes) should be at least one order of magnitude less than the smallest channel dimension. As systems move towards the nanoscale, the interactions with the walls (and other effects of confinement) will become increasingly important.

Consider first the electrophoresis of the colloidal particle of charge Q and radius a depicted in Fig. 3. As mentioned above, the particle dissociates into a single large, charged species (the macroion) and a number of small counterions. Since these species have different charges, they will move in opposite directions with respect to the electric field. Determining the electrophoretic mobility of a charged colloidal particle for an arbitrary Debye layer thickness is a daunting task. However, two simple limits can be computed relatively easily. The following two derivations follow very closely from Ref. [3].

In the case where the Debye layer is very large relative to the particle size, i. e. when $\kappa a \to 0$, then the counterions are distributed uniformly throughout space. As a result,



Electrophoresis, Figure 3 Schematic of the electrophoresis of a rigid colloidal particle. The electric field acts on both the counterions and the macroion, resulting in relative motion in opposite directions

their motion does not affect the motion of the colloidal particle and the electrophoretic mobility is given by Eqs. (5) and (6). We can further simplify this by noting that, for a spherical particle of total charge Q, Gauss's law requires that the particle's charge create an electric field

$$E = \frac{Q}{4\pi\varepsilon\varepsilon_0 r^2} \tag{9}$$

that decays like $1/r^2$ as we move away from a Gauss surface centered on and enclosing the particle. The potential ψ is related to the electric field by

$$E = -\nabla\psi\,. \tag{10}$$

In spherical coordinates, the potential at the surface of the particle is thus given by

$$\psi_\mathrm{s} = \int_a^\infty E\,\mathrm{d}r\,, \tag{11}$$

where we have set the potential at infinity to be zero. Integrating, we find the potential to be

$$\psi_\mathrm{s} = \frac{Q}{4\pi\varepsilon\varepsilon_0 a}\,. \tag{12}$$

If we assume that the drag on the sphere is given by Stokes Law,

$$\xi = 6\pi\eta a\,, \tag{13}$$

then substituting Eqs. (12)–(13) into Eq. (6) furnishes the mobility

$$\mu = \frac{2\varepsilon\varepsilon_0\psi_\mathrm{s}}{3\eta}\,. \tag{14}$$

While Eq. (14) is aesthetically pleasing, it is not particularly useful in practice for two reasons. First, although we can define a surface potential ψ_s for our calculation, in general it is not possible to measure the surface potential directly. Second, the presence of adsorbed counterions and oriented water in the Stern layer leads to an immobile layer immediately proximate to the sphere. To circumvent these problems, we define a zeta-potential, ζ. The zeta potential is a phenomenological parameter, which is often associated with the electrical potential at the edge of the Debye layer closest to the particle surface. Alternatively, the zeta-potential can be defined as the potential at the so-called "shear plane," i. e. the point at which the fluid begins to move at a different velocity than the sphere. In

principle, the zeta potential could be measured by electrophoresis through Eqs. (17) or (22), although it is normally determined by static methods (see ▶ zeta potential measurements).

As the Stern layer is quite thin, we can take the zeta-potential to be

$$\zeta = \psi(\delta + a)\,, \tag{15}$$

i. e. the potential ψ at some distance $a + \delta$ from the sphere center, where $\delta \ll a$. Returning to Eq. (11), we now have

$$\zeta = \int_{a+\delta}^{\infty} E\,\mathrm{d}r\,, \tag{16}$$

where the electric field E is still given by Eq. (9). Noting the thinness of the Stern layer relative to the particle size, the zeta potential is given approximately by Eq. (12), where upon the mobility in the infinite Debye layer limit is

$$\mu = \frac{2\varepsilon\varepsilon_0\zeta}{3\eta}\,. \tag{17}$$

The other simple result occurs in the opposite limit, $\kappa a \to \infty$, where the thickness of the Debye layer is very small relative to the size of the particle. This is particularly relevant for microfluidic applications in ionic buffers, which is the usual situation for bioanalyses. As the typical Debye layer thickness is several nanometers, the electrophoresis of any micron-sized particle will be governed by this limit.

Outside of the Debye layer, the fluid is electrically neutral. Inside the Debye layer, the fluid obeys the Navier-Stokes equation with an electrical body force

$$\eta\frac{\mathrm{d}^2 u}{\mathrm{d}z^2} + \rho^{(e)}E = 0\,, \tag{18}$$

where $\rho^{(e)}$ is the space charge inside the Debye layer. The latter is related to the electrical potential via Poisson's equation,

$$\varepsilon\varepsilon_0\frac{\mathrm{d}^2\psi}{\mathrm{d}z^2} = -\rho^{(e)}\,. \tag{19}$$

Working in a reference frame that moves with the particle, we require that the fluid velocity at the edge of the Stern layer (where $\psi = \zeta$) vanish due to the no-slip condition. As a result, Eq. (18) and the no-slip condition are satisfied by the fluid velocity

$$u(z) = -\frac{\varepsilon\varepsilon_0}{\eta}[\zeta - \psi(z)]E\,. \tag{20}$$

At the edge of the Debye layer, the potential drops to zero. As a result the bulk fluid is moving at a velocity

$$u = -\frac{\varepsilon\varepsilon_0\zeta}{\eta}E\,, \tag{21}$$

since the body force appearing in Eq. (18) is zero outside of the Debye layer. If we switch our frame of reference and consider a particle moving in an otherwise quiescent fluid, then the particle moves in the opposite direction to the fluid with a mobility

$$\mu = \frac{\varepsilon_0\varepsilon_\mathrm{b}\zeta}{\eta}\,. \tag{22}$$

Equation (22) reveals an important feature of electrophoresis in the small Debye layer limit: the electrophoretic mobility is independent of the size of the particle. As a result, particles of any size will move at the same speed in free solution. This is a desirable feature when the goal is to move the particles to different locations on a chip. On the other hand, Eq. (22) implies that the common task of sorting colloidal particles by size cannot be accomplished by free-solution electrophoresis.

Now consider the case of flexible polyelectrolytes such as DNA. There are two dominant hydrodynamic models for polymer motion, the Rouse model and the Zimm model [4]. In the Rouse model, the different parts of the chain are assumed to be hydrodynamically independent, so that the total friction of the chain is simply the sum of the friction of each segment. The Rouse model is also referred to as freely draining, since the polymer chain appears to be hollow to the fluid. The Zimm model includes both the Rouse friction of the individual segments with the fluid and the hydrodynamic interactions between different segments. The Zimm model is not freely draining; the polymer appears as a solid object to the surrounding fluid.

During electrophoresis in free solution, polyelectrolytes are freely draining and exhibit Rouse-like behavior. The reason for the absence of hydrodynamic interactions during electrophoresis is the exponential decay of electrostatic effects; the very thin Debye layer surrounding the polyelectrolyte screens the hydrodynamic interactions and allows each segment to act individually [2]. Thus, if the chain consists of N segments with charge q per segment, the total electrical force acting on the chain is

$$F_\mathrm{e} = qNE\,. \tag{23}$$

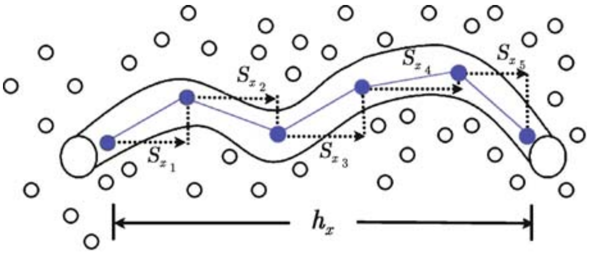
Likewise, if the friction on each segment is given by ξ, then the total frictional force on the chain will be given by

$$F_\mathrm{f} = -N\xi v\,. \tag{24}$$

Noting that these two forces balance one another, and making use of the definition in Eq. (6), the electrophoretic mobility of long polyelectrolytes is thereby independent of molecular weight,

$$\mu = \frac{v}{E} = \frac{qN}{N\xi} \sim N^0 \,. \tag{25}$$

The free solution electrophoresis of long polyelectrolytes is thus qualitatively the same as colloidal particles; all chains will move at the same speed, independent of molecular weight. Note that the latter scaling for the mobility does not hold for the diffusion coefficient. Polyelectrolyte chains still diffuse with a molecular weight-dependent Zimm diffusivity [4].



Electrophoresis, Figure 4 When a long polyelectrolyte like DNA is electrophoresed through a gel, the fibers of the gel confine the DNA to a reptation tube. The force acting on each segment of the tube depends on the orientation vector s_x of that segment in the electric field. The total projection of the chain, h_x, is the sum of the orientation vectors (Eq. (16)). The net velocity of the chain is computed from the average motion of the chain through many tubes, each of which has a different projection h_x

Gel Electrophoresis: Separating Polyelectrolytes by Size

The above discussion makes clear that colloidal particles and polyelectrolytes cannot be separated by size during free solution electrophoresis. As a result, many electrophoretic size separations for chemistry and biology are performed in gels. The precision afforded by microfabrication has led to miniaturized version of these classic protocols, as well as a number of novel separation techniques that differ distinctly from the separation principles prevailing in gels [5]. In order to best understand the current research in microfluidic separations of colloids and polyelectrolytes, in particular the important applications to protein and DNA separations, it is important to first understand the physics of gel electrophoresis.

For small particles, such as colloids and collapsed proteins, the dominant separation mechanism is Ogston sieving [1]. The underlying hypothesis behind the Ogston model is that the electrophoretic mobility is equal to the free volume available to that particle. In principle, this free volume argument should account for both the reduction in entropy due to excluded volume effects as well as the fact that large particles will run into "dead ends" in the gel. Although the Ogston hypothesis does not explicitly account for these effects, it nonetheless provides a useful model for the electrophoresis of globular particles in gels. The result of the model is that the mobility of a particle of size a in a gel of concentration c is given by

$$\frac{\mu(a, c)}{\mu(a, 0)} = \exp[-K(a)c] \,, \tag{26}$$

where $K(a) \sim a + R_{\text{fiber}}$ is the retardation factor, with R_{fiber} the size of the gel fibers.

The precision of micro- and nanofabrication should allow this model to be tested in well-controlled systems. Indeed, theoretical work by Slater and coworkers has questioned the validity of the Ogston model through a number of studies of electrophoresis in regular arrays of obstacles (see [6] and subsequent papers in this series).

Although their free-solution behaviors are similar, flexible molecules (like DNA and denatured proteins) exhibit dramatically different behavior in a sieving matrix. Once the size of the pores in the gel becomes small relative to the radius of gyration of the polyelectrolyte chain, the polyelectrolyte chain must uncoil in order to move through the gel. Although the uncoiling process is entropically unfavorable (since it reduces the number of available conformations for the chain), the entropy loss is offset by the reduction in the electrical potential energy as the chain moves in the field.

The mobility of flexible chains in gels is well described by the biased reptation model [1], which is indicated schematically in Fig. 4. In the model, the fibers of the gel are coarse-grained into a ►reptation tube that confines the chain. The chain thus slithers along the tube contour (the reptation part) under the influence of the electric field, which provides a tendency for the slithering motion to be in the direction of the electric field (the biased part).

The electrophoretic mobility can be computed from the picture presented in Fig. 4. The electric field exerts a force $\hat{q}Es_x$ on each segment of the chain, which depends on the orientation s_x of the segment in the direction of the electric field and its charge per unit length, $\hat{q}$. The total electric force acting on the chain is the sum of the force acting on each segment,

$$F_e = \sum (\hat{q}E)s_x \,. \tag{27}$$

As indicated in Fig. 4, the total projection of the chain is given by

$$h_x = \sum s_x \,, \tag{28}$$

whereupon the total electric force is given by summing the forces over the whole chain,

$$F_{\mathrm{e}} = QE\frac{h_{\mathrm{x}}}{L} \,. \tag{29}$$

In the latter, Q is the total charge of the chain and L is its contour length. The curvilinear friction counters the electrical force,

$$F_{\mathrm{f}} = -\xi_{\mathrm{c}} v_{\mathrm{c}} \,, \tag{30}$$

where ξ_{c} is the friction coefficient for motion along the contour at a velocity v_{c}. Balancing the friction against the electrical force, the velocity along the tube contour is thus

$$v_{\mathrm{c}} = \frac{F}{\xi_{\mathrm{c}}} = \frac{QEh_{\mathrm{x}}}{\xi_{\mathrm{c}} L} = \frac{\mu_0 E h_{\mathrm{x}}}{L} \,, \tag{31}$$

where the free solution mobility μ_0 is defined to be $\mu_0 = Q/\xi_{\mathrm{c}}$, analogous to Eq. (6). The time required to move through the tube is

$$t = \frac{L}{v_{\mathrm{c}}} \,, \tag{32}$$

during which time the chain has moved a distance h_{x} in the direction of the field. As a result, the velocity in the x-direction through a tube with an extension h_{x} is

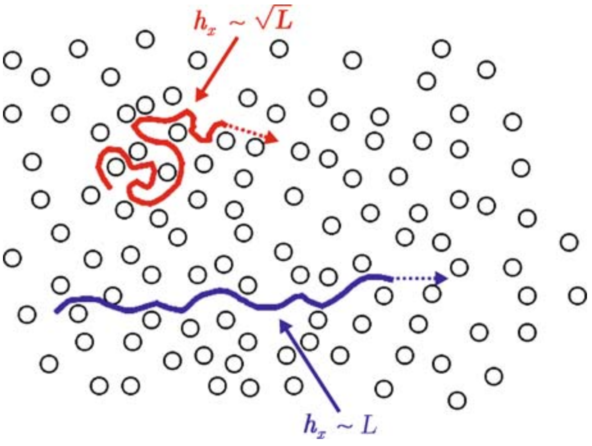
$$v_{\mathrm{x}} = \mu_0 E \left(\frac{h_{\mathrm{x}}}{L}\right)^2 \,. \tag{33}$$

After the motion through many such tubes, the electrophoretic mobility is given by the average of the velocity in each tube divided by the field,

$$\frac{\mu}{\mu_0} = \frac{\langle h_x^2 \rangle}{L^2} \,, \tag{34}$$

where $\langle \cdots \rangle$ represents the average over many tubes. Albeit overly simplistic [1], the analysis leading to Eq. (34) qualitatively captures much of the key phenomena observed experimentally. As indicated in Fig. 5, when the field acting on the chain is weak, then the chain is not strongly deformed and retains its Gaussian conformation (with a size proportional to $L^{1/2}$). The average conformation is thus a random walk. The reptation tubes have the average extension

$$\langle h_{\mathrm{x}}^2 \rangle \sim L \,, \tag{35}$$



Electrophoresis, Figure 5 Illustration of biased reptation with and without orientation. For weak fields and small chains (as indicated in the upper red figure), the electric field does not strongly perturb the conformation of the chain and it remains in a Gaussian coil. The projection of the coil in the direction of the field thus scales like $L^{1/2}$ for a chain of length L. For long DNA or strong fields (as indicated in the lower blue figure), the chain tends to be come oriented in the direction of the electric field. The projection of the chain then scales like its total length L

and the mobility depends on molecular weight. If the field is strong, then the chain is strongly extended and the tubes are almost fully extended and

$$\langle h_{\mathrm{x}}^2 \rangle \sim L^2 \,. \tag{36}$$

As a result, the separation is lost and all chains will move at the same speed. These scaling results agree well with experiments, and the so-called compression band, where all of the long chains co-migrate, is a major limitation of gel electrophoresis. As a result, a great deal of effort in microfluidics and nanofluidics research has focused on designing systems which permit the separation of long DNA and other polyelectrolyte chains by methods other than biased reptation.

The Joule Heating Problem and Applying Microscale Electric Fields

In addition to the difficulties in electrophoretically separating particles by size, a second challenge in electrophoresis is Joule heating. The heat generated by a conducting solution is given by Joule's law,

$$W_{\mathrm{Joule}} = \sigma E^2 \tag{37}$$

where σ is the conductivity of the fluid. Heating can be catastrophic for electrophoretic processes; non-uniform changes of temperature lead to viscosity gradients, which

in turn result in strong convective currents that can overwhelm the electrophoretic motion. In practice, Joule heating leads to a smearing of the separation bands (or a single plug of solute) and limits the maximum electric field that can be applied.

Microfluidics and nanofluidics offer an excellent solution to the Joule heating problem. The Joule heat must be removed from the system by thermal diffusion. The diffusive heat flux for a temperature drop ΔT across a channel of size w is given by

$$W_{\text{diff}} \sim k\frac{\Delta T}{w^2}\,, \tag{38}$$

where k is the thermal conductivity of the solution. If these two heat fluxes [Eqs. (37) and (38)] are balanced, then the maximum permissible electric field scales like the inverse of the channel width. As a result, much higher electric fields (and thus faster electrophoretic velocities) are possible as the channel sizes are reduced. As microfluidic and nanofluidic systems also require transporting the solute over small distances, the total gain in process speed can be significant.

Joule heating is not the only problem associated with applying strong electric fields. In typical microsystem applications, the electric field is applied via platinum electrodes inserted into the various reservoirs on the chip. The application of the field leads to electrolysis of the water (i. e., the dissociation of water into oxygen and hydrogen) and bubble formation. When large reservoirs are used, the bubbles are generally not troublesome because they will rise to the top of the reservoir and exit the system. Indeed, electrolysis and Joule heating have long been recognized as problems in conventional gel electrophoresis, but the large size of the system and buffer recirculation can relieve the problem to some extent. These are not options for microsystems. When small reservoirs are used or the electrodes are located inside a channel system, the resultant bubble formation can be catastrophic. The bubbles are very difficult to remove from the system, clogging the channels and causing sharp changes in the channel current.

Examples of Application

Electrophoretic separation of small charged species was one of the earliest applications of Lab-on-a-Chip and microfluidics. Indeed, the paper [7] that introduced the term µTAS (micro-total analysis system) dealt primarily with the electric field limits imposed by Joule heating. Microfluidic electrophoresis leads to tremendous gains in the separation time and strongly reduces the amount of sample consumed on chip.

Microfluidics and nanofluidics have also lead to a number of new separation techniques for long DNA that circumvent the limits of gel separations [5]. One of the simplest approaches is to make an artificial gel by microfabricating an array of posts [8]. In this strategy, the post diameters are commensurate with the radius of gyration of the long DNA ($\sim 1\ \mu$m), whereas the posts are spaced by several microns. As a result, the DNA no longer needs to unwind and reptate through the artificial gel. Rather, the motion is governed by a cyclic process of collisions with the posts, unraveling and unhooking of the chain in a rope-over-pulley process, and then motion towards the next post. These dynamics are referred to as geometration, because they resemble the motion of an inchworm, and the motion can be analyzed by continuous time random walk theory [9]. Post arrays are but one example of the different electrophoretic separation techniques that have been proposed [5].

Definition

The motion of electrically charged particles or molecules in a stationary medium under the influence of an electric field is called electrophoresis. In such transport the electric force is applied through a potential difference between electrodes. Selective use of the Lorentz force by applying a magnetic field can also induce such movement. Electrophoresis and electroosmosis are two key modalities of electrokinetic transport which are very useful in micro- and nanofluidics for a variety of applications including biomedical (bio-NEMS, etc.), fuel cell and micro total analysis systems (μ-TASs). In electroosmosis the bulk fluid moves due to the existence of a charged double layer at the solid–liquid interface. While one-dimensional electrophoresis is more commonly used, two-dimensional electrophoresis may also become a useful tool for the separation of gel proteins based on isoelectric property.

Overview

Let us consider an aqueous solution of a salt. A fraction of the salt dissociates into ions. Negatively charged ions are called anions, while positive ions are called cations. Such an ionic solution is called an electrolyte. If two electrodes are kept at a potential gap in such an electrolyte, the dissociated ions migrate towards oppositely charged electrodes at their characteristic speeds. Anions move towards the positive electrode, while cations are attracted by the negative electrode. The velocity and the number density of ions directly influence the electric current which increases with the strength of the electric field. Similar transport can also occur in a protein mixture that contains several charged species based on its degree of acidity. Chemical and electrical interactions may also occur during such transport. The electrons move across the electrochemical interface between the electrode and the electrolyte. The study of such migration of charged particles with or without the

movement of carrier fluid under an applied electromotive force is of great interest to biological systems, fuel cells and microelectronics [1, 2].

The history of electrokinetic transport is over 200 years old [1]. In 1771 Italian physician and physicist Luigi Galvani reported twitching of frog legs due to an electric arc. Twenty years later Allessandro Volta introduced a relationship between the potential difference and the electric force, and explained the twitching of frog legs using the concept of electrolytes. In 1884 Swedish chemist Svante Arrhenius wrote a thesis on galvanic conductivity of electrolytes which concluded that in water electrolytes dissociate into electrically positive (cation) and negative (anion) ions. His theory was inadequate for strong electrolytes. About 40 years later the Debye–Hückel theory was formulated for dilute ionic solutions. From then on, theoretical studies focused more on concentrated solutions involving large numbers of ions. Such problems include ion transport in the Stern layer, where finding a description for angstrom-scale models and related transport properties remains a challenge. Proper understanding of electrokinetic processes at this scale requires numerical modeling. Hjert'en [3] introduced electrophoresis through small capillaries. This was developed later over the next three decades by various groups.

The electrokinetic process in a small capillary is strongly influenced by the charge–surface interaction. For example, a selective surface ('gate') biasing in electrophoresis can influence directed charge transport resulting in specific charge depletion. Recently, Daiguji et al. [4] considered such electrophoretic transport in a nanochannel as a possible control device similar to a metal-oxide-semiconductor field effect transistor (MOSFET). Formation of the electric double layer is an important characteristic of a type of electrokinetic process, namely electroosmosis [5]. When negatively charged walls of a nanochannel come in contact with an electrolyte, the positive ions of the solution are attracted towards the surface as negative ions are repelled. Such redistribution creates a selective gradient of ions forming double layers called Stern or diffuse layers.

The ratio of electroosmotic to electrophoretic current increases as the surface charge density increases. Experimental study of Qiao and Aluru demonstrated that the amount of current flowing through a single-wall carbon nanoube channel can be modulated by five orders of magnitude by changing the voltage applied to a gate [6]. Our objective is to identify the effect of gate potential in selective electrokinetic transport of ions and to realize its potential for filtration of biological fluids. Similar but more extensive work for diffusion-limited patterning has been done recently by Karnik et al. [7].

Basic Methodology

The study of fluid behavior in nano-confinement is a relatively new research arena. The ratio of surface area to volume becomes extremely large at such small scales in which the non-dimensional Reynolds number Re is also typically low (< 1) and the flow remains laminar. Diaguji et al. [4] mention that, except for steric interactions, intermolecular interactions like van der Waals force and electrostatic force can be modeled as continua. Specifically, the continuum dynamics is an adequate description of liquid transport for length scales higher than 5 nm. In that context we aim to employ a hydrodynamic model to simulate ionic species transport through a 30 nm high nanofluidic channel with a reservoir upstream and a sink downstream.

This arrangement is similar to the field effect transistors in electronics where current flows along a semiconductor channel from the source electrode at one end to the drain electrode at the other end. A small voltage perturbation to a control electrode (gate) along the channel can cause large current change in the channel. Here we maintain the walls of the channel at negative bias. The distribution of ionic densities of aqueous solution and the resulting electric potential in the channel will be calculated using draft diffusion formulation. The product of the charge density and the electric field is incorporated into the fluid dynamic Navier–Stokes equation as the electrostatic body force to study the flow velocity change inside the channel. The channel height is orders of magnitude higher than the Stern layer thickness and thus neglected from detailed calculation.

We use a 5 μm long channel filled with KCl aqueous solution. Two reservoirs, $1\,\mu\text{m} \times 1\,\mu\text{m}$, are attached to either side of the channel. The channel is 30 nm in height. The problem of charge transport through the nanochannel is modeled using hydrodynamic equations for the ionic species. A 10^{-4} M ($\sim 6.022 \times 10^{22}\ \text{m}^{-3}$) aqueous solution of KCl is in contact with the walls of a silicon tube. The Debye length of ions is in the range of $500-40$ nm for ion density of $10^{-4}-10^{-2}$ M within the channel. When the height of the channel is smaller than the Debye length, the ionic current due to electrophoresis is dominant. For a given channel, as the charge density of wall surface increases, ionic current due to electroosmosis also becomes dominant and hence cannot be neglected [6]. The drift-diffusion-based Nernst–Planck approximation is utilized to represent the current (J) due to ionic species:

$$J_K = -eD_{\text{K}}\left(\nabla n_{\text{K}} + \frac{n_{\text{K}}}{kT}\nabla\phi\right), \quad (1)$$

$$J_{\text{Cl}} = -eD_{\text{Cl}}\left(\nabla n_{\text{Cl}} - \frac{n_{\text{Cl}}}{kT}\nabla\phi\right). \quad (2)$$

Here, n is the number density, ϕ is the potential, e is the electronic charge, D is diffusion coefficient of the ionic species and T is temperature in K. The Poisson equation represents charge difference as a function of potential in the system as

$$\nabla^2\phi = -\frac{e}{\varepsilon}(n_K - n_{Cl}) \ . \tag{3}$$

The system of Eqs. (1)–(3) is closed using the continuity equation

$$\nabla . J_K = 0 \quad \text{and} \quad \nabla . J_{Cl} = 0 \, . \tag{4}$$

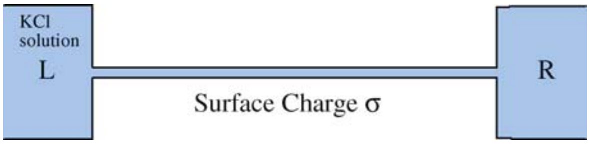
Temperature of the ionic species (T) is 298 K. The permittivity of KCl aqueous solution (ε) is 7×10^{-10} $C^2/(N\,m^2)$. For steady, low Reynolds number incompressible flow in the absence of external pressure gradient, the Navier–Stokes equation gets modified into

$$\nabla . \ (\mu \nabla u) + e\,(n_K - n_{Cl})\,E = 0 \tag{5}$$

where u is the velocity and μ is the dynamic viscosity.

The boundary conditions on various edges of the model are summarized in Table 1. In the reservoir all edges are fixed as Dirichlet boundaries based on the bulk density and fixed reservoir potential. Along the walls of the nanochannel, insulation current condition is ensured. This requires that the gradient of the ionic charge density be a function of potential gradient based on Eqs. (1) and (2). For the potential Eq. (3), the flux is specified based on the charge density σ on the surface of the nanochannel wall. For the velocity Eq. (5), a no-slip condition is imposed at the channel wall.

Figure 1 shows the schematic of the channel. The nature of the domain involving abrupt changes in aspect ratio of the geometry from a micrometer-size reservoir to nanometer-size channel introduces considerable numerical complexity into the problem. We used a maximum aspect ratio of about 248 in this case, which occurs near the center of the channel. This may be acceptable as the center does not create adverse concentration or potential gradients due to the symmetric nature of the geometry. We used a Galerkin *weak* formulation-based finite element method for solving Eqs. (1)–(5) in a self-consistent fashion. The details of the numerical procedures are given in our earlier work [8].



Electrophoretic Transport in Nanofluidic Channels, Figure 1
Schematic of a nanochannel for electrophoretic transport

Figures 2 and 3 show the distribution of normalized positive (K^+) and negative (Cl^-) ion number densities at steady state for surface charge of $\sigma = -10^{-3}$and -2×10^{-3} C/m^2 respectively on the channel wall. The distribution is plotted along the channel centerline (left) and across the mid-section of the channel (right). The left reservoir is at 0 V while the right reservoir is maintained at 1 V. As is evident from Fig. 2, the K^+ ion density is nine times more than that of Cl^- for $-1\,mC/m^2$ surface charge. Thus, the channel becomes a net unipolar (positively biased) solution of ions to neutralize the negative surface charge. A similar characteristic is also true for $\sigma = -2\,mC/m^2$, although in this case the ratio of positive to negative ions has nearly doubled. Interestingly, this trend continues for even higher negative wall bias.

Figure 4 plots the numerical results for $\sigma = -5\,mC/m^2$. Here the concentration of cations is about 40 times higher than that of the (negligible) anions making the channel essentially unipolar. The crosswise distribution of potential at the mid-section shows a sheath structure near the surface for all three cases (Figs. 2, 3 and 4). As expected the wall region is nearly devoid of anions for increasing surface charges. A sharp rise in the cation number density near the wall is also noticeable especially for $\sigma = -5\,mC/m^2$ (Fig. 4). Interesting effects in controlling the transport may be observed as one applies a gate charge σ_g along with the surface charge σ. The charge gradient due to net charge difference of $(\sigma - \sigma_g)$ over the surface affects the transport. For example, in Fig. 5 application of $\sigma_g = 0\,mC/m^2$ for $\sigma = -1\,mC/m^2$ leads to the Cl^- transport nearly tripling while the K^+ is quenched to only a third of its original density. This is uniquely suitable for separation of ions in a bio-transistor.

Electrophoretic Transport in Nanofluidic Channels, Table 1 Boundary conditions

Edge	Positive ion density	Negative ion density	Potential (V)
Boundary edges of left reservoir (L)	Bulk concentration	Bulk concentration	0
Boundary edges of right reservoir (R)	Bulk concentration	Bulk concentration	1
Nanochannel wall (σ = surface charge density)	$\nabla n_K = -\frac{en_K}{kT}\nabla\phi$	$\nabla n_{Cl} = \frac{en_{Cl}}{kT}\nabla\phi$	$\nabla\phi = -\frac{\sigma}{\varepsilon_0}$

Key Research Findings

We investigated the influence of surface charge in ion transport – a subject yet to be fully explored despite extensive recent research. We found the application of a surface charge gradient can significantly influence the local distribution of ion concentration in a nano-confinement. The accumulation of unipolar ions in the channel tries to neutralize the surface bias. A two-dimensional simulation demonstrated that selected ions can be attracted towards the wall region based on the charge density and polarity. The fluidic motion of the ions is also considered using an electrostatic force augmented Navier–Stokes formulation. The velocity distributions in streamwise and crosswise directions show a two-dimensional nature for high surface charge. Such charge separation is useful in many biomolecular applications.

Future Directions for Research

While significant experimental and theoretical studies have been done on the subject, consideration of the wall region (Stern double layer) will be required for capturing the physical processes governing such electrokinetic transport. For complicated tortuous nanochannels with realistic scales this is a modeling challenge. Similarly, detailed analysis is needed for understanding the two-dimensional electrophoresis specifically for a practical gel. A recent study [9] identified the design optimum of gate potential applied through a biased surface of a nanochannel for the most effective transport. Such sensitivity of the control mechanism needs to be carefully optimized.

Electroporation

Synonyms

Electropermeabilization

Definition

Electroporation is a technique in which an external electric field is applied to biological cells, causing an increase in cellular membrane permeability. Electroporation is often used as a means to transfect cells with extracellular material (e. g., with DNA in solution); it can also be used to permanently disrupt the cell membrane and effectively lyse the cell.

Electrospray Ionization

Synonyms

ESI

Definition

Electrospray ionization (ESI) is one of two “soft” ionization techniques used to introduce biological samples into a mass spectrometer. In ESI, an electric field is applied to a solution of analyte to form a spray of charged droplets. Subsequent solvent evaporation and ion release enables analysis by MS. The developer of ESI (along with the developers of MALDI) was awarded the 2002 Nobel Prize in Chemistry.

Microvalve

Definition

Electrostatic valves are microvalves that utilize the electrostatic force that is generated in the electric field of the actuator, for switching the valve.

Overview

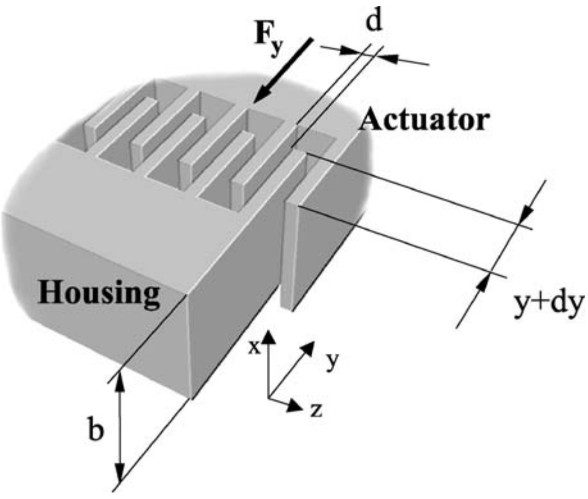
Electrostatic valves are microvalves that are driven by utilizing electrostatic forces. These valves can be suitable in industrial automation and medical engineering. The use of an electrostatic force as a valve drive is limited to a volume smaller than a few cm^3 due to scaling effects between electrostatic force and weight. The electrostatic valves are produced from silicon or in a new approach from metal-coated polymer materials using technologies for Moulded Interconnect Devices. The electrostatic drive is designed as a comb drive, where the actuator and housing are designed with electrodes, which are immersed into each other without an electrical contact. An electric field is formed by applying an electric voltage between the actuator and the housing and generates an attracting force always. The magnitude of the force can be estimated as the gradient of the stored energy. The energy in the electric field W_{el} is calculated in accordance with Eq. (1).

$$W_{el} = \frac{1}{2}CU^2 , \quad (1)$$

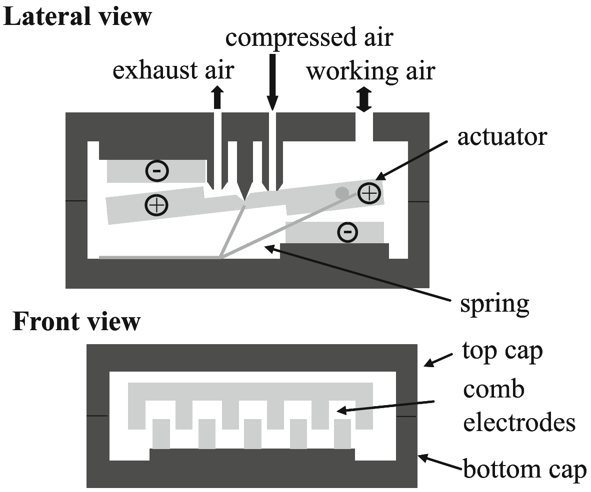
where C defines the capacitor and U is the voltage between the electrodes. The capacitance C is calculated from the electrode surface area A and the distance d between the electrodes (see Fig. 1). Not taking into account the stray fields and using the dielectric permittivity ε_0 of air the capacitance can be calculated in accordance with Eq. (2) as:

$$C = \frac{\varepsilon_0 A}{d} \quad (2)$$

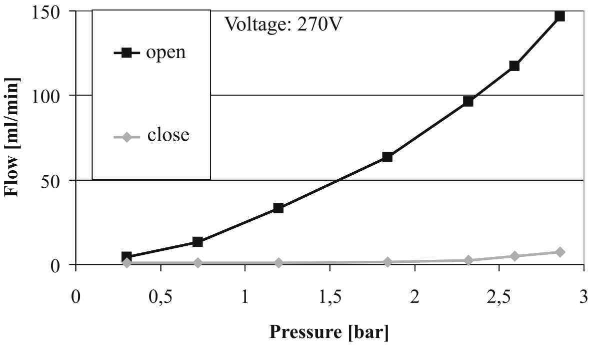
The acting force F is calculated from the gradient of the energy W_{el} corresponding to the direction of motion in



Electrostatic Valves, Figure 1 Comb drive structure



Electrostatic Valves, Figure 2 Schematic view of an electrostatic valve



Electrostatic Valves, Figure 3 Flow vs. pressure at compressed air supply

accordance with Eq. (3) as:

$$F = \left| \frac{dW_{el}}{dy} \right| = \left| \frac{1}{2} U^2 \frac{\varepsilon_0}{d} b \right| \quad (3)$$

where b is the width of the electrodes [1].

Figure 2 shows a schematic of one type of an electrostatic valve. The top and bottom form the housing of the valve in which an actuator is disposed in such a manner that it will be rotated. Both the actuator and the housing comprise comb drive electrodes. In the initial position, the actuator is rotated by the pretensioned restoring spring in such a way that the compressed air supply is closed. A torque is generated by applying an electric voltage between the comb electrodes of the actuator and the housing, and moves the actuator into its second position. This rotary motion of the actuator opens the compressed air supply and simultaneously closes the exhaust air connection and deflects the restoring spring. After switching off and grounding the electric voltage, the electrostatic force completely drops and the potential energy of the restoring spring moves the actuator into its initial position. The compressed air supply is thereby closed and the exhaust air connection is simultaneously opened such that the working air can escape through the exhaust air connection [2].

A remarkable feature of electrostatically driven valves is the comparatively low electric power consumption of a few µW. The small construction size also results in a small dead volume during switching. It must be noted that the maximum electric operating voltage is limited by the breakdown voltage of the insulating layer between the electrodes, which depends on the fluid, the operating pressure and the distance between the electrodes [3].

The valve described in [1] is made from metal plated plastic and has a volume of 1.7 cm^3. Figure 3 shows the flow characteristics versus the pressure of the compressed air supply. In the initial position the valve is leak tight up to a pressure of 2 bar. The cycle time of the valve was found to be in the range of a few ms.

Electrostrictive

Definition

Strain-electric field coupling induced by the formation of dipoles within the material either via applied strain or electric field which are then used to generate a further strain or electric field within the material based on a change in the applied electric field or strain, respectively. Generally, the electric fields as a quadratic function of the applied strain in electrostrictive materials. Many non-conducting materials are electrostrictive, though usually weak. The buzzing sound in the ballast of fluorescent lights is due to this phenomenon. Relaxor ferroelectrics like the especially important, single-crystal PMN-PT have especially large electrostrictive coupling coefficients and actually provide larger responses than the best piezoelectric materials.

Electrothermal flow

Definition

Electrothermal flows originate from the temperature gradient in a medium, which is generated as a consequence of the Joule heating effects. This temperature gradient induces local gradients in conductivity, permittivity, density and viscosity, which in turn, give rise to net forces which act on the liquid. For instance, conductivity gradients produce free volumetric charges and Coulombic forces, whereas permittivity gradients produce dielectric forces.

Overview

One can express the electrical force per unit volume in the following general form [1]:

$$f_e = \rho_e \boldsymbol{E} - \frac{1}{2}\boldsymbol{E}^2 \nabla\varepsilon + \frac{1}{2}\nabla\left(\rho \frac{\partial\varepsilon}{\partial\rho}\boldsymbol{E}^2\right) \tag{1}$$

where ρ_e is the volumetric charge density, $\boldsymbol{E}$ is the electric field strength, ε is the permittivity and ρ is the density of the medium. The first and second terms on the right-hand side of Eq. (1) are the Coulombic and dielectric forces, respectively. The last term is the electrostriction. As it is the gradient of a scalar, it can be combined with the pressure gradient term in the Navier–Stokes equation. For an incompressible fluid, this has no additional effect on the fluid dynamics, and accordingly, this term will be neglected in the subsequent analysis. The relative contributions of the first two terms in Eq. (1) can be assessed by adding a small perturbation field, $\boldsymbol{E}_1$, over and above the applied electric field, $\boldsymbol{E}_0$, such that $\boldsymbol{E} = \boldsymbol{E}_0 + \boldsymbol{E}_1$, with $|\boldsymbol{E}_1| \ll |\boldsymbol{E}_0|$. Noting that the charge density is given by the Poisson equation

$$\nabla\cdot(\varepsilon\boldsymbol{E}) = \rho_e \tag{2}$$

one can write

$$\nabla\cdot\left(\varepsilon\left(\boldsymbol{E}_0 + \boldsymbol{E}_1\right)\right) = \rho_e\,,$$

or equivalently

$$\nabla\varepsilon\cdot\boldsymbol{E}_0 + \nabla\varepsilon\cdot\boldsymbol{E}_1 + \varepsilon\nabla\cdot\boldsymbol{E}_0 + \varepsilon\nabla\cdot\boldsymbol{E}_1 = \rho_e\,. \tag{3a}$$

Since $\nabla\cdot\boldsymbol{E}_0 = 0$ and $|\boldsymbol{E}_1| \ll |\boldsymbol{E}_0|$, Eq. (3a) reduces to the following approximate form:

$$\nabla\varepsilon\cdot\boldsymbol{E}_0 + \varepsilon\nabla\cdot\boldsymbol{E}_1 = \rho_e\,. \tag{3b}$$

Using Eq. (3b) in Eq. (1) one obtains

$$f_e = \left(\nabla\varepsilon\cdot\boldsymbol{E}_0 + \varepsilon\nabla\cdot\boldsymbol{E}_1\right)\boldsymbol{E}_0 - \frac{1}{2}\boldsymbol{E}_0^2\nabla\varepsilon\,. \tag{4}$$

The charge conservation equation can be written in the following form:

$$\nabla\cdot\boldsymbol{J} + \frac{\partial\rho_e}{\partial t} = 0 \tag{5a}$$

where

$$\boldsymbol{J} = \underbrace{\sigma \boldsymbol{E}}_{\text{conduction current}} + \underbrace{\rho_e \boldsymbol{v}}_{\text{convection current}} \tag{5b}$$

where σ is the electrical conductivity. The relative contributions of conduction and convection currents in Eq. (5a) can be assessed by comparing the divergence of the convection charge with the divergence of the ohmic current

$$\frac{|\nabla \cdot (\rho_e \boldsymbol{v})|}{|\nabla \cdot (\sigma \boldsymbol{E})|} \approx \frac{|\rho_e \boldsymbol{v}|}{|\sigma \boldsymbol{E}|} = \frac{|\nabla \cdot (\varepsilon \boldsymbol{E})\, \boldsymbol{v}|}{|\sigma \boldsymbol{E}|} \approx \frac{\varepsilon v}{\sigma l}. \tag{6}$$

In Eq. (6), l and $\boldsymbol{v}$ are the length and velocity scales for the physical problem under consideration. Equation (6) can also be interpreted as the ratio of two timescales, namely, $t_{\text{relax}} = \varepsilon/\sigma$ and $t_{\text{advection}} = l/v$, where t_{relax} is the charge relaxation timescale and $t_{\text{advection}}$ is the advection timescale. With a typical value of $l \sim 10\,\mu\text{m}$ and $v \sim 200\,\mu\text{m s}^{-1}$, $t_{\text{advection}}$ is of the order of 0.1 s, which is several orders of magnitude higher than the typical values of t_{relax} in an aqueous solution. Thus, $\nabla \cdot (\rho_e \boldsymbol{v})$ can be neglected in comparison to $\nabla \cdot (\sigma \boldsymbol{E})$ in Eq. (5a). Accordingly, with the help of Eq. (3b), Eq. (5a) can be rewritten as (noting that $|\boldsymbol{E}_1| \ll |\boldsymbol{E}_0|$)

$$\nabla \sigma \bullet \boldsymbol{E}_0 + \sigma \nabla \bullet \boldsymbol{E}_1 + \frac{\partial \left(\nabla \varepsilon \bullet \boldsymbol{E}_0 + \varepsilon \nabla \bullet \boldsymbol{E}_1 \right)}{\partial t} = 0 \tag{7}$$

Assuming a time-varying electric field of the form

$$\boldsymbol{E}_0\,(t) = \text{Re}\big(\boldsymbol{E}_0 \exp\,(j\omega t)\big) \tag{8}$$

where $\boldsymbol{E}_0$ is the time-independent component (amplitude) of the unperturbed electric field, one obtains, from Eq. (7)

$$\nabla \sigma \cdot \boldsymbol{E}_0 + j\omega \nabla \varepsilon \cdot \boldsymbol{E}_0 + \sigma \nabla \cdot \boldsymbol{E}_1 + j\omega \varepsilon \nabla \cdot \boldsymbol{E}_1 = 0 \tag{9}$$

The divergence of the perturbation field can be obtained from Eq. (9) as

$$\nabla \cdot \boldsymbol{E}_1 = \frac{-\left(\nabla \sigma + j\omega \nabla \varepsilon\right) \cdot \boldsymbol{E}_0}{\sigma + j\omega \varepsilon} \tag{10}$$

Assuming that the liquid does not respond to the instantaneous value of the force at the frequency of the electric field, one can obtain the time-average of Eq. (4) and thus obtain

$$\langle f_e \rangle = \frac{1}{2}\text{Re}\left(\left(\nabla \varepsilon \cdot \boldsymbol{E}_0 + \varepsilon \nabla \cdot \boldsymbol{E}_1 \right) \boldsymbol{E}_0^* - \frac{1}{2} \boldsymbol{E}_0^2 \nabla \varepsilon \right) \tag{11}$$

where $\boldsymbol{E}_0^*$ is the complex conjugate of $\boldsymbol{E}_0$. Substituting Eq. (10) into Eq. (11), one obtains

$$\langle f_e \rangle = \frac{1}{2}\text{Re}\left[\left\{ \frac{(\sigma \nabla \varepsilon - \varepsilon \nabla \sigma) \cdot \boldsymbol{E}_0}{\sigma + j\omega \varepsilon} \right\} \boldsymbol{E}_0^* - \frac{1}{2} |\boldsymbol{E}_0|^2 \nabla \varepsilon \right] \tag{12}$$

For real $\boldsymbol{E}_0$, Eq. (12) can be simplified as [2]

$$\langle f_e \rangle = -\frac{1}{2} \left(\underbrace{\left(\frac{\nabla \sigma}{\sigma} - \frac{\nabla \varepsilon}{\varepsilon} \right) \cdot \boldsymbol{E}_0 \frac{\varepsilon \boldsymbol{E}_0}{1 + (\omega \tau)^2}}_{\text{Coulomb force}} + \underbrace{\frac{1}{2} |\boldsymbol{E}_0|^2 \nabla \varepsilon}_{\text{Dielectric force}} \right) \tag{13}$$

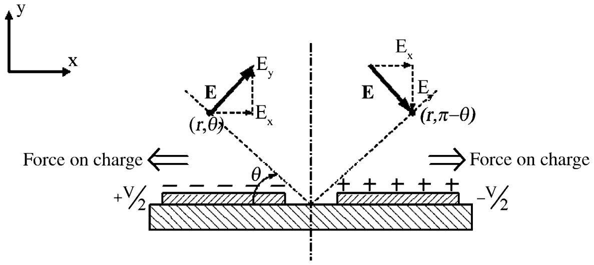
where $\tau = \varepsilon/\sigma$ is the charge relaxation time ($= t_{\text{relax}}$). The Coulombic force dominates in certain frequency ranges, but in other ranges the dielectric force dominates. At a certain frequency, say f_c, these two forces are of equal strength. This frequency can be estimated from Eq. (13) (noting that $\nabla \sigma = (\partial \sigma)/(\partial T) \nabla T$, $\nabla \varepsilon = (\partial \varepsilon)/(\partial T) \nabla T$), to yield

$$\omega_c = 2\pi f_c \approx \frac{1}{\tau} \left(\frac{2 \left| \frac{1}{\sigma} \frac{\partial \sigma}{\partial T} \right|}{\left| \frac{1}{\varepsilon} \frac{\partial \varepsilon}{\partial T} \right|} \right)^{\frac{1}{2}} \tag{14}$$

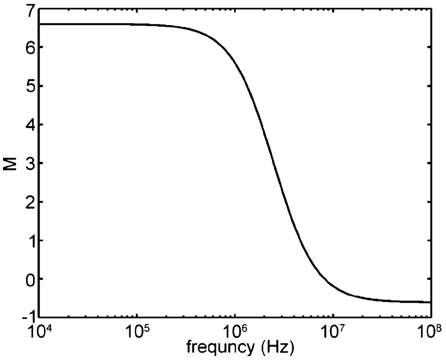
For water, $(1/\sigma)(\partial \sigma/\partial T) = 2\%$ per K and $(1/\varepsilon)(\partial \varepsilon/\partial T) = -0.4\%$ per K [2], for which $2\pi f_c \tau \approx \sqrt{10}$. In an order of magnitude sense, thus, $f_c \sim 1/\tau$, or $f_c = \sigma/\varepsilon$. For $f \gg \sigma/\varepsilon$ (typically high frequencies), the dielectric force dominates, whereas for $f \ll \sigma/\varepsilon$ (low frequencies) the Coulombic force dominates.

A detailed derivation of a comprehensive mathematical model of electrothermal effects has been presented in the review by Ramos et al. [2]. A brief description of the mathematical model is outlined here, for the sake of completeness. Following the analysis by Ramos et al. [2], simple analytical estimates of the electrothermal forces on a liquid can be obtained by considering two thin parallel metallic plates, with a very small interelectrode gap. The plates are covered in a dielectric liquid and are subjected to a potential difference of V across the gap, which sets up an electric field $\boldsymbol{E}\,(r, \theta)$ (see Fig. 1). Neglecting end effects, this electric field can be expressed as

$$\boldsymbol{E} = \frac{V}{\pi r} \boldsymbol{n}_\theta \tag{15}$$



Electrothermal Effects, Figure 1 Two parallel plates with a small inter-electrode gapwhich is covered by a dielectric. A potential V is applied across the gap in the direction as shown



Electrothermal Effects, Figure 2 Magnitude of the factor $M(\omega, t)$ as a function of frequency

The corresponding energy dissipation per unit volume (σE^2) can be introduced into the governing equation of energy conservation as a volumetric source term, to yield

$$\frac{k}{r}\frac{\partial}{\partial r}\left(r\frac{\partial T}{\partial r}\right)+\frac{k}{r^2}\frac{\partial^2 T}{\partial\theta^2}+\frac{\sigma V^2}{\pi^2 r^2}=0 \tag{16a}$$

where k is the thermal conductivity of the liquid. Writing $T^* = T + (\sigma V^2\theta^2/2\pi^2 k)$, one can express Eq. (16a) in the form

$$\frac{k}{r}\frac{\partial}{\partial r}\left(r\frac{\partial T^*}{\partial r}\right)+\frac{k}{r^2}\frac{\partial^2 T^*}{\partial\theta^2}=0 \tag{16b}$$

Assuming that the electrodes act as thermal baths, i. e., $T = 0$ (a suitably chosen reference temperature) for $\theta = 0, \pi$, one can conclude that T^* is independent of r, which implies that

$$\frac{\partial^2 T^*}{\partial\theta^2}=0 \tag{16b}$$

A general solution Eq. (16b) can be obtained in the form

$$T^* = a_0\theta + b_0 \tag{17}$$

where a_0 and b_0 are obtained from the boundary conditions at $\theta = 0, \pi$, as $a_0 = (\sigma V^2/2\pi k)$ and $b_0 = 0$. Thus

$$T=\frac{\sigma V^2\theta}{2\pi k}-\frac{\sigma V^2\theta^2}{2\pi^2 k} \tag{18}$$

The maximum temperature occurs at $\theta = \frac{\pi}{2}$, as $T_{\max} = (\sigma V^2/8k)$. It is important to note that for the calculation of electrothermal forces, the most critical factor is not merely the temperature itself but also its gradient. The latter can be estimated from Eq. (18) as

$$\nabla T=\frac{\sigma V^2}{2\pi k}\left(1-\frac{2\theta}{\pi}\right)\frac{1}{r}\boldsymbol{n}_\theta \tag{19}$$

Equation (19) can be substituted in Eq. (13), with $\nabla\sigma = (\partial\sigma/\partial T)\nabla T$, $\nabla\varepsilon = (\partial\varepsilon/\partial T)\nabla T$, to yield

$$\langle f_e\rangle = -M(\omega, T)\frac{\sigma\varepsilon V_{\mathrm{rms}}^4}{2k\pi^3 r^3 T}\left(1-\frac{2\theta}{\pi}\right)\boldsymbol{n}_\theta \tag{20}$$

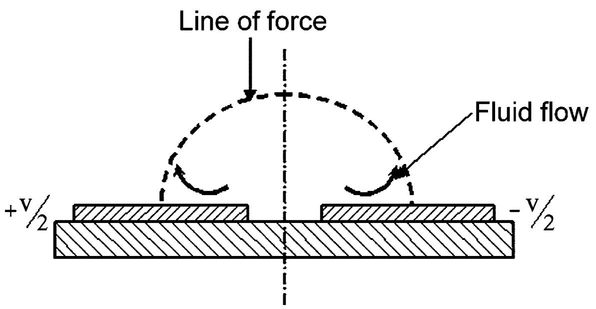
Here

$$M(\omega, T)=\left[\frac{\frac{T}{\sigma}\frac{\partial\sigma}{\partial T}-\frac{T}{\varepsilon}\frac{\partial\varepsilon}{\partial T}}{1+(\omega\tau)^2}+\frac{1}{2}\frac{T}{\varepsilon}\frac{\partial\varepsilon}{\partial T}\right] \tag{21}$$

is a dimensionless factor describing the variation of the time-averaged electrothermal force as a function of the applied frequency and the prevailing temperature. A plot of $M(\omega, T)$ as a function of frequency is shown in Fig. 2, with $T = 300$ K. The parameters considered for plotting this figure are as follows: $(1/\sigma)(\partial\sigma/\partial T) = 2\%$ per K, $(1/\varepsilon)(\partial\varepsilon/\partial T) = -0.4\%$ per K, $\sigma = 0.01\ \mathrm{Sm}^{-1}$, $\varepsilon = 640 \times 10^{-12}\ \mathrm{C^2/N{\cdot}m^2}$. It can be observed from the figure that M is positive for low frequencies, whereas it is negative for higher frequencies. For low frequencies, the force is dominated by the space charge and the flow occurs in the manner which is represented schematically in Fig. 3. At frequencies greater than the critical frequency, on the other hand, the flow direction is reversed and the liquid streams up in the center of the gap between the two electrodes. However, these conclusions are only valid if the interelectrode gap is infinitesimally narrow. For finite interelectrode spacings, a numerical solution of the fluid flow equations may be necessary to reveal the underlying flow picture.

In order to obtain analytical expressions for the velocity field of the physical problem described above, one can begin with the equation of motion (Navier–Stokes equation) in the steady state

$$-\nabla p+\eta\nabla^2\boldsymbol{v}+\langle f_e\rangle=0 \tag{22}$$



Electrothermal Effects, Figure 3 Flow patterns for frequencies below the charge relaxation frequency of the liquid

where η is the fluid viscosity and $\langle f_e \rangle$ is given by Eq. (20). One can eliminate the pressure gradient term from Eq. (22) by partially differentiating the r- and θ-components of that equation with respect to θ and r, respectively, and subtracting the two resultant equations, to obtain

$$-\eta \nabla^4 \psi + (\nabla \times \langle \boldsymbol{f}_e \rangle) \cdot \boldsymbol{n}_z = 0 \tag{23}$$

where $\boldsymbol{n}_z$ is a unit vector in the z-direction and $\boldsymbol{v} = \nabla \times (\psi \boldsymbol{n}_z)$. Incorporating the expression for $\langle f_e \rangle$ from Eq. (20) in Eq. (23), one can write

$$\left(\frac{1}{r} \frac{\partial}{\partial r} \left(r \frac{\partial}{\partial r} \right) + \frac{1}{r^2} \frac{\partial^2}{\partial \theta^2} \right)^2 \psi = \frac{2C}{r^4} \left(1 - \frac{2\theta}{\pi} \right) \tag{24}$$

where

$$C = M(\omega, T) \frac{\sigma \varepsilon V_{rms}^4}{2k\pi^3 T \eta}$$

Similarly to the considerations for the solution of the energy equation, one can also note that $\psi = \psi(\theta)$.This leads to the following general solution of Eq. (24):

$$\psi = -\frac{C}{2} \left(\frac{\theta^2}{2} - \frac{\theta^3}{3\pi} \right) + A_1 \sin 2\theta + A_2 \cos 2\theta + A_3 \theta + A_4 \tag{25}$$

where A_i are arbitrary independent constants of integration. Their values can be obtained by imposing the following boundary conditions:

$$\begin{aligned} &\psi = 0 \quad \text{at } \theta = 0, \pi \\ &\frac{\partial^2 \psi}{\partial \theta^2} = 0 \quad \text{at } \theta = 0, \pi/2 \quad \text{(from symmetry)} \end{aligned} \tag{26}$$

This gives the final solution of ψ as

$$\psi = -\frac{C}{2} \left(\frac{\theta^2}{2} - \frac{\theta^3}{3\pi} \right) - \frac{C\pi}{24} (\sin 2\theta - 2\theta) \tag{27}$$

The velocity distribution can be obtained from the above expression, as follows:

$$v_r = \frac{1}{r} \frac{\partial \psi}{\partial \theta} = \frac{C}{r} \left(-\frac{1}{2} \left(\theta - \frac{\theta^2}{\pi} \right) - \frac{\pi}{12} (\cos 2\theta - 1) \right) \tag{28}$$

It can be observed from Eq. (28) that $v_r = v_r|_{max} = (\pi C/24r)$ at $\theta = \frac{\pi}{2}$. Also, $v_r = 0$ at $\theta = 0.286\pi$ and $\theta = 0.714\pi$.

Key Research Findings

It is interesting to compare the electrothermal flow velocity (v_{fluid}) with the dielectrophoretic velocity (v_{DEP}) of submicron-size charged particles suspended in the aqueous medium. It should be noted that the time-averaged dielectrophoretic force on a particle of radius R can be described as $\langle \boldsymbol{F}_{DEP}(t) \rangle = 2\pi \varepsilon_m R^3 Re[K(\omega)] \nabla |\boldsymbol{E}_{rms}|^2$, where ε_m is the permittivity of the dielectric medium, $K(\omega)$ is the Clausius–Mossotti factor, given by $K(\omega) = (\tilde{\varepsilon}_p - \tilde{\varepsilon}_m)/(\tilde{\varepsilon}_p + 2\tilde{\varepsilon}_m)$. $\tilde{\varepsilon}_p$ and $\tilde{\varepsilon}_m$ are the complex permittivities of the particle and the medium, respectively ($\tilde{\varepsilon} = \varepsilon - j(\sigma/\omega)$), and $\nabla |\boldsymbol{E}_{rms}|^2$is the gradient of the square of the r.m.s electric field. Thus, one can compare the electrothermal and dieleletrophoretic flow velocities as

$$\frac{v_{fluid}}{v_{DEP}} \propto \frac{M(\omega, T)}{\mathrm{Re}[K(\omega)]} \frac{\sigma V_{rms}^2 r^2}{kTR^2} \tag{29}$$

This implies that the electrothermal flow velocity increases in proportion to the electrical conductivity of the medium. Not only that, the dielectrophoretic force also dominates near the electrode edges ($r \to 0$). On the other hand, the influence of the electrothermal forces becomes progressively stronger for larger particles.

The electrothermal effects in microflows can also be modulated by illuminating the electrodes with fluorescent light, as has been observed by Green et al. [3]. They described the importance of the illumination in generating the fluid flow, and found that the flow was dependent on both the intensity of illumination and the applied electric field. They also compared the theoretical estimates of the electrothermally induced flow velocities with their experimental observations. A reasonable agreement was found between the experiments and the theory, with the light

generating temperature gradients, and therefore gradients in the fluid permittivity and conductivity, and the electric field being responsible for the motive force. Although there may be several mechanisms through which the light could produce heat in the system, some of these mechanisms could be excluded by the experimental conditions that were used. For example, because an infrared filter was used the possibility of infrared heating was eliminated. Further, although the fluorescent particles could gain energy through the absorption/re-emission process and could generate heat, no global temperature gradients could be generated in this process, since the particles were uniformly distributed. One of the major reasons for the electrothermal flow could be the heating of the electrodes by the light, since a percentage of the light was absorbed by the metal during reflection. As the thin electrodes are more thermally resistant than water, the heat could easily be radiated away through the electrolyte, thereby creating temperature, conductivity and permittivity gradients. The electrothermal fluid flow, could therefore be attributed to the interaction between the electric field and these gradients.

Sinton et al. [4] have demonstrated that an axially nonuniform temperature distribution can induce a pressure disturbance, which in turn, can give rise to velocity gradients. This can lead to velocity profiles that are significantly different from the ideal plug-like electroosmotic flow velocity profiles in microchannels. In their experiments, the axial thermal gradients were induced passively by increased dissipation of Joule heat through the optical infrastructure of a viewing window surrounding a capillary. When large fields were applied, their temperature measurements indicated that the temperature of the fluid in the viewed region was as much as 30 °C lower than that elsewhere in the capillary. Despite an increase in viscosity because of this local cooling effect, this also resulted in a locally increased electroosmotic wall velocity, which induced a concave velocity profile in the viewed portion and a convex velocity profile elsewhere.

The electrothermal effects can also be exploited to design efficient microactuators, as has been demonstrated by Li and Uttamchandani [5] who presented a modified design to generate a large deflection and to control the peak temperature of the hot beam of a two-beam asymmetric thermal microactuator. Their analysis revealed that by changing the dimensions of a section of the hot beam, it was possible to achieve a higher average temperature but a lower peak temperature within the beam. Their analysis also demonstrated the effect of the geometry of the hot beam on the temperature distribution, and possible methods of optimization so as to avoid local hot spots which lead to thermal failure.

Future Directions for Research

Although electrothermal flows have been extensively studied in the literature, significant work is yet to be done to examine the interactions between AC electroosmosis and electrothermal flows. Significant research effort also needs to be devoted to investigate the electrothermal flows from a stochastic viewpoint, primarily because of the uncertainties in the various factors that eventually dictate the magnitude and direction of the net body force that acts on the fluid under these conditions.

Electrothermal Flow

► Electrothermal Effects

Electroviscosity

Definition

For pressure-driven flow of a dilute electrolyte solution in a small microchannel, due to the presence of electric double layer near the channel wall, the flow-induced streaming potential drives the counterions to move in the direction opposite to the pressure drop. These moving counterions drag the surrounding liquid molecules with them. This generates an opposite flow to the pressure-driven flow

and hence a reduced flow rate in the pressure-drop direction. This reduced flow rate seems to suggest that the liquid have an apparent higher viscosity. The apparent viscosity is called the electro-viscosity.

Definition

Electrowetting concerns the use of an externally applied electric field to actuate or manipulate small volumes of liquid by altering its interfacial tension and hence the macroscopic contact angle or by inducing bulk liquid motion through an interfacial electric stress.

Chemical and Physical Principles

Electrowetting derives its roots from early observations of electrocapillary phenomena by Gabriel Lippmann in 1875, who noted variations in interfacial tension as an electric potential is applied between an electrolyte solution in direct contact with a metal, in this case, mercury. This culminated in the classical Lippmann equation:

$$\left.\frac{\partial\gamma}{\partial V}\right|_{T,p,\mu} = -\frac{CV}{A}\,, \tag{1}$$

where γ is the interfacial tension (between the metal and electrolyte), V the applied potential, T the temperature, p the pressure and μ the chemical potential. The right hand side of Eq. (1) is the surface charge density, where C is the capacitance with cross sectional area A and separation d. Since $C = \varepsilon_0\varepsilon_l A/d$, where ε_0 is the permittivity of free space and ε_l the liquid dielectric constant, Eq. (1) can be written as

$$\Delta\gamma = -\frac{\varepsilon_0\varepsilon_l}{2d}V^2\,. \tag{2}$$

The term on the right hand side of Eq. (2) is hence the electrocapillary force per unit length (linear force density) in the solid plane along the contact line.

Strictly, the term *electrocapillarity* therefore refers to the change in the solid or liquid metal–electrolyte interfacial tension, as shown in Fig. 1a. For the principle to be practical, however, it was necessary to avoid electrolysis of the aqueous solution. This was later overcome by coating the electrode surface with a thin dielectric layer (e. g., polymer substrate) several microns to millimeters in thickness, from which the term *electrowetting-on-dielectric* (EWOD) or *electrowetting on insulator coated electrodes* (EICE) arises [1], as shown in Figs. 1b and 1c. In cases where the insulating layer is not hydrophobic (e. g., parylene), a very thin hydrophobic layer such as a fluoropolymer of order nanometers in thickness, is coated onto the insulator.

In general, the term *electrowetting*, at least for EWOD or EICE configurations in which spontaneous spreading does not occur and hence the contact angles are *static* (we shall deal with the case of *spontaneous electrowetting* below), has traditionally been associated with the change in the macroscopic liquid–solid wetting angle θ subtended at the three-phase contact line where the vapor, liquid and solid phases converge [2]. Henceforth, we shall delineate the distinction between *static* and *spontaneous electrowetting*. A force balance at the contact line (Fig. 2) yields Young's equation,

$$\gamma_{LV}\cos\theta = \gamma_{SV} - \gamma_{SL}\,, \tag{3}$$

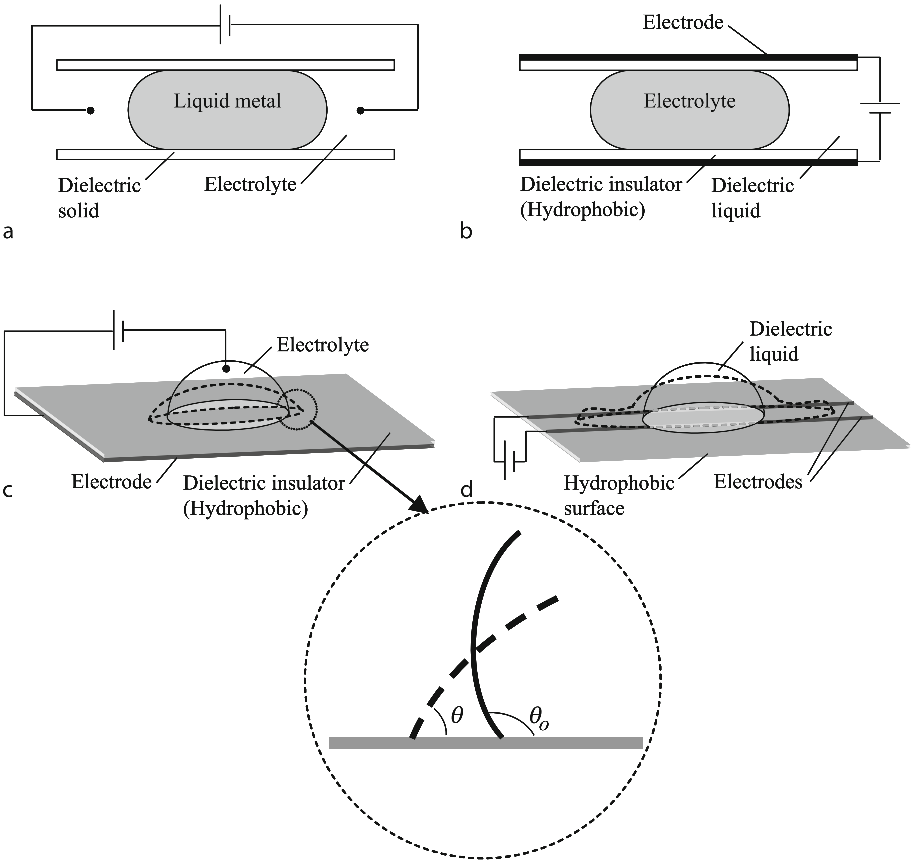
where γ_{LV}, γ_{SV} and γ_{SL} are the vapor–liquid, vapor–solid and liquid–solid interfacial tensions, respectively. Substituting Eq. (3) into Eq. (1) with $\gamma = \gamma_{SL}$ gives

$$\frac{\mathrm{d}\cos\theta}{V\,\mathrm{d}V} = \frac{C}{\gamma_{LV}}\,, \tag{4}$$

which then leads to the equivalent Lippmann condition for electrowetting:

$$\cos\theta = \cos\theta_0 + \frac{\varepsilon_0\varepsilon_l V^2}{2d\gamma_{LV}}\,, \tag{5}$$

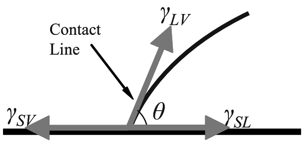
where θ_0 is the contact angle in the absence of an electric field. The electric field has changed the vapor–liquid surface force and hence altered the static contact angle when all three surface forces balance.



Electrowetting, Figure 1 Schematic illustration of the various electrode configurations used to demonstrate electrocapillary and electrowetting phenomena. (**a**) Electrocapillary phenomena involving a static change in the liquid metal–electrolyte contact angle. (**b**) Dielectric film coated top and bottom plate electrodes giving rise to static changes in the liquid–solid contact angle. (**c**) Dielectric film coated planar plate electrode giving rise to static changes in the liquid–solid contact angle. (**d**) Planar parallel line electrode configuration giving rise to spontaneous and dynamically advancing thin electrowetting films [2]. The inset shows an enlargement of the contact line region for case (**c**) wherein the macroscopic drop contact angle is altered from its equilibrium value θ_0 given by the Young equation to a new equilibrium value θ upon application of an electric field

The incorporation of a dielectric layer would result in a larger potential drop and a corresponding reduction in the capacitance. As most of the potential drop now occurs across the dielectric layer, the Lippmann condition in Eq. (5) can be written as

$$\cos\theta = \cos\theta_0 + \frac{\varepsilon_0\varepsilon_\mathrm{d} V^2}{2d\gamma_\mathrm{LV}}\,, \qquad (6)$$



Electrowetting, Figure 2 Surface forces acting at the contact line

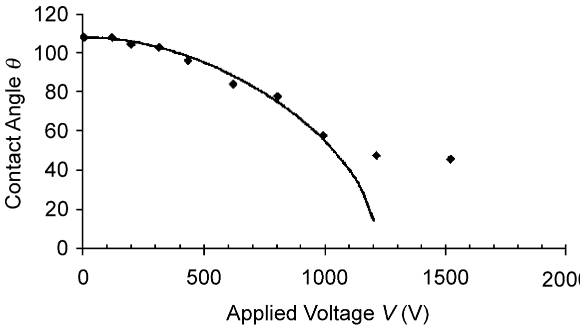
where ε_d is the permittivity of the dielectric layer, which is much smaller than ε_l. The above assumes the double layer capacitance, which is in series with the dielectric layer capacitance, to be negligible; this is not unreasonable given that the thickness of the double layer is typically much smaller than the dielectric layer thickness d, at least for conducting liquids. In any case, the reduction in the electric field intensity for electrowetting due to the presence of the dielectric layer requires a larger applied voltage to achieve the same electrowetting effect obtained in the absence of the dielectric layer. However, any increases in the applied voltage is restricted by a threshold voltage above which dielectric breakdown of the material occurs. Dielectric breakdown at these increased applied voltages can however be avoided by employing an AC field with a forcing frequency that is above the inverse of the RC time scale (R being the resistance of the bulk electrolyte

and C the dielectric layer capacitance) such that the potential drop across the dielectric layer is minimized.

Spontaneous electrowetting, in contrast, can arise using the parallel line electrode configuration shown in Fig. 1d, in what we shall term as *electrowetting on line electrodes* (ELE). This was first observed by Jones et al. [3], who noticed that a thin liquid film, several microns thick, is pulled out ahead of the macroscopic spreading drop when an electric potential is applied across the line electrodes, and advances much faster than the macroscopic spreading drop itself. This spontaneous and dynamically advancing film arises due to a bulk electric pressure gradient in the contact line region, which produces a negative capillary pressure that induces bulk liquid to flow into the contact line region, thus spontaneously pushing out a thin electrowetting film ahead of the macroscopic drop [2, 4].

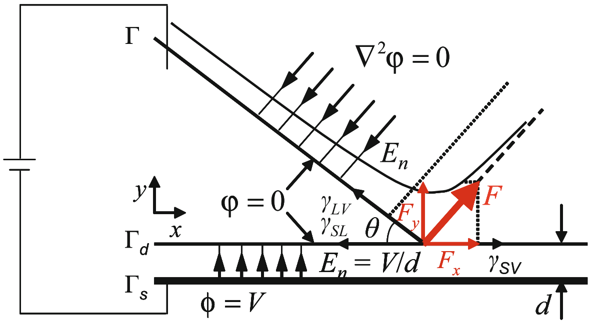
Key Research Findings

Figure 3 shows a typical contact angle response to the applied voltage when the EWOD/EICE configuration is adopted. The observed change in the contact angle is *static* and proportional to the square of the voltage, and thus universally described by the Lippmann condition in Eq. (6) up to a limiting value in the voltage before complete wetting is achieved when deviation begins to occur. This is attributed to contact line saturation. In addition, near the saturation point, contact angle hysteresis is observed: The receding contact angle upon decreasing the voltage is observed to be smaller than the advancing contact angle at increasing voltage. It should be noted that this hysteresis effect is distinct from the usual contact angle hysteresis that occurs in drops on inclined planes, where the receding contact angle is always greater than the advancing contact angle.



Electrowetting, Figure 3 Typical contact angle/voltage response in electrowetting-on-dielectric (EWOD) experiments. This particular set of experimental data corresponds to a 75 % aqueous glycerol drop sitting above a 100 μm poly(tetrafluoroethylene) dielectric layer under an applied AC field [5]

Contact line saturation has been attributed to several factors, although these are not well understood and it may be possible that these different factors could each give rise to saturation independent of the other [6]. One possible factor is the dielectric breakdown of the atmosphere in the contact line region. When the atmosphere ionizes, the ambient phase no longer acts as an insulator wherein the charges that accumulate at the contact line exert an outwardly directed electric force which gives rise to the spreading. As a result, the leakage of charges into the ambient phase weakens this force, thus suppressing the electrowetting effect [7]. When the ambient medium is water surrounding a dielectric liquid drop, contact line saturation has been suggested to arise due to charge leakage from the aqueous phase into the insulating polymer layer at high field intensities [8]. It has also been suggested that contact angle hysteresis occurs because of the delayed release of these leaked charges from the polymer surface back into the aqueous phase when the voltage is decreased. Several theoretical descriptions have been proposed to describe the electric field induced change in the macroscopic liquid–solid contact angle in *static electrowetting*. These are based on thermodynamic, molecular kinetic, electromechanic and static approaches [2]. Vallet et al. [7] and Kang [9] considered an infinite planar wedge analysis in the three-phase contact line region, as shown in Fig. 4. As the top electrode is in contact with the drop phase, represented by the wedge, it is assumed to be at constant potential, surrounded by a perfectly insulating ambient phase whose permittivity is assumed to be equal to that of the dielectric layer of thickness d. In the absence of free charges, the electrostatic potential in the ambient phase ϕ



Electrowetting, Figure 4 Schematic illustration of the wedge representing the drop geometry in the contact line region in the *static electrowetting* analysis of [7] and [9]. The black arrows indicate the direction of the field and the light bold arrows indicate the resultant point force and its components at the contact line. The curve depicts the charge density or the normal field intensity along the drop interface which is singular at the tip or the three-phase contact line for all $\theta < \pi$ [2]

then obeys the Laplace equation:

$$\nabla^2\varphi = 0\,. \tag{7}$$

The boundary conditions are stipulated by the constant potential interfaces

$$\varphi = 0 \text{ on } \Gamma \text{ and } \Gamma_\mathrm{d} \qquad \text{and} \qquad \varphi = V \text{ on } \Gamma_\mathrm{s}\,, \tag{8}$$

where Γ, Γ_d and Γ_s denote the interfaces between the drop and the ambient phase, the drop and the dielectric layer and the dielectric layer and solid interfaces, respectively. Solving Eqs. (7) and (8) for small contact angles $\theta \to 0$ then yields a normal interfacial electric field that scales as

$$E_\mathrm{n}|_\Gamma \sim \frac{1}{|r|^{\frac{1}{2}}}\,, \tag{9}$$

where r is the distance along the drop interface away from the wedge tip where the contact line is located.

We note from Eq. (9) that E_n is weakly singular for $\theta < \pi$ and diverges only in a small region with length scale of order d away from the wedge tip. Since the electric pressure scales as $p_\mathrm{e} \sim E_\mathrm{n}^2$, the pressure gradient that arises as a result is localized in this small confined region at the contact line and cannot give rise to any bulk flow below the advancing contact angle. Yeo and Chang [2] also show that the solution of the biharmonic equation for the hydrodynamics within the wedge gives rise to an expression for the hydrodynamic pressure near the wedge tip as $r \to 0$ that is incompatible with the interfacial normal stress jump condition involving a singular electric stress given by Eq. (9), again suggesting the absence of any bulk flow in the contact line region. Moreover, the confined region in which the electric pressure gradient is significant is too small to be resolved in the continuum limit. As such, it is necessary to average out the electric stress, which results in a point electric force at the contact line [9]:

$$F = \frac{\varepsilon_0\varepsilon_\mathrm{d}}{2}\int_\Gamma E_\mathrm{n}^2\,\mathrm{d}r = \frac{\varepsilon_0\varepsilon_\mathrm{d}V^2}{2d}\operatorname{cosec}\theta\,. \tag{10}$$

Decomposing Eq. (10) into its horizontal and vertical components yields

$$F_x = \frac{\varepsilon_0\varepsilon_\mathrm{d}V^2}{2d}\,, \quad \text{and}\,, \quad F_y = \frac{\varepsilon_0\varepsilon_\mathrm{d}V^2}{2d}\cot\theta\,, \tag{11}$$

which, upon balancing the surface forces at the contact line, leads to the recovery of the Lippmann condition in Eq. (6). The electric pressure correction in Eq. (11) therefore accounts for the static change in the macroscopic contact angle. Since the point electric force balances the surface forces exactly, there is no net force and hence no bulk liquid flow into the contact line region. Thus, only a static change in the macroscopic contact angle results; no spontaneous electrowetting film is produced in the absence of any bulk fluid motion, therefore demonstrating why spontaneous electrowetting films cannot be produced when the EWOD/EICE configurations are adopted [2].

Yeo and Chang [4], on the other hand, have derived a lubrication model which couples the electrodynamic and hydrodynamic interactions in order to capture the formation and propagation of a spontaneous electrowetting film. Assuming a liquid with large dielectric constant, the electric field is largely confined to the liquid drop and film sitting on top of the line electrodes, as shown in Fig. 5. At the interface Γ the electric field is therefore predominantly tangential, and any normal field leakage into the ambient phase can be neglected:

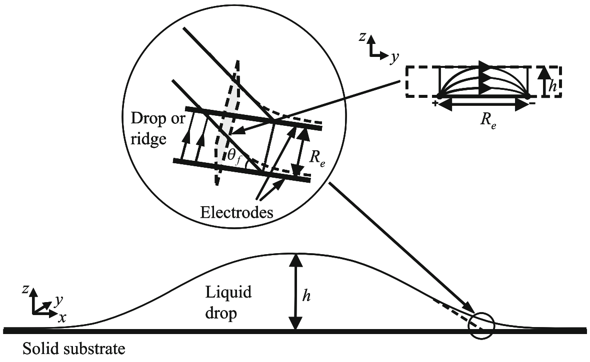
$$E_\mathrm{n}|_\Gamma = -\left.\frac{\partial\varphi}{\partial z}\right|_\Gamma = 0\,. \tag{12}$$

At the line electrodes, constant potential conditions apply:

$$\varphi|_{\Gamma_\mathrm{s}} = \pm\frac{V}{2} \quad \text{at} \quad y = \mp\frac{R_\mathrm{e}}{2}\,. \tag{13}$$

In the above, x, y and z are the streamwise, transverse and vertical coordinates, respectively, and, R_e is the electrode separation.

The solution of the Laplace equation in Eq. (7) describing the potential in the liquid phase subject to the boundary conditions given by Eqs. (12) and (13) then yields the following tangential interfacial electric field near the wedge



Electrowetting, Figure 5 Schematic depiction of the drop and film geometry for *spontaneous electrowetting* on parallel line electrodes. The inset shows a magnification of the contact line region in which the drop or the capillary ridge of the electrowetting film resembles a wedge-like geometry. A cross-section of this wedge and the transverse field lines arising due to the line electrodes, which resemble two point charges in this plane, is also shown [4]

tip as $h/R_e \to 0$, h being the film thickness:

$$E_t|_\Gamma = \frac{4V}{\pi R_e}\left(1 - \frac{8h^2}{R_e^2}\right) . \quad (14)$$

Given that $p_e \sim E_t^2$ and $h \sim (x_f - x)\tan\theta_f$, where x_f and θ_f are the position and contact angle of the advancing film front, the hydrodynamic pressure in the lubrication limit then reads

$$p = \gamma\frac{\partial^2 h}{\partial x^2} - \frac{8\varepsilon_0\varepsilon_1 V^2}{\pi^2 R_e^2}\left[1 - \frac{16\tan^2\theta_f}{R_e^2}(x_f - x)^2\right] , \quad (15)$$

from which we note that the hydrodynamics is enslaved to the electric field via the film thickness.

We therefore observe from Eq. (14) that the tangential field is maximum at the three-phase contact line where $h = 0$, and decays linearly along the interface away from the contact line at $x = x_f$. Unlike the *static electrowetting* case above, however, the field is non-singular in the contact line region and thus a macroscopic electric pressure gradient arises from the linearly decaying interfacial electric stress. It is this macroscopic electric pressure gradient that is responsible for a negative capillary pressure that forces liquid from the bulk into the contact line region, thus pushing out a thin spontaneous electrowetting film ahead of the macroscopic spreading drop. This is observed in the numerical results shown in Fig. 6a; we note the existence of a critical electric Bond number

$$B = \frac{8\varepsilon_0\varepsilon_1 V^2 L\tilde{L}}{\pi^2\gamma R_e^2 H} , \quad (16)$$

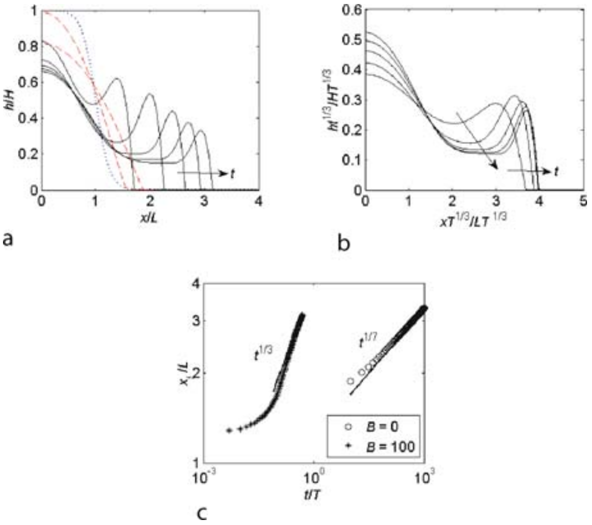
of approximately 10 for the formation of the electrowetting film. In Eq. (16), H and L are the characteristic height and length scales of the drop whereas $\tilde{H}$ and $\tilde{L}$ are those for the advancing film.

A dominant force balance between viscous and electric stresses at the contact line gives

$$\frac{\eta\tilde{U}}{\tilde{H}^2} \sim \frac{p_e}{\tilde{L}} , \quad (17)$$

where η is the viscosity, $\tilde{U} \sim \tilde{L}/T \equiv \gamma/\eta$ is the characteristic velocity of the film and T the time scale. It is possible to assume, consistent with the numerical results in Yeo and Chang [4] that the slope of the capillary ridge at the advancing front of the electrowetting film θ_f and the volume per unit width of the electrowetting film $V_f \sim \tilde{H}\tilde{L}$ are constant. From Eq. (15), the electric pressure gradient in Eq. (16) for constant θ_f then scales as

$$\frac{\partial p_e}{\partial x} \sim \frac{p_e}{\tilde{L}} \sim \frac{\gamma H B\tan^2\theta_f}{LR_e^2} , \quad (18)$$



Electrowetting, Figure 6 (**a**) Transient drop and film evolution profiles for electric Bond number $B = 100$ for five equal time steps up to $t/T = 0.5$, where $T = \tilde{L}/U$ is the characteristic time scale with $U = H^3\gamma/\eta L^3$ being the characteristic system velocity. The dotted line shows the initial profile and the dashed lines indicate the spreading drop due to pure capillary motion when no electric field is applied ($B = 0$) at $t/T = 1$ and 10. (**b**) Similarity behavior of the advancing electrowetting film with the collapse of the interface profiles in time by replotting the data in (**a**) using a similarity transform. (**c**) Time dependent position of the advancing front of the drop radius or the electrowetting film x_f/L [2, 4]

which, together with Eq. (17), leads to

$$\tilde{L} \sim \left(\frac{\gamma H B\tan^2\theta_f V_0^2 T}{\eta L R_e^2}\right)^{1/3} . \quad (19)$$

Since θ_f is constant, the electric pressure gradient in Eq. (18) is also constant for a specific electrode separation R_e and hence Eq. (19) rendered dimensionless has the following similarity scaling for constant V_0:

$$x \sim t^{\frac{1}{3}} , \quad (20)$$

t being the time. Equation (20) suggests that the electrowetting film advances in a self-similar manner for electric field induced spreading. This is shown in Fig. 6b in which the film height profiles in Fig. 6a are rescaled using the similarity scaling in Eq. (20). The dynamics of the film is also shown in Fig. 6c showing that the electrowetting film advances as $t^{1/3}$, much faster than the $t^{1/7}$ behavior at which the drop spreads by pure capillary action in the absence of any electrical stresses [4]. It should be noted that the $t^{1/3}$ self-similar spreading is analogous to the self-similar gravity-driven fronts first observed by Huppert in 1982. This is because the electric pressure gradient,

given by Eq. (18) for constant θ_f acts as a constant body force term similar to gravity.

A detailed similarity analysis of the constant volume electrowetting film gives a prediction for the position of the advancing film as a function of time:

$$x_f = 0.4\left[\frac{\varepsilon_0\varepsilon_1 V^2 R_e t}{\eta}\right]^{\frac{1}{3}} . \tag{21}$$

We note therefore that the film advances independent of the dimensions and dynamics of the bulk macroscopic drop. Equation (21) can also be expressed as

$$x_f = 0.43 R_e\left[\frac{t}{T_{cap}}\right]^{\frac{1}{3}} , \tag{22}$$

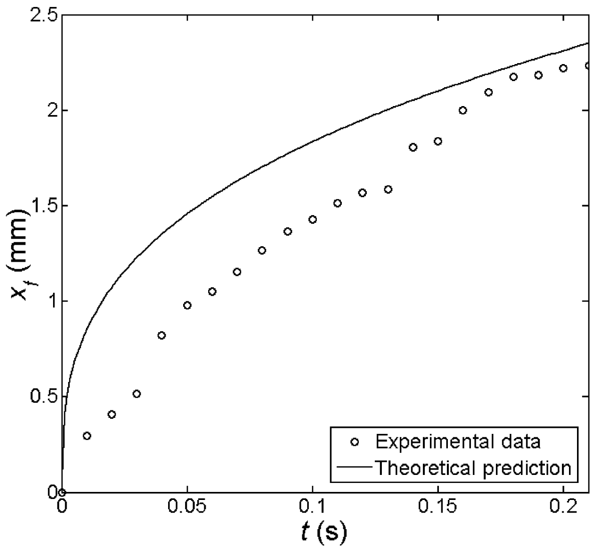
where

$$T_{cap} \equiv \frac{\eta L_{cap}}{\gamma} \equiv \frac{\pi^2 \eta R_e}{8\varepsilon_0\varepsilon_1 V^2} , \tag{23}$$

and

$$L_{cap} \equiv \frac{\pi^2 \gamma R_e^2}{8\varepsilon_0\varepsilon_1 V^2} , \tag{24}$$

are the electrocapillary time and length scales, respectively. Fig. 7 shows a comparison between the prediction given by Eq. (22) with data from the *spontaneous electrowetting* experiments of Ahmed et al. [11] for deionized water in which parallel line electrodes were employed, indicating close agreement without the need for any empirical fitting parameters.



Electrowetting, Figure 7 Position of the advancing electrowetting film front x_f as a function of time t showing the close agreement between the model prediction (solid line) and the experimental data of Ahmed et al. [11] without the need for empirical fitting parameters. The experiments were carried out for deionized water ($\eta = 1$ cp , $\varepsilon_1 = 78$, $V = 200$ V and $R_e = 40$ µm); these same values were utilized for the parameters in the theoretical model [2, 4]

Examples of Application

The ability to control the wettability of a liquid, ideally without mechanically moving parts, is paramount in the handling and actuation of fluids in microfluidic devices. This has prompted a recent resurgence in electrowetting studies, which allows a rapid, reversible, and precise means for delivering and manipulating very small volumes of liquid with relatively low power consumption [10]. The success in generating fluid velocities in excess of several cm/s has also attracted significant interest in electrowetting for other applications such as electrostatic-assist coating and miniature optical focusing devices.

Definition

Electrowetting employs an externally applied electric field to actuate or manipulate small volumes of liquid by altering its interfacial tension and hence the macroscopic contact angle or by inducing bulk liquid motion through an interfacial electric stress. Due to the low power consumption, electrowetting therefore affords an efficient, rapid, reversible, and precise means for actuating and manipulating very small volumes of liquid in microfluidic devices without the need for mechanical components.

Overview

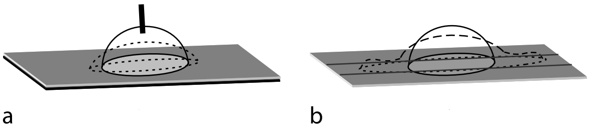
At microscale dimensions, the surface area to volume ratio, which scales as the inverse of the characteristic length scale of the system L, becomes increasingly large, thus stipulating the dominance of surface forces over body forces. This makes it extremely difficult to move and manipulate small volumes of fluid in miniaturized fluidic devices. Several schemes that exploit Marangoni (surface tension gradient) and thermocapillary (temperature gradient) stresses to control the interfacial energy and hence drop motion have been proposed. Nevertheless, these suffer from several limitations in terms of reliability, controllability, response times and compatibility.

In contrast, the use of electrokinetics has generally been heralded as the preferred method for microfluidic manipulation due to the ease/low costs of electrode fabrication given the recent advances in micro/nano-fabrication technology, the precision and controllability afforded by electric fields, and, the reliability in the absence of mechanically moving parts. Electric field driven actuation is also rapid since the limitation is usually imposed by the hydrodynamic time scale $\mu_l L/\gamma \sim 10^{-4}$ s, which is typically larger than the time scale for charge separation $\varepsilon_0\varepsilon_l/\kappa_l \sim 10^{-6}$ s; μ_l, $\varepsilon_0\varepsilon_l$ and κ_l denote the liquid viscosity, permittivity and conductivity, respectively, and γ is the interfacial tension. As such, the use of electrowetting, in which an external electric field is exploited to modify the wettability of the drop through a change in its interfacial tension or by inducing bulk motion through an interfacial stress, has become increasingly attractive as a means for microfluidic actuation and manipulation.

Yeo and Chang [1, 2] proposed that electrowetting phenomena can, in general, be classified into *static electrowetting* and *spontaneous electrowetting*, depending on the electrode configuration adopted. Static electrowetting, in which the drop sits above a planar dielectric coated plate electrode (synonymous to the configurations employed in electrowetting-on-dielectric (EWOD) or electrowetting on insulator coated electrodes (EICE); see, for example, Fig. 1a), involves the alteration of the macroscopic contact angle of the drop due to the applied electric field. It was shown in [1] through an analysis of a conducting drop that the dominant gas-phase electric field endows the drop interface with an interfacial charge and hence normal interfacial electric stress that is weakly singular towards the three-phase contact line. Nevertheless, due to the confinement of this singularity in a very small region, of the order of the dielectric coating thickness (typically microns), the interfacial stress is insufficient to result in a bulk pressure gradient in the liquid; an electric force, which can be obtained by coarse graining, simply arises at the contact line that balances the surface forces. This is shown to give rise to a modification of the macroscopic contact angle of the drop θ which obeys the Lippmann condition:

$$\cos\theta = \cos\theta_0 + \frac{\varepsilon_0\varepsilon_l V^2}{2d\gamma_{LV}}, \tag{1}$$

where θ_0 is the equilibrium contact angle in the absence of the electric field, V the applied voltage, d the dielectric coating thickness and γ_{LV} the liquid–vapor interfacial tension.



Electrowetting, Applications, Figure 1 Schematic illustration of (**a**) static electrowetting in which the applied electric field induces a macroscopic change in the contact angle, and, (**b**) spontaneous electrowetting in which a thin front-running electrowetting film is pulled out and advances ahead of the macroscopic spreading drop. The film thickness in (**b**) is not drawn to scale

Spontaneous electrowetting, on the other hand, arises when a thin front-running electrowetting film is pulled out and advances ahead of the macroscopic drop when parallel line electrodes are employed [2, 3], as shown in Fig. 1b. This has been termed electrowetting on line electrodes (ELE). In [2], the electric field in the liquid phase is dominant and gives rise to a non-singular tangential interfacial electric stress that decays away from the contact line with increasing interfacial height. This electric stress gradient consequently gives rise to a negative macroscopic pressure gradient that induces liquid flow from the bulk of the drop towards the contact line region, therefore pushing out a thin spontaneous electrowetting film ahead of the macroscopic drop, which advances with a constant contact angle self-similarly in time t as

$$x_f = 0.43 R_e \left(\frac{t}{T_{cap}} \right)^{1/3} , \tag{2}$$

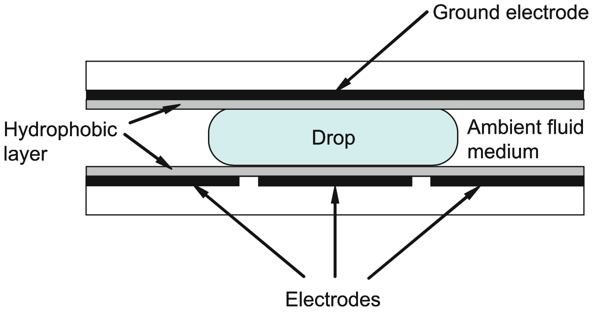
independent of drop dimension, interfacial tension or wettability; x_f is the position of the advancing front, R_e the electrode separation and

$$T_{cap} = \frac{\pi^2 \mu_1 R_e}{8 \varepsilon_0 \varepsilon_1 V^2} , \tag{3}$$

is the electrocapillary time scale.

Basic Methodology

The majority of effort in developing applications based on electrowetting has largely centered on static electrowetting processes. As a result, the motion is essentially in the form of discrete steps rather than a single continuous process as in spontaneous electrowetting. In general, these static electrowetting schemes for moving and manipulating individual drops in open systems have collectively been described by the term *digital microfluidics* in order to provide a distinction to microfluidics systems involving continuous flow within closed microchannels. Less common is the use of the synonymous term *flatland microfluidics*. Although digital microfluidics is perhaps not particularly useful for continuous flow analysis, and particularly that involving larger liquid volumes, discrete drop microfluidics allows the possibility of scalability and reconfiguration such that analyses can be carried out in similar fashion to traditional benchtop protocols [4]. Besides, drops are often useful as carriers for biological entities and hence different biological agents can be transported separately in different drops without coming into contact with the other providing the drops never meet. Digital microfluidics also has the advantage of minimizing the amount of liquid required as well as



Electrowetting, Applications, Figure 2 Schematic depiction of a typical static electrowetting setup for drop actuation in a microfluidic device

the contact between the liquid and solid surface. The latter is crucial in applications, most commonly those that involve biomolecules, in which surface adsorption is undesirable [5]. Protein adsorption is commonly due to electrostatic interactions and the degree to which it occurs is dependent on the charge, polarity on the protein as well as the applied voltage [6]. The open system also eliminates the attenuation of detection signals through channel walls although it is prone to contamination and evaporation. A possibility to circumvent the problem due to evaporation is to house the system within an oil medium, which has been found to also suppress adsorption.

Practical static electrowetting schemes typically involve the use of a patterned array of multiple electrodes, each of which can be individually controlled, as shown in Fig. 2; note that the use of a wire electrode in contact with the drop in the usual EWOD/EICE setup in Fig. 1a is impractical due to the moving drop. The drop should also span across two electrodes at any one time to facilitate continual discrete motion [7]; the smallest liquid volume that can be manipulated is therefore constrained by the electrode size. The activation and subsequent deactivation of an applied potential across one electrode in the array and the ground electrode (top electrode plate in Fig. 1), then allows the drop to march forward discretely towards the next electrode in the array sequence which is then subsequently activated (and then deactivated again) to translate it forward to yet the next electrode. The programming of a sequential logic scheme for the activation/deactivation of individual electrodes then allows the drop to be translated in a desired direction. Increasingly complex control schemes have since been proposed to perform more complicated and sophisticated tasks such as drop splitting, recombination and mixing. This therefore allows applications in widespread areas, although efforts have largely concentrated around two major areas, i. e. microfluidic Lab-on-a-Chip devices as micro total analysis systems (μTAS) and electro-optic devices.

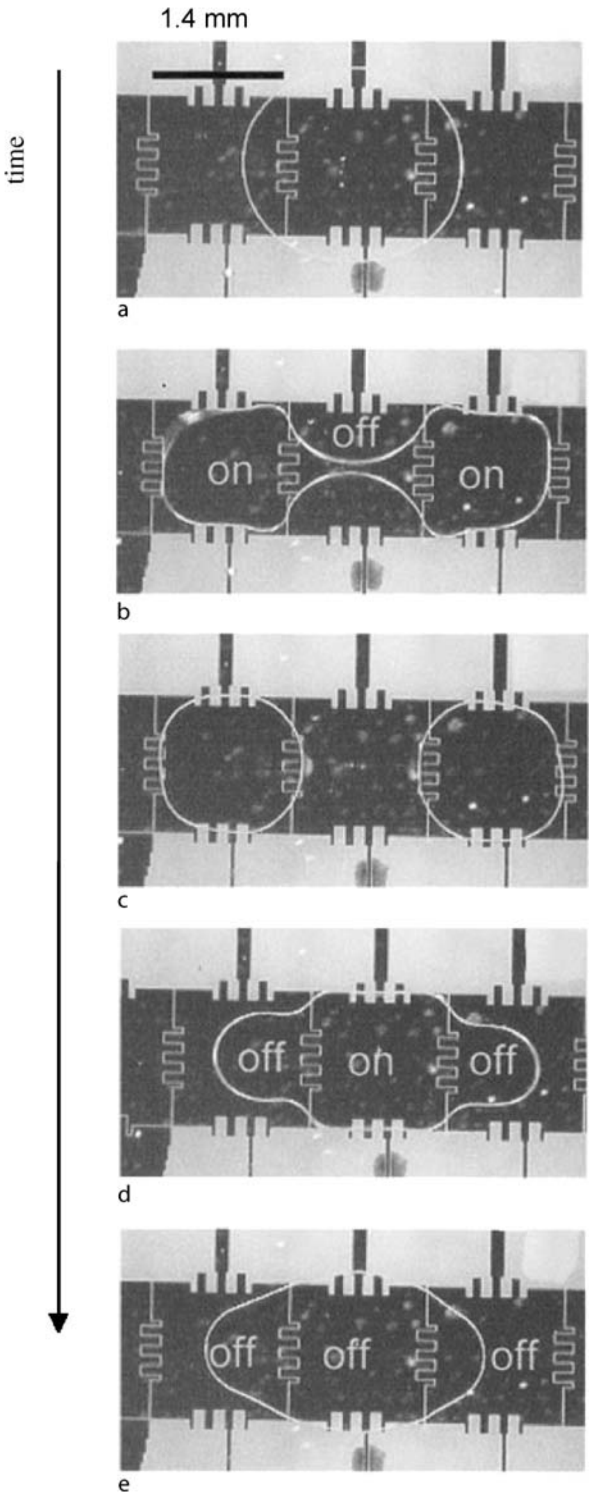
Key Research Findings

Microfluidic Components for Lab-on-a-Chip Devices

Electrowetting is most commonly used in Lab-on-a-Chip devices for microfluidic actuation and manipulation. In a typical system, very small amounts of analytes are metered into drops which are then transported, for example, to a reaction chamber where they are merged for the reaction to occur. Successive reactions can also be performed by merging drops containing intermediate reaction products. Parallel manipulation or detection can also be carried out by splitting the drop into smaller droplets [4]. All of these drop operations, namely, metering, translation, merging and splitting, can be carried out using static electrowetting schemes.

Early work on static electrowetting for these microfluidic applications focused on these individual tasks separately. These initial efforts were concentrated on driving a conductive drop through an open channel using electrowetting. The setup is similar to that shown in Fig. 2. The channel however is required to be open for positioning of the drop within, which required a fair amount of precision, and the filling of the medium around the drop; the channel could later be closed by employing a cover slip. Lee and Kim [8] employed a liquid metal drop surrounded by a liquid electrolyte medium. In this case, however, the electrodes were positioned at the end of channel instead of comprising the top and bottom plates. Although they termed their setup *continuous electrowetting*, the use of electric fields to change the macroscopic liquid metal–electrolyte contact angle is more akin to the classical electrocapillary experiments [1]. In any case, however, their work culminated in one of the first demonstrations of drop transport in a miniaturized fabricated device. An extension of this work is the fabrication of a 2 mm circular loop track along the periphery of which several electrodes are embedded in order to drive the drop around the track at rotation speeds up to 420 rpm with an operating voltage of 2.8 V. A similar demonstration is reported in Pollack et al. [7] with electrolyte drops within an air or oil medium. Drop translation with speeds over several cm/s were obtained with applied voltages of 1 – 100 V.

Elegant protocols for drop metering, splitting and merging were later proposed by Cho et al. [9]. The drop splitting process is illustrated in the image sequences given by Figs. 3a–3c. Of vital importance in order for the drop to split is the necking (negative radius of curvature at the neck position R_n) and rupture (when the drop radius of curvature at its ends, which is proportional to the drop size and roughly commensurate with the electrode width R_t, become equal, i. e. $R_n = -R_t$) processes, which, can be caused by removal of the voltage on the middle elec-



Electrowetting, Applications, Figure 3 Drop surgery by programmable static electrowetting protocols. The voltage on and voltage off states of individual electrodes are indicated. Images (**a**), (**b**) and (**c**) depict drop splitting whereas images (**c**), (**d**) and (**e**) show drop merging (from [9])

trodes. For necking to occur, however, the ratio of the channel height to the drop radius of curvature at its ends h/R_t needs to be below a critical value; this critical value itself increases as the ratio $|R_n|/R_t$ increases [9].

The procedure for drop metering from a reservoir is related to the drop splitting process. Again, this is facilitated by smaller channel heights and smaller drop reservoirs. Figure 4 shows the drop metering process; lateral electrode arrays are required to hold the drop reservoir in position whilst the electrodes ahead of the reservoir are activated in order to pull a drop out from the reservoir. By turning off the electrodes in the middle, necking occurs to split the drop from the reservoir. For the entire reservoir to be drained, however, the surface of the reservoir must be rendered hydrophobic [9]. The merging of drops, on the other hand, can be carried out by translating the drops together such that coalescence occurs by removing the voltage on the electrodes beneath the drops and activating the electrode between the drops [9]. This is shown in Figs. 3d and 3e.

Other microfluidic components have also been developed using static electrowetting. An electrowetting-actuated valve was proposed by Cheng & Hsiung [10]. A hydrophobic layer comprising plasma-modified poly(tetrafluoroethylene) was coated onto the channel to prevent through-flow; the plasma modification served to reduce the hydrophobicity of the poly(tetrafluoroethylene) slightly so that upon modification of the advancing liquid meniscus contact angle via an electric field, through-flow can be obtained.

Electrowetting-based platforms have also been proposed as a convenient means for driving micro-mixing of discrete drops of different chemicals. The simplest form of such mixing is to adopt a passive scheme in which two drops are translated together and merged by electrowetting using the procedures described above. However, it is also possible to induce active mixing after the coalescence event in order to reduce the mixing time. A straightforward way is to oscillate the merged drop between two or more electrodes in a linear arrangement at a fixed frequency. Paik et al. [11] observed that the mixing times decreased with increasing number of electrodes and the switching frequency (inverse of the time that the drop is present on one electrode), both of which increases the complexity of the flow recirculation within the drop. Electrowetting-driven mixing of ionic liquids containing different reagents was investigated by Dubois et al. [12]. These ionic liquids which have negligible vapor pressure are environmentally-friendly alternatives to the volatile organic solvents commonly used in chemical synthesis which are subject to evaporation problems in open microfluidic systems and problems due to oil/solvent miscibility and cross-contamination when the

Electrowetting, Applications, Figure 5 Electrowetting based integrated microfluidic device for glucose assays (from [15])

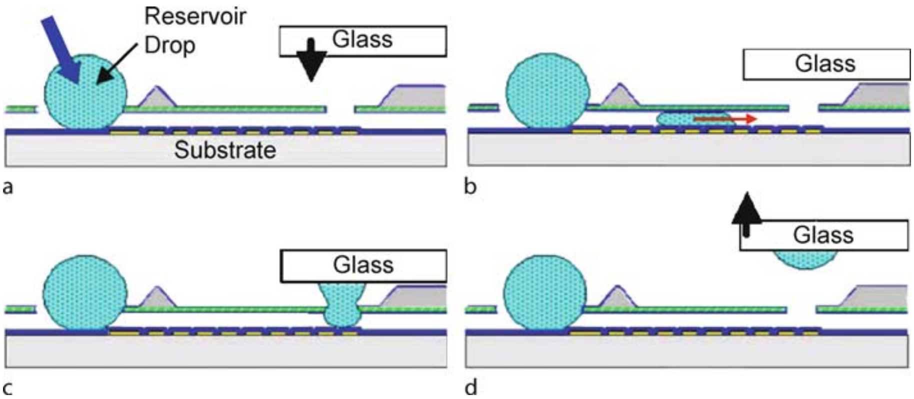
drop analysis carried out under an oil layer to minimize evaporation.

These various drop actuation and manipulation schemes and microfluidic components have been integrated into more complex devices to perform multiple chip based tasks. Pollack et al. [13] employed a combination of electrowetting-driven microfluidic components for drop dispensing, actuation and merging/splitting to discriminate alleles with single base pair variations on an integrated polymerase chain reaction (PCR) microchip. Srinivasan et al. [14] developed an electrowetting-based microfluidic chip platform to perform glucose detection via colorimetric enzyme kinetics. The glucose assay consisted of three steps, namely, dispensing, mixing and detection; dispensing was carried out by manual pipetting, drop translation leading up to mixing by electrowetting and detection by measuring the absorbance signal corresponding to the color change in the system subsequent to an enzymatic reaction.

A more complex and integrated prototype miniaturized medical diagnostic platform based on electrowetting, as shown in Fig. 5, was engineered by Srinivasan et al. [15], in which it was confirmed that electrowetting actuation can be carried out, at least in principle, reliably and with a high degree of reproducibility on physiological liquid samples such as a whole blood, saliva, sweat, plasma, serum and urine. Biocompatibility issues, and, in particular, the problem of protein adsorption was discussed, in which it was found that a thin oil film wetting the hydrophobic substrate to avoid direct drop/surface contact led to suppression of the undesirable adsorption effects.

The highly programmable and controllable handling of individual drops using electrowetting lends itself conveniently to various microarray technologies. One example is the possibility of microfluidic chip multistep synthesis or multiplex reactions for high throughput combinatorial drug screening [16]. Another example is the preparation of drop arrays for matrix assisted laser desorption/ionization (MALDI) mass spectrometry proteomic analysis [17].

A way of spotting these microarray patterns onto a substrate is proposed by Yi and Kim [18] who drew out a drop from a liquid reservoir, transported it through a hydrophobic channel by electrowetting to a location where it can be deposited by capillarity onto the desired hydrophilic substrate, as shown in Fig. 6. They termed this as *soft printing* because biological materials contained within a liquid drop acting as a carrier can be spotted on a substrate without requiring solid to solid contact or drop ejection, for example, mechanical spotting or ink-jet printing, which are associated with problems such as splashing and spreading that lead to non-uniformities in the spot shape and size. Multiple spots can be achieved with multiple orifices at



Electrowetting, Applications, Figure 6 Illustration of the *soft printing* process. (**a**) Loading of the sample and approach of the glass plate on which the drop is desired to be spotted. Electrowetting, Applications, Figure 7 Experimental setup of the *microchannel-like* flow type electrowetting device of Satoh et al. [19]. Panels (**a**) and (**b**) are cross-sectional views of the electrode and flow channel geometry, and, panel (**c**) shows the architecture of the device (from [19])

predetermined locations, the size of the spots being controlled by the metered drop volume.

We briefly mention an attempt to employ electrowetting to drive *microchannel-like* flow as opposed to individual drop translation by using arrays of elongated electrodes (Fig. 7) instead of the short electrode array shown in Fig. 2 [19]. Their setup consisted of a large reservoir, from which a liquid meniscus advances, much like the electrocapillary-driven height-of-rise experiments between two vertically oriented electrode plates [20]. However, by adopting horizontal channels, gravity is eliminated allowing the meniscus to advance much easier. The advancement of the meniscus front, however, remains discrete unlike true continuous microchannel flow, for example driven by electroosmosis. This is due to the need to sequentially activate successive electrodes, as in all static electrowetting schemes. The setup was subsequently extended to allow for two converging flow channels such that mixing could occur [21]. An additional electrode was employed where the two flows converged, as shown in Fig. 8. Upon activation, this mixing electrode causes both fluids to wet the area above it in order to drive the mixing. An ammonium detection component was also integrated into the device by introducing a third channel that drove an electrolyte solution towards the mixing area (Fig. 8c), which is separated from the electrolyte by an air gap. Ammonia gas released due to the mixing then diffuses across this air gap and into the electrolyte solution, thus increasing its pH, which is subsequently detected by a pH indicator electrode.

Electrowetting has also been proposed for inducing rapid reversible switching of the lateral position of a liquid stream flanked by two side gas streams in a microfluidic channel, as depicted in Fig. 9 [22]. By careful alignment of the electrodes housed under the microchannel substrate, fluid streams can be merged or split using this method. This is potentially useful in the control and sorting of two-phase microfluidic flows. Another potential application for this flow switching technique is for generating parallel and sequential lamination between streams for micro-mixing without requiring complex fabricated geometries.

Electro-Optical Applications

Static electrowetting techniques are also extremely attractive for many electro-optical devices. Electrowetting was first employed in these applications for the dynamic and latchable tuning of optical waveguides [23, 24]. In these fiber optic applications, electrowetting is employed to alter the amount by which a conducting fluid (the choice of which is contingent on its viscosity being sufficiently low and its refractive index being greater than that of the fiber) housed in an insulating lubricant medium surrounds a section of an optical fiber stripped of its coating which runs through the fluidic channel loop; the loop allows fluid recirculation to eliminate back pressure. This voltage adjustable overlapping then modifies the transmission characteristics of the fiber due to electromagnetic field leakage of the cladding resonance modes, obtained with the aid of in-fiber gratings, into the fluid. Mach et al. [22] reported attenuation beyond 45 dB across both narrow and broad bands at 10^{-3} s order switching speeds; the insertion losses, attributed to mechanical coupling between the fiber and the light source and spectrum analyzer with the use of a fusion splice, were observed to be approximately $2-3$ dB.

The ability to alter the interfacial shape of the drop via the application of an external electric field thus allows it to be used as an adaptive liquid lens whose focal length can be flexibly, reversibly and accurately adjusted via manipulation of the drop shape. The optical microcell consisted of two density-matched immiscible liquids (low conduc-

Panel (**c**) is a magnification of the mixing and sensing chambers in which ammonia is detected (from [16])

tivity non-polar organic liquid drop under a conducting aqueous solution) to eliminate gravitational effects on the interfacial shape. As a consequence of the contact angle dependence on the applied voltage, the focal length and refractive power is also a function of the voltage. Berge and Peseux [25] observed very short response times which thus allowed the lens to be switched rapidly at typical frequencies of order $10^2 – 10^3$ Hz. This switching frequency is dependent on the liquid viscosity; liquids with low viscosity resulted in excessive oscillation prior to obtaining an equilibrium shape whereas extremely viscous liquids led to overdamping and hence slow response times. This variable focusing technology was later developed for specific applications such as mobile phone cameras [26] although other applications such as optical modulators and amplifiers are also envisaged [27]. Photopolymeric conductive liquid drops can also be used in order to solidify the drop and hence retain its drop interfacial shape in a fixed position through exposure to ultraviolet irradiation [28].

Another interesting electro-optical application that has been developed using static electrowetting is in display technology. This idea was initially proposed in the 1980s by Beni and Hackwood [29] although a demonstrable prototype concept was only produced in 2003 by Hayes and Feenstra [30]. The principle is illustrated in Fig. 10a. A dyed oil drop under a transparent aqueous solution is confined within a cell that represents a single pixel in the reflective display; the cell is placed atop a white substrate. A hydrophobic layer is coated at the bottom of the cell such that in the absence of an applied potential, the oil forms a thin equilibrium layer covering the entire cell area. Upon application of the electric field, however, the contact angle increases and the oil film retracts to form a drop in the corner of the cell. The extent to which the drop retracts is thus dependent on the applied voltage. The 250 μm^2 pixels are also believed to be sufficiently small such that an area average is only apparent to the observer; the retracted spot should therefore go unnoticed. The pixel can thus be switched between the colored (voltage on) and transparent (voltage off) states rapidly, the switching speed, typically milliseconds, depending on pixel size and the thickness and physical properties of the oil film [31], being sufficiently fast for current display applications, such as video graphics and electronic paper.

An electrowetting colored display was also demonstrated by subdividing the pixel cell into three subcells, as shown in Fig. 10b, above each of which a different color filter is placed. An additional oil layer/drop is included in each pixel, this time on the top of the cell, the interfacial shape of which can be altered independently of the bottom layer through the application of a potential between the aqueous phase and the top electrode. Hayes and Feenstra [30] reported that the brightness (in terms of intrinsic reflec-

Different color filters are placed above each subcompartment (from [30])

tivity) of their full color display was approximately four times that of liquid crystal displays.

Other Applications

Various other applications based on static electrowetting have also been suggested. For example, Welters and Fokkink [32] propose that the spreading of drops due to static electrowetting is useful for temporary adhesion enhancement (e. g. in the drying of paint) or as a fast capillary switch. Prins et al. [20] demonstrated the use of electrically-induced capillary height-of-rise for the individual filling and draining of an array of vertical capillary channels. They demonstrated this by adding CsCl into the aqueous solution, which has the capability of absorbing X-rays, therefore presenting the capability of the device as a tunable optical filter, which can be exploited for X-ray shielding.

Applications Based on Spontaneous Electrowetting

Compared to static electrowetting, spontaneous electrowetting research is still in its infancy stages. Nevertheless, the technology holds substantial promise to be exploited in various microfluidic applications. The premise of generating a thin spontaneous front-running electrowetting film ahead of a macroscopic spreading drop using parallel line electrodes fabricated onto a hydrophobic substrate was first reported by Jones et al. [3] as a possible mechanism for microfluidic actuation. With slight

modification of the electrodes at predetermined locations downstream, Jones et al. showed the possibility of creating nanodrops at these locations upon removal of the electric field, upon which the film ruptures and dewets due to capillary instabilities [3].

Future Directions for Research

Given that electrowetting is now moderately well understood, the main thrust in this area of research has been in the development of microfluidic and electro-optical devices based on the technology. There are one or two electrowetting driven electro-optical devices now within reach of commercial product development stage. Nevertheless, there are several technical challenges that have to be addressed before most electrowetting based devices can be translated from laboratory bench type devices to that close to commercial realization. An important limitation is contact angle saturation at high voltages; at present there is no general consensus on why this arises. Joule heating is a problem that needs to be overcome, in particular, for microdevices. In addition, a reduction in typical magnitudes in the applied voltage to obtain the desired response will make electrowetting more attractive for integration into real microfluidic devices.

Definition

Electrowetting is the electrostatically-induced decrease of the liquid contact angle at a contact line formed at the intersection of a liquid, solid, and a third fluid that can be a gas or immiscible liquid. The contact angle is measured within the droplet between the solid surface and the fluid–fluid interface. It ranges from 0 for complete wetting to 180 degrees for non-wetting. As applied to droplets, electrowetting can be used to spread droplets, change the shape of droplets, induce shape-mode oscillations, split droplets, move droplets across the surface, and merge and mix droplets.

Overview

Electrostatic manipulation of droplets has been utilized for ink-jet printing, ESI mass-spectrometry and flow cytometry applications. In contrast to these droplet-in-air applications, electrowetting involves the electrostatic manipulation of droplets attached to solid surfaces. Applications that utilize this method include micro-optofluidic manipulations of droplets to serve as electrically-controlled zoom lenses [1, 5] and as shutters or color filters for flat panel displays [4]. Another application is in performing biological and chemical assays by manipulating sample and reagent droplets using electrowetting [9, 10]. Thus, electrowetting of droplets on surfaces is viewed as a method that may provide a Lab-on-a-Chip (LOC) platform to replace the use of pipettes, glass beakers, tubes, pneumatic and piezoelectric automated dispensers, as well as standard (as defined by Society for Biomolecular Screening (SBS)) wells and plates in the laboratory.

The focus of this entry is on some unique physical characteristics of electrowetting applied to droplets. In particular, electrowetting-induced droplet shape changes, mixing, and droplet translation are discussed and some novel results involving shape-mode oscillations with and without simultaneous droplet translation are presented.

Basic Methodology

Shape Changes

Electrowetting can be used to manipulate the curvature of a droplet immersed in an immiscible fluid. As described by researchers from Varioptic [1] and Philips [5], this change in curvature can provide a lens with a variable focal length. Varioptic (www.varioptic.com) reports that zoom lenses and autofocus lenses for cameras and video cameras used in cell phones, scanners, printers, barcode readers and other applications are being developed using electrowetting to adjust the curvature of the meniscus between two fluids. The engineering of a system of this type, an example of which is shown in Fig. 1, requires that fluids be selected with appropriate optical properties, appropriate temperature dependence of the refractive indices and viscosities appropriate to provide rapid response and stability of the meniscus shape. If the viscosity is too low, a change in the contact angle will cause a time-decaying oscillation of the shape corresponding to underdamped motion. However, if the viscosities are too large, the system may respond in an overdamped manner that relaxes too slowly to be acceptable for use as an adjustable lens.

Another application of electrowetting control of droplet shapes is within a pixel of a flat panel display. As described by researchers from Liquavista, a VC-backed spin-out company from Philips, electrowetting can be used to spread water over a pixel to displace colored oil into a corner of the pixel [4]. With an array of pixels of this type, a flat panel video display can be generated as shown in Fig. 2. This approach is well-suited to monochrome displays and triplet sub-pixelation can be used to gener-

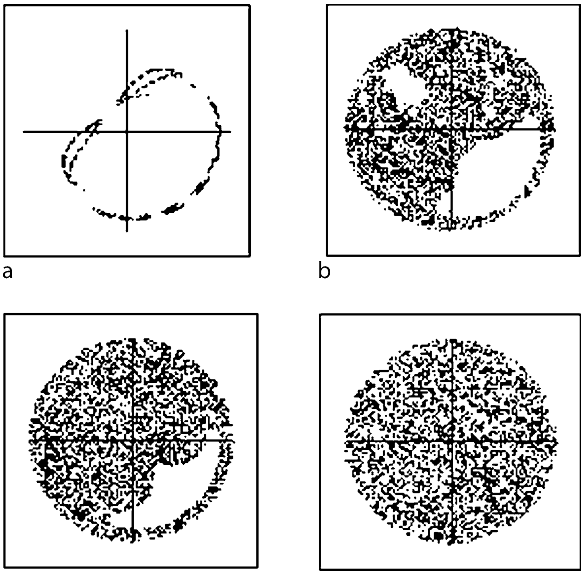
Electrowetting and Droplets, Figure 3 Flow field model for droplet motion in a square pattern. The actual three-dimensional electrowetting flow will be substantially different than this model but is expected to display similar chaotic advection with dependence on the period of the cycle. The flow model here is a time-dependent, high Peclet-number (low diffusion), two-dimensional Marangoni flow where the surface tension around the droplet periphery is varied in four phases: (**a**) for the first quarter of cycle $\sigma = (\sigma_1 + \sigma_2)/2 - (\sigma_1 - \sigma_2)\cos(\theta)/2$; (**b**) for the second quarter $\sigma = (\sigma_1 + \sigma_2)/2 + (\sigma_1 - \sigma_2)\sin(\theta)/2$; (**c**) for the third quarter the expression in (a) is used with σ_1 and σ_2 swapped; and (**d**) same as (b) with σ_1 and σ_2 swapped

ate a palette of apparent colors as used in current RGB schemes. An improved design allows the use of 3-layers of Cyan, Magenta, and Yellow oil dyes that can each be displaced to provide a broad range of colors without requiring any sub-pixelation.

Fluid Mixing

Upon coalescence of two droplets, the fluids from each droplet remain unmixed unless flows are generated within the newly-formed droplet in some manner. Internal flows and mixing can be induced through evaporation [3] which may also lead to thermal gradients and natural thermocapillary flows, but here we consider two electrowetting-induced mixing strategies that have been developed to accelerate the mixing process.

The first involves using an array of electrodes to move a droplet across a surface to generate fluid motion within the droplet. Using this approach there are two droplet movement patterns that have been considered: the droplet can be moved back-and-forth many times [7] or it can be moved in a square pattern on the array. The results of Paik et al. indicate that approximately 50 to 100 cycles of back-and-forth motion over a distance of 2–4 droplet diameters are required to obtain complete mixing. The type of flow generated by droplet movement through a square pattern can be modeled by the flow field shown in Fig. 3, which is a model flow within a two-dimensional, circular, viscous drop with non-uniform surface tension along its boundary generating the internal flow. The driving is switched periodically in time to generate the sequence of flows shown in the figure. This sequence of flows can result in chaotic advection of particles to provide thorough mixing. If the position of a single tracer particle is plotted after each complete cycle, a Poincaré map showing the basin of attraction of the particle can be generated.



Electrowetting and Droplets, Figure 4 Poincaré maps of a single tracer particle location after each of 6400 periods of square pattern motion. The period of a complete cycle of the 4 flows from Fig. 1 is called T. Since we consider the droplet translation speed to be fixed, T can also be considered to be the size of the square pattern. The figures represent the Poincaré maps for four different periods of switching (**a**) $T = 4$, (**b**) $T = 8$, (**c**) $T = 9$, (**d**) $T = 10$

The maps shown in Fig. 4 demonstrate that, with convective flows alone (no diffusion), a particle can be made to visit any location within the droplet if the switching period is long enough. Mixing is quantified by tracking an initial swarm of particles whose population moments are observed to approach the completely-mixed values over time. The main result found using this model flow is that as the period increases, the number of cycles required for complete mixing decreases. However, as the period becomes long, corresponding to droplet motion over many droplet diameters, we find that no further reduction in the number of cycles for complete mixing can be obtained. The result is that further increases in the period proportionally increase the time for mixing.

The second method of mixing is through the generation of internal flows by the excitation of surface capillary waves. Mugele's research group has identified a condition of droplet oscillation in which a sessile droplet periodically attaches and detaches from a ground electrode wire whose axis is perpendicular to the surface of an EWOD chip. Through visualization of a fluorescent dye in the droplet, vertical mixing structures have been observed and mixing has been characterized [6]. We have generated similar oscillations of droplets using a unique *grounding-from-below* design for which a sessile droplet on an EWOD chip is grounded by a grid of microfabricated gold lines deposited after the dielectric so that good electrical contact with the droplet is maintained [2]. Application of an alternating current to the drive electrodes at an appropriate frequency is observed to generate large amplitude droplet motion. Improvements in mixing over a sandwiched-droplet configuration are described. The research results in the following section describe the details of the droplet shape-modes that are excited by application of an alternating potential.

E

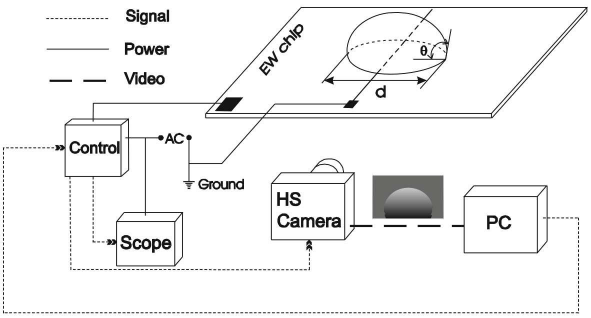
Key Research Findings

The frequencies of the various Legendre modes of oscillating spherical droplets of liquid were first described by Lord Rayleigh [8] as

$$\omega_n = \sqrt{n(n-1)(n+2)\left(\frac{\gamma_{SV}}{\rho R^3}\right)}, \quad n = 2, 3, \ldots$$

where γ_{SV} is the liquid–vapor surface tension, ρ is the density of the liquid, and R is the radius of the droplet. He noted the interesting result that the oscillation of a droplet of water at 1 Hz requires a droplet radius of almost exactly 1 inch. This result is directly analogous to a mass-spring mechanical system in which the restoring force is surface tension which tends to force the droplet towards the unperturbed spherical shape. For a droplet attached to a surface, modes associated with even values of n in the above equation can be excited with the surface representing a plane of symmetry. This is a good approximation to the actual droplet shape if the contact angle remains close to $\pi/2$ and viscous boundary layers (i. e., the oscillatory Stokes layers) are thin.

In order to study the shape oscillations of a sessile drop, the experimental setup shown in Fig. 5 was designed and



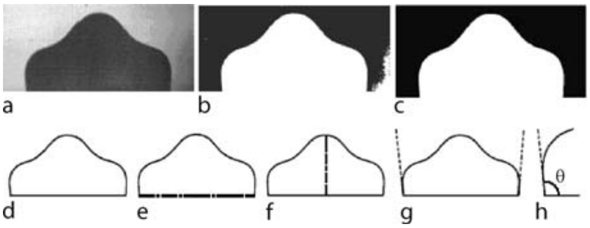
Electrowetting and Droplets, Figure 5 Experimental layout for electrowetting-induced droplet shape-mode oscillation experiments showing electrowetting chip, high-speed camera, and driving signal-generation system

assembled. The setup consists of an electrowetting chip, high-speed imaging unit and electronic timing devices. Forcing by AC signals was provided by a power-supply (California Instruments model 351-TL) with an output voltage of 60 V RMS and frequencies ranging from 1 to 4000 Hz. Imaging was performed using a Photron Inc. FASTCAM-X 512 PCI 10-bit high-speed camera. Typical imaging speeds were 2000 and 4000 frames per second depending on frequency of oscillation. Imaging was performed within a 512×256 pixel window corresponding to a 3.8 by 1.9 mm field of view. The field of view was illuminated using two 150 W fiber optic lamps illuminating a white screen behind the droplet resulting in high contrast between the droplet and the background screen. To avoid excessive heating of the droplet and light scattering from the surface of the drop, a tent-shaped shield made from regular paper was positioned over the droplet (not shown in Figure). To synchronize the excitation voltage, signal measurement and high-speed imaging during the oscillation of the droplet, triggering software was developed using LabVIEW™. The diameter, contact angle and maximum height were obtained using image processing techniques and were correlated for the entire duration of the oscillations. Typical activation time of the electrodes was 0.1 – 0.2 ms corresponding to 400 – 500 acquired frames.

The electrowetting chip used for excitation of the droplet was made of a 2.5 cm long by 2.5 cm wide glass slide covered by 120 nm of Indium Tin Oxide (CG-51IN-3084 from Delta Technologies). A 1 μm layer of Paralyne C (Cookson Electronics) was deposited using chemical vapor deposition to create the dielectric layer. Chromium/gold electrical grounding lines were patterned with a photolithographic lift-off technique on the dielectric. The entire surface of the chip was coated with 120 nm Teflon-AF (601, 6%, Dupont) diluted in a perfluoro-compound (FC75, Acros) creating a hydrophobic surface. The entire surface of the ITO-coated glass was considered one single electrode on which droplets were positioned. Grounding was performed via *grounding-from-below* as described in [2] through the ground line shown schematically in Fig. 5.

As seen in Fig. 6, excitations of the mode for $n = 6$ are shown for four phases during a cycle of oscillation of a 7 μL sessile droplet. Although the alternating current is applied at 180 Hz, the effective forcing is at 360 Hz in accordance with the Young–Lippman equation which describes that the electrowetting-induced changes are driven by the *square* of the applied voltage. Rayleigh's equation for $n = 6$, a 14 μL droplet (to include the reflection across the surface plane of symmetry of the 7 μL droplet) and surface tension equal to 73 mN/m indicates an oscillation frequency of 364.4 Hz. Thus we were forcing the droplet very close to this natural mode frequency.

The boundary of the droplet at any time (i. e., from an image frame) was determined through an automated image processing script. Fig. 7 demonstrates different stages of



Electrowetting and Droplets, Figure 7 Boundary detection scheme applied to the acquired images. Raw images (**a**) are converted to gray-scale (**b**) and threshold filtering to get rid of noise (**c**). Subsequent to detection of the droplet boundary (**d**), diameter, maximum height and contact angles are estimated (**e**) to (**h**)

the image processing technique for individual frames. First, the frame was converted to a gray-scale image. Using a threshold value, the image was then converted to black-and-white based on a comparison of each pixel to the threshold. The border of the largest, contiguous, white region within this image was determined to be the boundary of the drop. To determine the width of the drop, a pixel sweep was performed for the left-most and right-most points on the boundary at the bottom of the drop. The difference in the resulting values represented the width of the drop. The height of the drop was determined to be equivalent to the value of upper-most point of the boundary which intersects the center of the width of the droplet. Contact angles were found by selecting all the left-most points and all the right-most points on the boundary of the drop between the bottom of the drop and 25 pixels (~ 0.2 mm) above the contact line. A linear fit was performed on both sets. The slope of each line represented the left and right side contact angles. Spectral analysis of the time series of these droplet height, radius and contact angles show the dominant response of the droplet at the forcing frequency with minor superharmonic components. A phase-portrait of the reconstructed time series is shown in Fig. 8.

Translation: Translation and oscillation of the droplet are caused by contact angle variations at the three-phase contact line resulting from the application of an electrical potential between the droplet and an electrode that underlies only a portion of the droplet. The platform used to experimentally study these phenomena consists of a grounded-from-below electrowetting chip patterned with arrays of 1 mm^2 electrodes, together with the high-speed imaging signal analysis. As seen in Fig. 9, AC excitation results in the formation of shape mode oscillations that occur while the droplet translates across the surface. Here, we see a droplet translation speed of approximately 1.5 cm/sec. A general observation of using AC excitation for sessile droplet translation is that a lower threshold voltage is required to initiate droplet motion than either a 2-plate sandwiched configuration or when DC electrowetting is performed. The lower required threshold voltage is attributed to the excitation of shape modes that apparently assist in breaking pinned contact-lines.

Future Directions for Research

There is substantial interest in the application of electrowetting to optofluidics and to the control of biological and chemical protocols for assays and biomedical diagnostics. Research efforts to control droplet shapes for lenses and displays are ongoing and are likely to lead to increased efforts to place electrowetting within chip-based optofluidic networks. Multi-step protocols remain a challenge for electrowetting-based systems because of the need to perform filtration and biomolecular separations as well as to handle multiple types of fluids that may contain surfactants, whole cells, lysates, proteins, nucleic acids, and other multi-component fluids. Thus, Lab-on-a-Chip applications will continue to be developed to address this multitude of challenges and to improve protocols, assays or diagnostics through miniaturization or acceleration of existing laboratory automation methods.

Element Connectivity

Synonyms

Element connectivity matrix

Definition

The element connectivity is a set of data associated to an element that determines which nodes (or vertexes) form the element. This is frequently formed by moving about the element counter-clockwise and registering the node numbers as they are met. The number of entities in the connectivity of an element is equal to its number of nodes. When all element connectivities belonging to a computational grid are stored in a matrix, the so-called connectivity matrix is formed.

Definition

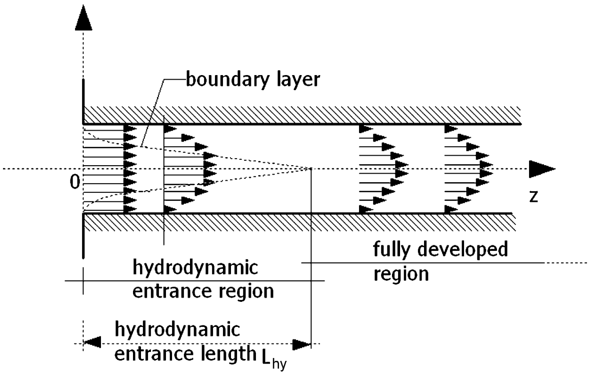
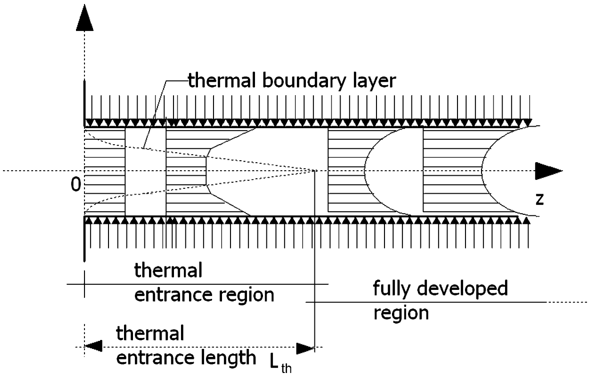
The entrance region of a microchannel corresponds to the part of the channel in which the velocity and/or the temperature fields are not completely developed.

Overview

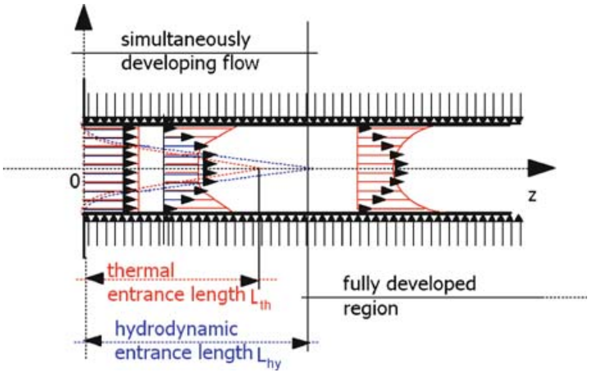
The *hydrodynamic entrance region* of a microchannel is that region where the velocity boundary layer is developing from zero thickness at the entrance up to cover the whole cross-section far downstream. Usually, this region coincides with the part of the channel near the inlet section. The flow in this region is designated as hydrodynamically developing (Fig. 1).
For microchannels in which the flow is originated by means of electro-osmosis the hydrodynamic entrance region can start from an internal point of the channel where the zeta potential at the wall differs from zero.



Entrance Region, Figure 1 The hydrodynamic entrance region



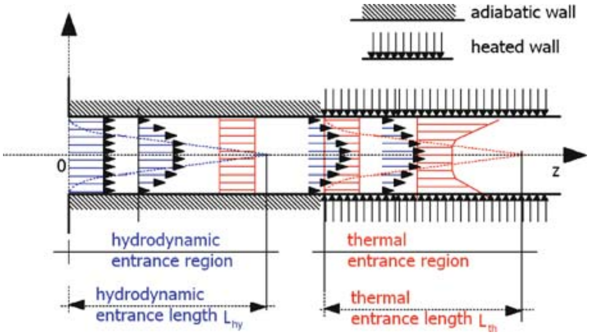
Entrance Region, Figure 2 The thermal entrance region



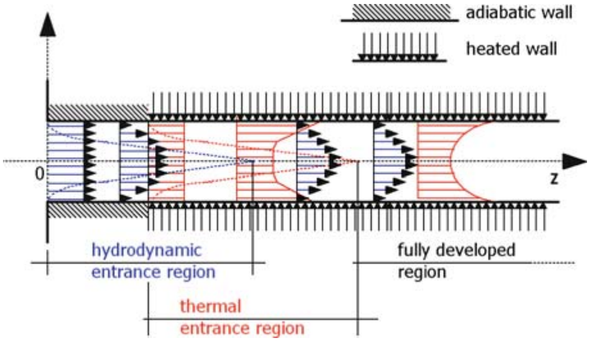
Entrance Region, Figure 3 Hydrodynamically laminar fully developed and thermally developing flow

In analogy, the *thermal entrance region* of a microchannel is defined as that region where the temperature boundary layer is developing (Fig. 2). The thermal entrance region can or cannot correspond with the inlet region of the microchannel; for example, if the heating begins only at some point after the inlet section the thermal entrance region can be uncoupled from the hydrodynamic entrance region. For this reason, in the thermal entrance region the velocity profile can be either developed or developing. In general, it is possible to individuate the following three categories of thermal entrance problems:

- The velocity profile is fully developed in the thermal entrance region and it remains fixed while the temperature profile develops. In this case the flow is designated as *hydrodynamically fully developed* and *thermally developing* flow; this situation can be obtained in a microchannel with adiabatic walls in the region near the entrance (*adiabatic preparation*) (see Fig. 3).



Entrance Region, Figure 4 Simultaneously developing flow



Entrance Region, Figure 5 Partially simultaneous developing flow

- The velocity and the temperature profiles develop simultaneously. In this case the flow is designated as *simultaneously developing flow*; this situation is obtained in the region near the entrance in a uniformly heated microchannel (see Fig. 4).
- The temperature profile starts developing at some point in the hydrodynamic entrance region (see Fig. 5). This situation can be obtained if the heating starts at some point within the hydrodynamic entrance region.

Basic Methodology

The rate of developments of velocity and temperature profiles in the entrance region depends on the Prandtl number defined as the ratio of fluid momentum diffusivity ν (kinetic viscosity) to fluid thermal diffusivity α:

$$\mathrm{Pr} = \frac{\nu}{\alpha} = \frac{\nu}{\frac{k}{\rho c_p}} = \frac{\mu c_p}{k} \tag{1}$$

where k is the fluid thermal conductivity, ρ is the fluid density, μ is the dynamic viscosity and c_p is the fluid specific heat.

The Prandtl number depends on the thermophysical properties of the fluid only. Typical values of the Prandtl number are 0.001 – 0.03 for liquid metals, 0.2 – 1 for gases, 1 – 10 for water, 5 – 50 for organic liquids and 50 – 2000 for oils. The Prandlt number depends on the bulk temperature of the fluid since the viscosity is a strong function of temperature; for this reason, especially in very narrow microchannels in which the viscous heating effects are not negligible (see ►viscous heating and ►viscous dissipation), the Prandlt number cannot be considered as a constant along the channel.

For $\mathrm{Pr} = 1$, the velocity and temperature profiles develop at the same rate, if both are uniform at the entrance; this situation is typical for gases. For $\mathrm{Pr} > 1$ (e. g. water), the velocity profile develops more rapidly than the temperature profile; for large values of the Prandtl number, such as for oils, the analysis of the thermal development in the entrance region can be conducted by considering the velocity as fully developed (see Fig. 3). For the limiting case of $\mathrm{Pr} = \infty$ the velocity profile is developed before the temperature profile starts developing; this case can be considered as a good approximation for highly viscous fluids. For $\mathrm{Pr} < 1$, the temperature profile develops more rapidly than the velocity one. For the limiting case of $\mathrm{Pr} = 0$ the velocity profile remains uniform over the cross-section (*slug flow*) while the temperature profile is developing; this case is generally used in order to model the entrance region for liquid metals or for electro-osmotic flows.

The velocity and temperature profiles in the entrance region have to be determined by solving the complete set of Navier–Stokes equations and the energy balance:

$$\begin{aligned} -\frac{1}{\rho}\frac{\mathrm{d}\rho}{\mathrm{d}t} &= \nabla\cdot\boldsymbol{v} \\ \rho(\boldsymbol{v}\cdot\nabla\boldsymbol{v}) &= -\nabla p + \rho\boldsymbol{g} - \nabla\cdot\tau \\ \rho c_p(\boldsymbol{v}\cdot\nabla T) &= -\nabla\cdot\boldsymbol{q} + \beta T\boldsymbol{v}\cdot\nabla p) - \tau : \nabla\boldsymbol{v} \end{aligned} \tag{2}$$

in which $\boldsymbol{v}$ is the velocity vector, ρ is the fluid density, t is the time, p is the pressure, D/Dt is the total derivative, τ is the viscous tensor, T is the temperature, β is the thermal expansion coefficient and $\boldsymbol{q}$ the heat flux (see ►viscous dissipation and ►convective heat transfer in microchannels).

For steady-state incompressible Newtonian flows the governing equations can be simplified as follows:

$$\begin{aligned} \nabla\cdot\boldsymbol{v} &= 0 \\ \rho(\boldsymbol{v}\cdot\nabla\boldsymbol{v}) &= -\nabla p + \rho\boldsymbol{g} + \mu\nabla^2\boldsymbol{v} \\ \rho c_p(\boldsymbol{v}\cdot\nabla T) &= -\nabla\cdot\boldsymbol{q} + \mu\Phi_{\mathrm{inc}} \end{aligned} \tag{3}$$

in which Φ_{inc} is the rate of viscous dissipation for an incompressible fluid (its expression can be found in ▶ viscous dissipation) and $\boldsymbol{v} = (v_x, v_y, v_z)$ where z is the axial coordinate.

The boundary conditions that have to be used together with Eq. (3) can be found in ▶ pressure-driven single phase liquid flow and in ▶ pressure-driven single phase gas flows for the momentum equation and in ▶ convective heat transfer in microchannel for the energy balance equation.

The hydrodynamic and thermal entry length problem can be solved either by employing the boundary layer-type idealizations or by considering the complete set of equations [1].

It may now be added here that rounded entrances or square-edged entrances can influence the values assumed by the convective heat transfer coefficient but especially by the friction factor in the entrance region.

All the numerical results obtained by solving numerically Eq. (3) for developing flows are obtained by considering the following entrance conditions:

- A uniform velocity profile (equal to the mean velocity W) at the entrance with negligible transversal components ($v_z = W$; $v_x = v_y = 0$). In this case the vorticity defined as $\varpi = (\partial v_z/\partial y - \partial v_y/\partial z; \partial v_x/\partial z - \partial v_z/\partial x; \partial v_y/\partial x - \partial v_x/\partial y)$ is not zero at the entrance. This situation can be obtained experimentally only by using a screen at the channel inlet. This is the entrance boundary condition that is most frequently used for hydrodynamic entrance problems.
- A uniform velocity profile with zero vorticity ($\varpi = 0$) at the entrance. This entrance condition is referred to as *irrotational flow entry*.
- Since an entrance condition of a uniform velocity profile cannot exist when axial diffusion of momentum or vorticity is included in the analysis, a mathematically more appropriate entrance condition imposes the velocity profile as uniform and parallel at the virtual section $z = -\infty$ by considering an impermeable frictionless wall between $z = -\infty$ and $z = 0$.

Since data cover only a few simple entrance geometries, the designer must exercise judgment in the application of the correlations proposed to calculate the friction factor and the convective heat transfer coefficient in the entrance region of a microchannel.

Hydrodynamic Entrance Length

The *hydrodynamic entrance length* (L_{hy}) is defined as the channel length required to achieve a maximum value of the velocity of 99% of the corresponding fully developed magnitude when the entering flow is uniform.

The hydrodynamic entrance length L_{hy} can be written in dimensionless form as follows:

$$L^+_{hy} = \frac{L_{hy}}{D_h \mathrm{Re}} \tag{4}$$

For conventional channels the hydrodynamic entrance length can be estimated for laminar flows by means of the following approximated equation:

$$L^+_{hy} = \frac{L_{hy}}{D_h \mathrm{Re}} = 0.05 \tag{5}$$

Let us consider a microtube with a fixed internal diameter D; the length of the microtube (L) is equal to 2000 times the internal diameter. Water flows through the microtube by means of an imposed pressure difference between the ends of the microtube. The water flow rate through the microtube increases with the imposed pressure difference. If the maximum value of the imposed pressure difference is fixed to 200 bar one can calculate the maximum value of the Reynolds number that it is possible to reach in the microtube (see ▶ pressure-driven single-phase liquid flow entry). In correspondence of the maximum value of the Reynolds number one can estimate the entrance length by using Eq. (5).

In Table 1 are quoted the maximum Reynolds number, the corresponding hydrodynamic entrance length and the length to entrance length ratio (L/L_{hy}) as a function of the internal diameter of the microtube for water as working fluid. The results quoted in Table 1 allow one to highlight the following main aspects:

- The typical Reynolds numbers that characterize liquid laminar flows in microchannels are in general lower than those obtained by working with conventional channels under the same pressure difference at the ends.

Entrance Region, Table 1 Maximum Reynolds number, hydrodynamic entrance length and total axial length to entrance length ratio for circular microchannels with a fixed L/D value ($L/D = 2000$) and pressure drop ($\Delta p = 200$ bar) as a function of the microtube internal diameter

D [μm]	L [m]	Re_{max}	L_{hy} [μm]	L/L_{hy}
5	0.01	10.4	2.6	3864
10	0.02	41.4	20.7	966
15	0.03	93.2	69.9	429
20	0.04	165.6	165.6	242
25	0.05	258.8	323.5	155
35	0.07	507.2	887.7	79
50	0.1	1035.2	2587.9	39
75	0.15	2329.1	8734.2	17

- The entrance length becomes very low for low internal diameters; for $D < 10\,\mu\text{m}$ the hydrodynamic entrance region is comparable to the diameter of the microtube.
- For a fixed value of the ratio L/D equal to 2000, the entrance region holds a larger part of the microchannel length if the internal diameter is increased.

From the data quoted in Table 1 it is evident that for microtubes having a diameter less than 20 μm the flow is usually characterized by very low Reynolds number (Re < 100 for a maximum Δp of 200 bar). It is easy to demonstrate that for nanotubes ($D < 1\,\mu\text{m}$) the maximum Reynolds number that corresponds to the maximum pressure drop of 200 bar approaches rapidly to 0. This fact highlights that for water laminar flows through microchannels with $D < 20\,\mu\text{m}$ viscous forces completely dominate inertial forces; this kind of flow is named in the literature *creeping flow*. This kind of flow becomes predominant for the smaller microchannels.

It has been numerically demonstrated that Eq. (5) no longer holds for creeping flows where the dimensionless hydrodynamic entrance length seems to be a function of the Reynolds number. It has been demonstrated that for very low Reynolds numbers the hydrodynamic entrance length has to be calculated by means of the following equation:

$$L_{\text{hy}}^{+} = \frac{L_{\text{hy}}}{D_{\text{h}}\text{Re}} = 0.056 + \frac{0.6}{\text{Re}(0.035\text{Re} + 1)} \qquad (6)$$

Equation (6) is useful in order to calculate the hydrodynamic entrance length for liquid flows characterized by very low Reynolds numbers (Re < 10) through small microchannels.

Another conclusion that can be highlighted by the data of Table 1 is that for the microchannels with a low value of the inner diameter the ratio L/L_{hy} tends to increase; this fact underlines that the entrance region of the smaller microchannels plays a negligible role with respect to the more extended fully developed region. On the contrary, when the inner diameter increases the entrance region tends to take place in a large part of the axial length of the microchannels and the role played by the entrance region on the pressure drop and on the convective heat transfer coefficients becomes more important.

On the other hand, it is important to underline that for gas flows in microchannels, for the same maximum pressure difference (200 bar) between the ends of a microtube, larger Reynolds numbers can be obtained (up to 2800 with nitrogen for $D = 5\,\mu\text{m}$). The entrance length obtained for gas flows is larger than that obtained for liquids if the same internal diameter (D), length (L) and Δp are considered. For a large pressure difference through the microtube the gas density variation in the axial direction becomes important and the gas flow tends to accelerate axially (gas compressibility effect). The conventional theory underlines that compressibility effects become important for a gaseous flow through a channel when at least one of the following inequalities is satisfied:

$$\begin{cases} Ma_{\text{avg}} > 0.3 \\ \frac{\Delta p}{p_{\text{in}}} > 0.05 \end{cases} \qquad (7)$$

where Ma_{avg} is the average value of the Mach number along the microtube and p_{in} is the value of the pressure at the inlet of the microtube. When the first inequality is satisfied, the gas flow cannot be considered as locally incompressible and the momentum and energy equation have to be solved as coupled. When the second inequality is satisfied, even if the gas flow can be locally modeled as incompressible, the density variation along the tube cannot be ignored. In this case, the effects due to the gas acceleration along the tube become important, even if the Mach number is low: this is usually the case for microchannels. In fact, since in microchannels the pressure drop along the tube length is much larger than for conventional-size tubes, the effects of the gas acceleration cannot in general be neglected, even for very low values of the Mach numbers. The gas acceleration leads to changes in the velocity profile not only in magnitude but also in shape. The magnitude increments produce additional pressure drop while the shape changes alter the friction factor at the walls. The continuous variation in shape of the velocity profile means that no fully developed and no locally fully developed flow occur. In this case the entrance region holds entirely the microchannel length. This fact influences also the convective heat transfer coefficient since no fully developed temperature profiles can occur if the flow is developing.

The hydrodynamic entrance length is also influenced by the cross-sectional geometry of the microchannel. In order to take into account the role played by the geometry of the microchannel cross-section on the hydrodynamic entrance length, Eq. (5) can be replaced by the following approximate equation:

$$L_{\text{hy}}^{+} = \frac{V_{\max}^{2} - 1 - K(\infty)}{4f\text{Re}_{\text{fd}}} \qquad (8)$$

This equation allows the evaluation of the hydrodynamic length if one knows, for the considered cross-section, the value of the fully developed Poiseuille number ($f\text{Re}_{\text{fd}}$), the fully developed ratio between the maximum and the mean value of the velocity and $K(\infty)$, the asymptotic incremen-

tal pressure drop number:

$$V_{\max} = \frac{v_{z,\max}}{W} \qquad K(\infty) = 2(K_e - K_d) \tag{9}$$

The fully developed values of $V_{\max}$, K_d, K_e and $f\mathrm{Re}_{fd}$ can be found in ►pressure-driven single phase liquid flow for the most common microchannel cross-sections.

Sometimes, the rarefaction effects for gas flows through microchannels cannot be ignored (especially for $D_h <$ 40 μm). For rarefied gases through microchannels (for which the Knudsen number (Kn) is larger than 10^{-3}) the gas rarefaction tends to increase L_{hy} in the slip flow regime, due to slip at the walls (see ►pressure–driven single phase gas flows for the definition of slip flow regime and Knudsen number). Barber and Emerson [3] used a two-dimensional finite-volume Navier–Stokes solver to simulate the flow of a gas entering a parallel-plate microchannel in the slip-flow regime, with first-order boundary conditions. Their simulated data for $\mathrm{Kn} \in [0; 0.1]$ and $\mathrm{Re} \in [0; 400]$ were fitted by a least-squares technique and led to the following expression for the hydrodynamic development length:

$$\frac{L_{hy}}{D_h} = \frac{0.332}{0.0271\mathrm{Re} + 1} + 0.011\mathrm{Re}\frac{1 + 14.78\mathrm{Kn}}{1 + 9.78\mathrm{Kn}} \tag{10}$$

where D_h is the hydraulic diameter equal to $2h$ with h defined as the distance between the parallel plates.

Pressure Drop

The ratio between the local wall shear stress τ_z to the flow kinetic energy per unit volume is defined as the local Fanning friction factor:

$$f_z = \frac{\tau_z}{\left(\frac{\rho W^2}{2}\right)} \tag{11}$$

where W is the value of the average fluid velocity and z is the axial coordinate. For very small microchannels and for nanochannels this way to normalize the local wall shear stress can be difficult to follow.

The mean Fanning friction factor in the hydrodynamic entrance region is defined as follows:

$$\bar{f} = \frac{1}{z}\int_0^z f_z \, \mathrm{d}z \tag{12}$$

In the hydrodynamic entrance region, the pressure drop can be considered as due to the wall shear and to the change in momentum flow. The total pressure drop for constant density flow between the entrance ($z = 0$) and z can be written by introducing the *apparent friction factor*:

$$\frac{\Delta p}{\frac{\rho W^2}{2}} = 4 f_{app} \frac{z}{D_h} \tag{13}$$

The value of the apparent friction factor can be calculated by means of Eq. (13) if the total pressure drop from $z = 0$ to z is known. The apparent value of the friction factor takes into account both the skin friction and the change in momentum rate due to change in the shape of the velocity profile in the hydrodynamic entrance region (see Fig. 1).

Sometimes, the pressure drop in the hydrodynamic entrance region is calculated by introducing the incremental pressure drop number $K(z)$; this term takes into account the additional pressure drop due to momentum change and the accumulated increment in wall shear between developing flow and developed flow. By introducing $K(z)$ the total pressure drop is calculated as follows:

$$\frac{\Delta p}{\frac{\rho W^2}{2}} = 4 f\mathrm{Re}_{fd}\left(\frac{z}{D_h \mathrm{Re}}\right) + K(z) \tag{14}$$

where $f\mathrm{Re}_{fd}$ is the Poiseuille number for the fully developed flow; the values of $f\mathrm{Re}_{fd}$ for the most common cross-sectional geometries for microchannels can be found in ►pressure-driven single phase liquid flow.

By combining Eqs. (13) and (14) the relation between the apparent Fanning friction factor and the incremental pressure drop number can be written as follows:

$$K(z) = 4(f\mathrm{Re}_{app} - f\mathrm{Re}_{fd}) z^{+} \tag{15}$$

where $z^{+} = z/(D_h \mathrm{Re})$.

Circular Cross-Section

The following correlation, proposed originally by Shah [2], can be used in order to calculate the apparent Poiseuille number for microtubes as a function of the dimensionless axial coordinate z^{+} for laminar flows:

$$f\mathrm{Re}_{app} = \frac{3.44}{(z^{+})^{0.5}} + \frac{1.25/(4z^{+}) + 16 - 3.44/(z^{+})^{0.5}}{1 + 0.00021(z^{+})^{-2}} \tag{16}$$

Parallel Plate Cross-Section

The following correlation gives the apparent Poiseuille number for parallel plate microchannels as a function of the dimensionless axial coordinate z^{+} for laminar flows:

$$f\mathrm{Re}_{app} = \frac{3.44}{(z^{+})^{0.5}} + \frac{0.674/(4z^{+}) + 24 - 3.44/(z^{+})^{0.5}}{1 + 0.00029(z^{+})^{-2}} \tag{17}$$

Entrance Region, Table 2 Apparent Poiseuille number for rectangular channels as a function of the axial dimensionless coordinate z^+ and of the aspect ratio β

Rectangular Cross-Section

The values of the apparent Poiseuille number for rectangular channels as a function of the dimensionless axial coordinate z^+ and of the rectangular aspect ratio β (defined as the ratio between the height and the width of the channel) are quoted in Table 2.

Developing Nusselt Number

If one knows the temperature distribution in the entrance region the local value of the Nusselt number in a point on the heated perimeter can be calculated from its operational definition:

$$\mathrm{Nu}_z = \frac{h_z D_\mathrm{h}}{k} = \frac{D_\mathrm{h} \left.\frac{\partial T}{\partial n}\right|_\Gamma}{T_\mathrm{wm} - T_\mathrm{b}} \tag{18}$$

in which the peripheral mean wall temperature T_wm and the bulk temperature T_b have been defined as

$$T_\mathrm{wm} = \frac{\int_{\Gamma_\mathrm{h}} T|_\Gamma \,\mathrm{d}\Gamma}{\Gamma_\mathrm{h}} \qquad T_\mathrm{b} = \frac{1}{\dot{m} c_p} \int_\Omega \rho v_z c_p T d\Omega \tag{19}$$

where Γ_h is the heated perimeter, Ω is the microchannel cross-sectional area, and $\dot{m}$ is the mass flow rate.
The mean Nusselt number in the thermal entrance region is calculated as follows:

$$\mathrm{Nu}_\mathrm{m} = \frac{1}{z} \int_0^z \mathrm{Nu}_z \,\mathrm{d}z \tag{20}$$

For laminar flows, the value of the mean Nusselt number depends on the thermal boundary condition considered; a description of the most common thermal boundary conditions for microchannels can be found in ►convective heat transfer in microchannels (i. e. T, H1, H2 boundary conditions).

Circular Cross-Section

For laminar flows under the T boundary condition (see ►convective heat transfer in microchannels) with a fully developed velocity profile (*hydrodynamically fully developed* and *thermally developing* flow; Fig. 3), the following correlation, proposed originally by Shah [2] for conventional channels, can be used in order to calculate the mean Nusselt number in the entrance region for circular microtubes as a function of the dimensionless axial coordinate z^*:

$$\mathrm{Nu}_{\mathrm{m},T} = \begin{cases} \frac{1.615}{(z^*)^{1/3}} - 0.7 & \text{for } z^* \le 0.005 \\ \frac{1.615}{(z^*)^{1/3}} - 0.2 & \text{for } 0.005 < z^* < 0.03 \\ 3.657 + \frac{0.0499}{z^*} & \text{for } z^* \ge 0.03 \end{cases} \tag{21}$$

where z^* is defined as follows:

$$z^* = \frac{z}{D_\mathrm{h} \mathrm{Re}\,\mathrm{Pr}} \tag{22}$$

On the contrary, under the H boundary condition (see ►convective heat transfer in microchannels) with a fully developed velocity profile (*hydrodynamically fully developed* and *thermally developing* flow; Fig. 3) the mean Nusselt number for circular microtubes as a function of the dimensionless axial coordinate z^* for laminar flows can be calculated as follows:

$$\mathrm{Nu}_{\mathrm{m},H} = \begin{cases} \frac{1.953}{(z^*)^{1/3}} & \text{for } z^* \le 0.03 \\ 4.364 + \frac{0.0722}{z^*} & \text{for } z^* > 0.03 \end{cases} \tag{23}$$

Theoretically, the mean and the local Nusselt number along a channel having a length equal to L can be predicted

Entrance Region, Table 3 Coefficients of the generalized Hausen correlation (Eq. (22)) for hydrodynamically fully developed and thermally developing flow and for simultaneously developing flow in microtubes

Boundary condition	Velocity	Pr	Nu	$\overline{\text{Nu}}$	K_1	K_2	b
T	Developed	Any	mean	3.66	0.0668	0.04	2/3
T	Developing	0.7	mean	3.66	0.104	0.016	0.8
H	Developed	Any	local	4.36	0.023	0.0012	1
H	Developing	0.7	local	4.36	0.036	0.0011	1

by means of the following generalized *Hausen correlation*, valid for $\text{Re} < 3000$:

$$\text{Nu} = \overline{\text{Nu}} + K_1 \frac{\left(\frac{\text{Re}\,\text{Pr}\,D_\text{h}}{L}\right)}{\left(1 + K_2\left(\frac{\text{Re}\,\text{Pr}\,D_\text{h}}{L}\right)^b\right)} \tag{24}$$

In the *Hausen correlation* the Nusselt number is calculated as a sum of two terms: the first term ($\overline{\text{Nu}}$) is the fully developed value of the Nusselt number; its value can be found in ►convective heat transfer in microchannels for the most common microchannel cross-sections. The second term takes into account the effects of the thermal entrance region. The values of the coefficients K_1, K_2 and b for circular microchannels are quoted in Table 3.

Parallel Plate Cross-Section

For laminar flows under the T boundary condition (see ►convective heat transfer in microchannels) with a fully developed velocity profile (*hydrodynamically fully developed* and *thermally developing* flow; Fig. 3), the following correlation, proposed originally by Shah for conventional channels, can be useful to calculate the mean Nusselt number in the entrance region of parallel plate microchannels as a function of the dimensionless axial coordinate z^* :

$$\text{Nu}_{\text{m},T} = \begin{cases} \frac{1.849}{(z^*)^{1/3}} & \text{for } z^* \le 0.0005 \\ \frac{1.849}{(z^*)^{1/3}} + 0.6 & \text{for } 0.0005 < z^* \le 0.006 \\ 7.541 + \frac{0.0235}{z^*} & \text{for } z^* > 0.006 \end{cases} \tag{25}$$

On the contrary, under the H boundary condition (see ►convective heat transfer in microchannels) with a fully developed velocity profile (*hydrodynamically fully developed* and *thermally developing* flow; Fig. 3) the following correlation can be used in order to calculate the mean Nusselt number for parallel plate microchannels as a function of the dimensionless axial coordinate z^* for laminar flows:

$$\text{Nu}_{\text{m},H} = \begin{cases} \frac{2.236}{(z^*)^{1/3}} & \text{for } z^* \le 0.001 \\ \frac{2.236}{(z^*)^{1/3}} + 0.9 & \text{for } 0.001 < z^* < 0.01 \\ 8.235 + \frac{0.0364}{z^*} & \text{for } z^* \ge 0.01 \end{cases} \tag{26}$$

Rectangular Cross-Section

In Tables 4 and 5 the mean Nusselt numbers for *hydrodynamically fully developed* and *thermally developing* flow in rectangular microchannels are reported as a function of the dimensionless axial coordinate z^* and of the aspect ratio β for T and H1 boundary conditions (with four heated sides) respectively.

For *simultaneously developing flows* in rectangular microchannels the values of the mean Nusselt number are reported in Tables 6 and 7 for T and H1 boundary conditions respectively for a fluid having a Prandtl number equal to 0.72. By observing the mean Nusselt numbers quoted in Tables 4, 5, 6 and 7 it is evident that the Nusselt numbers for H1 boundary condition are larger than those obtained for T boundary condition. In addition, the mean Nusselt numbers for simultaneously developing flows are larger that those for *hydrodynamically fully developed* and *thermally developing* flows. The Nusselt number increases if the aspect ratio decreases.

Thermal Entrance Length

The *thermal entrance length* (L_th) is defined as the microchannel length required to achieve a value of the local Nusselt number Nu_z equal to 1.05 times the value of the Nusselt number for fully developed flow.

The thermal entrance length L^+_th can be written in dimensionless form as follows:

$$L^+_\text{th} = \frac{L_\text{th}}{D_\text{h}\text{Re}\,\text{Pr}} \tag{27}$$

In order to calculate the thermal entrance length one can investigate where the temperature at the channel centerline deviates from the inlet fluid temperature; in fact, at this point the thermal boundary layers merge. However, since the radial heat conduction becomes important near the region where the boundary layers merge the real centerline temperature at the end of the thermal entrance region may be significantly higher than the inlet fluid temperature.

When the effect of the fluid axial heat conduction is considered the thermal entrance length increases for decreasing Péclet number ($\text{Pe} = \text{Re}\,\text{Pr}$).

220	9.70	10.00	10.30	10.58	10.90

The thermal entrance length required for the *simultaneously developing flows* (Fig. 4) is in general larger than that obtained by considering a fully developed velocity profile (Fig. 3).

Especially for laminar flows, the thermal entrance length depends on the thermal boundary conditions considered. For example, for a *hydrodynamically laminar fully developed* and *thermally developing* flow through circular microtubes the dimensionless thermal entrance length (L_{th}^{+}) is equal to 0.03347 for a T boundary condition (*constant wall temperature*) and equal to 0.04305 for an H boundary condition (*constant wall heat flux*). For a parallel plate channel the dimensionless thermal entrance length (L_{th}^{+}) is equal to 0.00797 for T boundary condition (*constant wall temperature*) and equal to 0.01154 for H boundary condition (*constant wall heat flux*).

In Table 8 the values of the dimensionless thermal entrance length for rectangular channels, parallel plates ($\beta = 0$) and for circular tubes are quoted as a function of the aspect

ratio for T and H1 boundary conditions and for *simultaneously developing flows* and for *hydrodynamically laminar fully developed* and *thermally developing* flow.

It is evident that the thermal entrance length is larger for H1 boundary condition and for simultaneously developing flows.

Future Directions for Research

Most experimental data obtained by testing microchannels have been obtained in situations for which the entrance effects are not negligible. However, sometimes the experimental conditions are not suitable for comparison with the analytical results presented for laminar flows for the following reasons. Firstly, the numerical results of Tables 3–8 have been obtained by considering fluids with constant thermophysical properties. Some authors [4] have numerically demonstrated that in the entrance region of straight microchannels both temperature dependence of viscosity and viscous dissipation effects cannot be neglected in a wide range of operative conditions (see ► convective heat transfer in microchannels, ► viscous dissipation and ► viscous heating). For example, they demonstrated that, by taking into account a temperature-dependent viscosity and non-negligible viscous dissipation, the dimensionless hydrodynamic entrance length in microchannels can become about one order of magnitude larger than that in the corresponding constant property flow.

Secondly, the effect of the wall–fluid conjugate heat transfer tends to be very strong for moderate Reynolds numbers especially in the entrance region of a microchannel where the wall heat flux distribution becomes non-uniform (see Fig. 6) even for a uniformly heated microchannel (H boundary condition). For these reasons, further investigations on the combined effect of the conjugate heat transfer and of the temperature-dependent fluid properties (i. e. viscosity) on the mean value of the Nusselt number in the entrance region for the most common microchannel cross-sectional geometries can be considered mandatory.

Enzyme Assay

Definition

An enzyme assay is a procedure used to evaluate the properties of an enzyme. Such assays are used to determine the kinetic characteristics of the enzyme, as well as its interactions with various substrates and inhibitors. In a homogeneous enzyme assay, enzymes, substrates, and inhibitors are mixed in the solution phase, while in a heterogeneous assay, one constituent (typically the enzyme) is immobilized on a solid surface while the other constituents are delivered via the solution phase.

Definition

The process of lithography with sub-micrometer resolution, with the aid of ►enzymes.

Overview

The importance of nanolithography cannot be overemphasized, in the context of Nano-Fluidics. It is the process by which nano-channels, nano-wells, and other components are fabricated in the material that serves as the support, or substrate, of the nano-fluidic devices.

Bio-lithography differs from the lithography employed in micro and nano electronics in the fact that it aims at producing the same kind of features *with* biomolecules, *on* biomolecules or *in* biomolecules. Since biomolecules are much more sensitive to their environment than inorganic materials (such as semiconductors and noble metals), most of the lithography technologies used in micro and nano electronics are unsuitable for bio-lithography. High or ultra high vacuum is unacceptable, evaporation/sputtering is inapplicable, etching with strong acids would damage biomolecules, irradiation with UV light would destroy DNA and proteins. Bio-lithography techniques, therefore,

must operate in close to ambient atmosphere and/or in liquid, close to room temperature and moderate pH. *Nano-biolithography* techniques have to comply with all the above *and* provide nanometer precision of positioning and nanometer-sized features. This is the reason that the most natural candidate for nano-bio-lithography is the Scanning Probe Microscope (SPM), which enjoys all these abilities. Since many (micro- and/or nano-) fluidic applications are targeted at biological molecules (DNA separation, protein purification, etc.), bio-lithography is of great importance to these areas. Although it is perfectly conceivable to have the fluidic platform manufactured in non-biological materials (silicon, polymers, elastomers, etc.), using conventional methods, and later using these platforms with biological molecules, this approach usually requires additional steps, such as surface functionalization (usually a multi-step process). Moreover, aided by evolution over a very long period, biology has come up with *specificity*, the ability to specifically recognize target molecules.

Enzymes, in particular, are proteins that act as chemical catalysts of specific biochemical reactions. An enzyme typically speeds up, or makes possible at all, a reaction between a set of reactants, which converts them into specific products.

The main difference between using enzymes and non-biological materials for purposes of lithography is that enzymes possess very high specificity for their substrate (the reactants), unlike their non-biological counterparts. Such ability to specifically recognize the substrate can lead to very sophisticated lithography schemes, based on biological recognition.

To summarize: enzymes possess biological specificity, an advantage over non-biological materials, in what concerns lithography. Since enzymes are biological molecules, and their catalytic action is performed on biological molecules, nano-lithography using enzymes needs to fulfill the demands presented by biological molecules (bio-nanolithography). For this purpose, the scanning probe microscopy (SPM) family of instruments is best suited, since it is able to operate in ambient conditions and in liquid.

Enzyme nanolithography has been introduced in 2003 and has gradually advanced since, using several SPM-based and non-SPM-based techniques.

Basic Methodology

Lithography in general and nano-lithography in particular can be subdivided into several categories, according to how it is done and what the resulting features are.

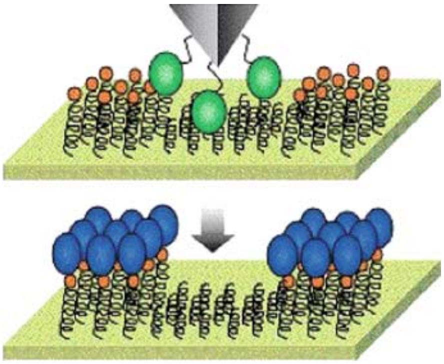
One classification is into *positive* and *negative* lithography, corresponding to whether the end-result is addition (positive) of material or removal (negative) of material. Positive lithography results in protrusions from the surface (mounds, ridges, etc.) while negative lithography results in depressions in the surface (holes, trenches, etc.)

Another classification is into *direct* and *indirect* lithography. The difference is that in indirect lithography – a multi-step procedure – the pattern is first inscribed in some way on the surface and in subsequent steps the features are fabricated according to this original *blue-print*, while in direct-write lithography the features are directly fabricated onto the surface.

By no means does the nomenclature imply advantages or disadvantages of the approaches. *Direct* is not necessarily better than *indirect* (or vice-versa) and *negative* is not necessarily worse than *positive* (or vice-versa). The various approaches have their advantages and should be carefully chosen in the context of the desired patterns, the substrates, reactants and deposition materials involved.

One more term that needs to be elucidated, is nanolithography using Scanning Probe Microscopy (SPM) techniques. SPM is a name describing a family of instruments, with the most widely known one being the Atomic Force Microscope (AFM), also known as Scanning Force Microscope (SFM). Very briefly, a soft cantilever (typical dimensions $\sim 100\ \mu m$) with a very sharp probe is scanned across a surface, while making contact (or intermittent contact) with the surface. An auxiliary system (typically a laser beam reflected from the back of the cantilever) is used to monitor the motion of the cantilever (up and down) as it follows the topography of the scanned surface. This leads to formation of a three dimensional image of the surface with extremely high resolution (in some cases, atomic resolution, and in most other cases a resolution of ~ 1 nm).

This family of *microscopes* can in fact be used also for surface modification and not only for surface imaging. The



Enzyme Nanolithography, Figure 1 V8 protease is immobilized to the apex of an AFM probe, to create a depression in the peptide film (Fig. 2 from [1])

system controlling the probe-sample position with very high accuracy is used to position the probe in selected positions and modify the surfaces using many various mechanisms (a few examples include: mechanical indentation, scraping, electric field oxidation, deposition of various *inks*, etc.).

SPM-based lithography is a very advantageous methodology in what regards enzyme nanolithography (and bionanolithography in general) because SPMs can operate in ambient conditions (no vacuum) and in liquid, while applying very gentle forces that do not damage the biomolecules.

Key Research Findings

Negative, Direct, Enzyme Nanolithography

This type of nanolithography has been demonstrated so far using two SPM-based methods, and two different enzyme-substrate systems.

- The substrate was composed of synthetic peptides, immobilized to a mica surface. The *etching* enzyme was *Staphylococcal* serine V8 protease, an enzyme that recognizes either glutamic or aspartic acid residues in the peptide and digests the peptides carboxyl acid terminus [1]. The enzyme was immobilized to the apex of an AFM probe and the enzyme functionalized tip was scanned across the surface, in solution (phosphate buffer). This process created a rectangle shaped depression with a depth of a few nanometers.
- The substrate was composed of a dried film of bovine serum albumin (BSA) deposited on glass. The *etching* enzyme was trypsin, a proteolytic enzyme that cleaves on the carboxyl side of lysine and arginine residues. The enzyme was loaded in solution into a *nano-fountain pen* (NFP) probe (a capillary, heat-drawn into a sharp tip with an aperture of ~ 100 nm) [2] mounted as the probe of an AFM, and delivered in solution (phosphate buffer) to the BSA surface. Using this approach, it was possible to carve nano-wells with diameters as small as 600 nm and volumes of 0.2×10^{15} l, depending on the time spent by the probe in the specific position [3]. Also, trenches, or nano-channels with controlled dimensions have been fabricated by dragging the probe along the sample. It was also shown that crossing nano-channels (and networks of nano-channels) can be fabricated using this approach, and solutions may be flown along them [4].

Negative, Indirect, Enzyme Nanolithography

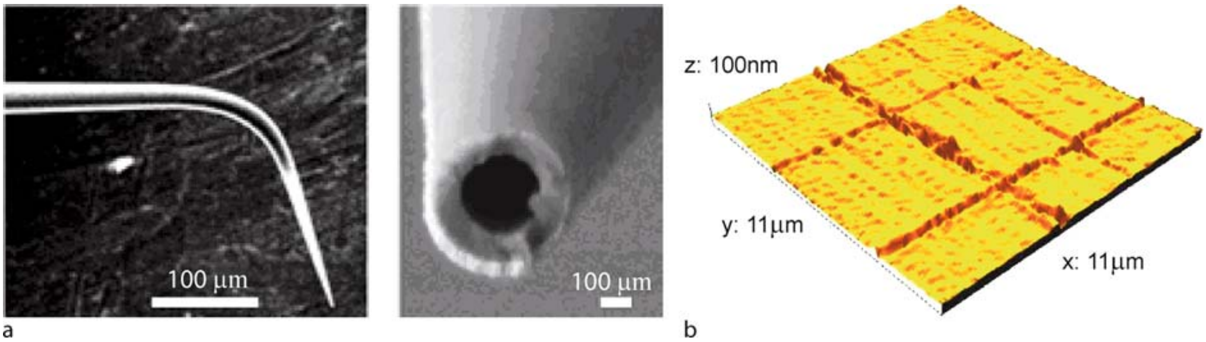
SPM-Based

- The first ever demonstration of negative enzyme lithography was reported in 1998 [5]. The study was not targeted to lithography per-se, however the authors showed a possible application and predicted *enzyme-controlled nanolithography in molecular thin films*. Subsequently, the same group showed a study dedicated to enzyme lithography on the same enzyme-substrate system [6].

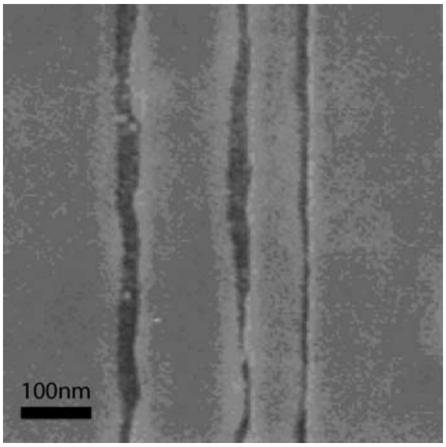
  The substrate was a supported phospholipid bilayer made of dipalmitoylphosphatidylcholine (DPPC). DPPC is known to separate phases into solid-phase (or gel) domains and liquid-phase domains.

  The studied enzyme was Phospholipase A_2 (PLA_2) which is an interfacially activated enzyme that catalyzes regio- and stereospecific hydrolysis of the sn-2 acyl ester linkage of sn-3-glycero-phospholipids, producing fatty acid and lysophospholipid as reaction products.

  The enzyme was applied in solution on the DPPC bilayer and allowed to hydrolyze it. With the aid of an AFM tip, a uniform region of solid (gel) phase was perturbed, by applying some pressure with the tip, along a line. PLA_2 hydrolizes preferentially at phase inter-



Enzyme Nanolithography, Figure 2 (**a**) SEM image of a nanopipette (**b**) Nano-channels etched in BSA by Trypsin deposited with NFP



Enzyme Nanolithography, Figure 3 A gel-phase supported DPPC bilayer with lines which were etched into the bilayer by (PLA_2), after packing defects in the lipid bilayer were induced with the AFM tip (Fig. 2 in [6])

faces (or packing defects), and therefore *etched* the lipid bilayer along this line, creating a channel with a depth of 1.5 nm.

The two-stage process employed here, leading to the *indirect* classification is described as follows: *first stage* – creation of a pattern on the substrate (various phases with interfaces, or inducing the interfaces with the AFM tip) and *second stage* – etching along this previously introduced pattern.

- The substrate was composed of an oligonucleotide-terminated self-assembled monolayer of alkanethiols, tethered to the surface of gold by chemical self-assembly. The *etching* enzyme was DNase I, a non-specific endonuclease that digests double-stranded and single-stranded DNA into nucleotide fragments [7].

  In the *first stage* the enzyme was deposited onto the oligonucleotide SAM, using dip-pen nanolithography (DPN) – a method whereby an AFM probe is dipped into an *ink*, and subsequently used to *write* this ink onto a substrate [8]. The enzyme was not active at this stage, but was adsorbed on the surface in the precise positions where it has been written with DPN. In the *second stage*, the pre-patterned substrate was immersed in a solution containing Mg^{2+}, which activates DNase I. The activated enzyme produced nano-channels with depth of ~ 3 nm.

Non-SPM-Based

The substrate was composed of phospholipid bilayers consisting of condensed or solid-like DPPC stripes in a fluid DLPC matrix, onto a mica substrate [9]. The stripe pattern results from the superposition of the condensed DPPC stripe domains and fluid DLPC phases present in the layers.

The enzyme was phospholipase A_2 (PLA_2), which, in addition to its characteristics described above, is known to have stereoselectivity, i. e. it hydrolyzes the (natural) L lipid form, while it only binds, but does not cleave, the physicochemically identical D form.

It is shown that using various combinations of DPPC/DLPC (to create the stripes pattern), the enzyme cleaves the L stripes wile leaving untouched the D stripes. For example, D-DPPC stripes are left intact, while L-DLPC bilayer between the D-DPPC stripes is removed. This is an excellent demonstration of the specificity of enzymes and how it can be used in the context of nano-lithography.

The process is considered indirect due to the two stage approach: *first stage* consists of imprinting the pattern into the substrate, by creating the phase-separated stripe pattern. In the *second stage*, the enzyme etches along these patterns.

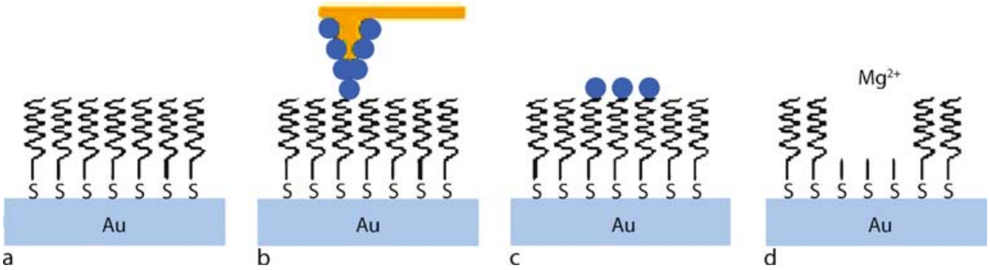
Positive, Direct, Enzyme Nanolithography

In the example described here [10], the enzyme used was alkaline phosphatase that dephosphorylates the substrate BCIP and forms in the presence of the cofactor NBT an insoluble precipitate. The enzyme was immobilized to the apex of an AFM tip and the substrate and cofactor were present in the buffer solution. Upon approaching the AFM tip to the mica surface, the authors were able to fabricate nano-mounds of reaction product. This shows how an enzyme can be used to deposit the reaction product of an enzyme in precise positions, and create nanostructures of a size depending on the enzyme activity.

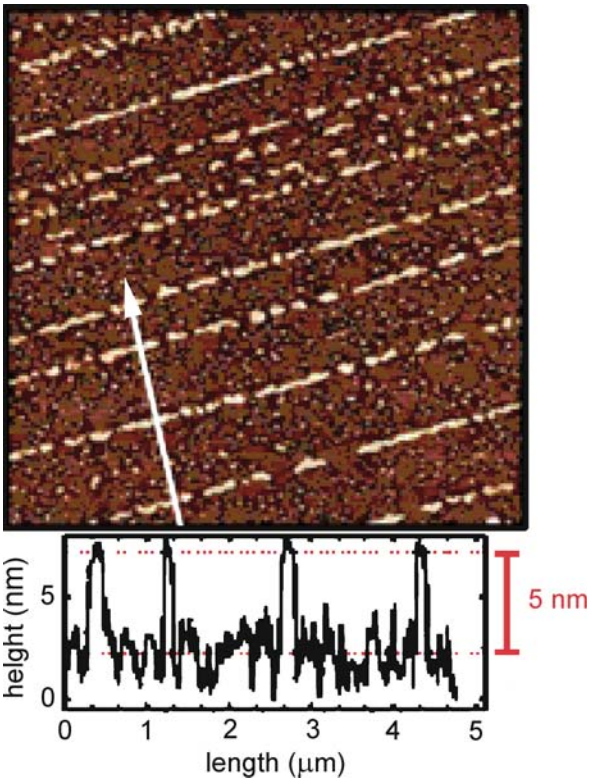
Positive, Indirect, Enzyme Nanolithography

SPM-Based

In this example [11], several enzymes were studied and shown to catalyze the enlargement of metal seeds into fully developed metal nanowires. The enzymes were glucose oxidase (GOx), galactose oxidase (GalOx), and alkaline phosphatase (AlkPh). The enzymes were first modified with gold nanoparticles (NP). The NP-enzyme complexes served as the *biocatalytic ink*, which was patterned in the *first stage* on a silicon-oxide/silicon surface, using dip pen nanolithography (DPN) [8]. Following this stage, the patterns were exposed to a *developing* solution in the *second stage* that caused the deposition of additional metal (Au or Ag) on top of the patterned line. This enlargement process was catalyzed by the respective enzyme, and could not have occurred in the absence of the enzyme. The selectivity and specificity of enzyme lithography is very ele-



Enzyme Nanolithography, Figure 4 (**a**) Oligonucleotide SAM (**b**) Deposition of DNase I with DPN (**c**) inactive DNase I patterned on SAM (**d**) Mg^{2+} ions activate the enzyme, which digests the oligonucleotide layer (Scheme 1 from [7])



Enzyme Nanolithography, Figure 5 A D-DPPC/L-DLPC layer selectively etched by PLA_2 (Fig. 2B in [9])

gantly demonstrated in this case, by showing the ability to deposit metal nanowires of *different* metals on the same substrate, using a single first stage: Au – NP – GOx and Au – NP – AlkPh lines are patterned using DPN. The final *identity* of the fully developed nanowires is established in the second stage, where the GOx catalyzes the enlargement with Au of the wire on which it is presents, while AlkPh catalyzes the enlargement with Ag of the wire on which it is present. Although both reactions are not performed simultaneously (due to some *cross-talk*, leading to deposition of both Au and Ag on the same wires), this is still a very impressive demonstration of how the enzymes can serve for *addressing* of chemical reactions, due to their high selectivity and specificity.

Non-SPM-based

The enzyme terminal deoxynucleotidyl transferase (TdTase) repetitively adds mononucleotides to the 3′ end of single- or double-stranded DNA, thus extending an existing oligonucleotide. TdTase can directly catalyze the 5′ to 3′ extension of a short oligonucleotide template without the need for a separate DNA primer, unlike DNA polymerases. The authors of this manuscript [12] immobilized an oligonucleotide self assembled monolayer (SAM) onto gold pads. The gold pads (100 nm × 100 nm to 4 µm × 4 µm) were fabricated using conventional (nano-) lithography methods (e-beam lift-off), constituting the *first stage* of the process. The gold features were coated with a SAM of oligonucleotides (a 25-mer poly-T). These DNA fragments served as the *initiator* of the polymerization catalyzed by TdTase, and this constitutes a *second stage* of the process. In the *third stage*, a solution containing TdTase and a mononucleotide (dTTP proved to be the most efficient among those studied) was applied to the sample. The enzyme caused the addition of more T bases to the initial 25-T oligonucleotides, thus increasing the height of the features considerably.

Future Directions of Research

Enzyme nanolithography is a young research area, a technology being born. It is nowadays in its proof of concept stage and development of tools. The basic idea, of harnessing biological specificity, selectivity and finely tuned chemical catalysis – a result of a very long evolution – to creating nano-structures at will, is exciting and imaginative. The examples described above show that all approaches to lithography are attainable using enzymes, including direct and indirect methods of positive and neg-

ative lithography, using SPM based methods or others. It is envisioned that future research will concentrate on two main tracks:

- Creation of complex patterns, making use of the selectivity of enzymes. Note that most works published to date (with a few exceptions) create one type of feature using one enzyme and its matching substrate. The big promise in enzyme lithography, though, is the enzymes' ability to distinguish between their substrate and something else. Thus, they should be able to act on some parts of the surface, while leaving others intact, such as demonstrated in [9] and [11]. This will most probably require a mixture between direct and indirect approaches, whereby the *road-signs* are imprinted in some way into the substrate, such that various enzymes will recognize some of them and disregard others. Use of SPM based methods in combination with such an approach should allow an even more precise control over the x,y dimensions and position of the created features.
- Studying the quantitative aspects of enzyme lithography. Parameters such as concentrations, time of reaction, etc. and their quantitative influence on the dimensions of the resulting features will allow a good control over the processes and enable the transformation of enzyme nanolithography into a true technology.

Epitaxial

Synonyms

Epitaxy

Definition

Epitaxy is a kind of interface between a thin film and a substrate. Epitaxial growth refers to the formation of crystals of one material on the crystal face of another or the same material. The lattice structure and orientation or lattice symmetry of the thin film material is identical to that of the substrate on which it is deposited.

Etch Directionality

Synonyms

Etch profile

Definition

The etch directionality is due to directed energy input an etching reaction at a surface and can be accomplished by radical atoms, electrons, photons or ion bombardment of a surface exposed to a chemical etchant. It can be obtained by controlling the interaction between the plasma physical and chemical mechanisms to achieve the required etching profiles using the suitable reactor and adjusting the plasma parameters. Three types of plasma etched profiles are isotropic etching, sloped wall via etch and vertical wall (anisotropic etching).

Definition

When an electromagnetic wave (light) in a dielectric medium of index n_1 is incident upon an interface of a different dielectric material of a lower optical density, n_2 at an angle θ_1 greater than the critical angle, $\theta_c = sin^{-1}(n_2/n_1)$, total internal reflection (TIR) occurs. Although all of the incident energy is reflected, an electromagnetic field with exponentially decreasing intensity propagates in the less dense medium. This field is known as an ►evanescent wave and has a decay length or penetration depth, d, on the order of the wavelength of the incident light, λ_0. The confined nature of the evanescent wave close to the interface is ideal for studying surface and near-surface phenomena pertaining to fluid mechanics and mass transport typically by fluorescence microscopy, which is known as total internal reflection fluorescence microscopy (TIRFM) or simply ►TIRF.

Overview

As fluid mechanics reaches into the micro- and nano-scale, interfacial phenomena become increasingly important, and several diagnostic techniques have been adapted from other fields to quantify fluid phenomena at these scales. In addition to general and fluorescence microscopy, an important technique for fluid-surface studies is the use of ►evanescent wave microscopy.

Origins

Evanescent wave microscopy or total internal reflection microscopy (TIRM) has been employed in the fields of biology and chemistry since the 1970s. The TIRM technique has long been used in cell biology studies and more recently cell-substrate contacts, vesicle fusion, and single-molecule observation. Here, cells on a microscope cover glass are illuminated by an evanescent field, which is produced through a total internal reflection (TIR) created at the cell/cover glass interface and imaged by a microscope. The technique has been used to measure chemical kinetics and surface diffusion, molecular conformation of adsorbates, cell development during culturing, visualization of cell structures and dynamics, and single molecule visualization and spectroscopy [1].

Applications to Fluid Mechanics

In micro- and nano-scale fluid mechanics, measurements of diffusion and velocity are used to probe fundamental physical phenomena and evaluate the performance of devices. ►Evanescent wave illumination has been combined with several other diagnostic techniques to make such measurements within the order of the penetration depth (about 100 – 200 nm) of fluid-solid interfaces with resolution sometimes as small as several nanometers. Laser–Doppler velocimetry has been applied to measure single point tracer particle velocities in the boundary layer

of a fluid within 1 µm of a wall. By seeding fluid with fluorescent dye, total internal reflection fluorescence recovery after photobleaching (FRAP) has been used to measure near-wall diffusion coefficients and velocity (for a summary of initial applications see Zettner and Yoda [2]).

A critical contribution of ▶ evanescent wave microscopy to micro- and nano-fluidics is the application of micro/nano-particle velocimetry techniques to measure velocity fields. Particle image velocimetry (PIV) and particle tracking velocimetry (PTV) have been viable macro-scale diagnostic techniques for measuring two-dimensional velocity fields since the 1980s. These techniques were later adapted to the micro-scale [3] (known as micro-PIV and micro-PTV), which made use of fluorescence microscopy. More recently, Zettner and Yoda [2] used the micro-PIV technique combined with evanescent wave illumination to measure the near-wall velocity field in a rotating Couette flow within about the penetration depth of the evanescent field from the wall. Micro-PTV has also demonstrated great success in measuring the near-wall velocity fields in an evanescent wave as well as the diffusion of tracer particles and even three-dimensional tracer displacements/velocities [4–6].

Advantages

The small length scales involved in micro- and nano-fluidics do not allow for the convenient production of a light sheet to visualize distinct planes of fluid. Instead, imaging was typically limited to volumetric flood illumination as the only visualization technique, which used the depth of focus (DOF) of the microscope objective to designate distinct fluid planes [3]. The DOF is generally described by

$$\mathrm{DOF} = \frac{\lambda_0 n_1}{\mathrm{NA}^2} + \frac{n_1}{M \cdot \mathrm{NA}} e. \tag{1}$$

where λ_0 is the illumination wavelength, n_1 is the index of the immersion medium, M is the magnification and e is the smallest distance that can be resolved by the detector. The DOF can be quite large for low magnification or low numerical aperture (NA) objectives, and even for high magnification, large NA objectives the DOF is on the order of several hundreds of nanometers. More importantly, flood illumination excites out-of-plane fluorophores outside of the DOF, which are imaged as background noise and significantly lower the signal-to-noise-ratio SNR).

Evanescent wave illumination provides an illuminated fluid layer of smaller dimension than by using the DOF alone, allowing for measurements closer to liquid–solid interfaces. The exponential decay of the light intensity away from the interface is well known, and studies have shown that the intensities of fluorescent tracer particles excited by the evanescent field closely follow the local field intensity [5]. Thus, through careful calibration, tracer particle intensity can be mapped to relative distance from the interface allowing for three-dimensional tracking. Finally, since only a thin layer of fluid is illuminated, there is virtually no background noise from out-of-plane excitation resulting in a very high SNR (Fig. 1).

Basic Methodology

Evanescent Field Theory

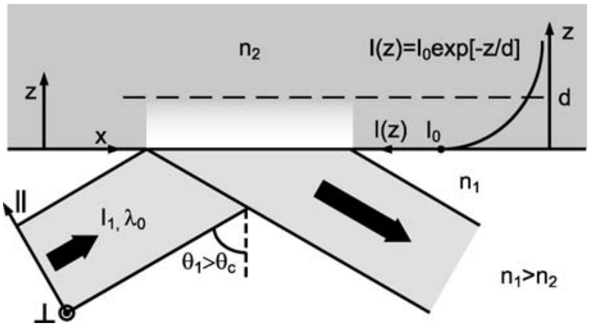
When an electromagnetic wave (light) in a dielectric medium of index n_1 is incident upon an interface of a different dielectric material with a lower optical density, n_2, at an angle θ_1 Snell's law predicts the refracted angle, θ_2, by:

$$n_1 \sin(\theta_1) = n_2 \sin(\theta_2) . \tag{2}$$

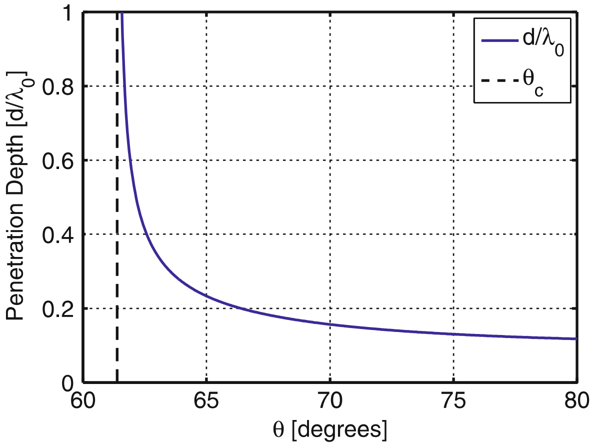
For incident angles greater than the critical angle,

$$\theta_c = \sin^{-1}\left(\frac{n_2}{n_1}\right) , \tag{3}$$

total internal reflection occurs as illustrated in Fig. 2. Although all of the incident energy is reflected, the solution of Maxwell's equations predict the existence of an electromagnetic field in the less dense medium with intensity decaying exponentially away from the interface. This evanescent wave propagates parallel to the interface and has a decay length, d, on the order of the wavelength of the illuminating light, λ_0. However, photons are not actually reflected at the interface, but rather tunnel into the low index material by optical tunneling. As a result, the reflected beam of light is shifted along the interface by a small amount ($\Delta x = 2d \tan\theta_1$), which is known as the



Evanescent Wave Microscopy, Figure 2 Illustration of geometry and parameters for an evanescent wave produced by the total internal reflection of plane waves incident on a dielectric interface



Evanescent Wave Microscopy, Figure 3 Behavior of the penetration depth d normalized by the incident wavelength λ_0 as a function of the incident angle θ_1 for a typical glass–water interface with $n = 0.878$

Goos–Haenchen shift. This shift is typically small for fluid diagnostic applications ($\Delta x < 1\,\mu$m) as compared to the field of view, which is on the order of 100 μm.

The full details to the solution of Maxwell's equations are outlined in several other resources [1]. Here, only the results relevant to ►evanescent wave microscopy are presented, specifically the functionality of the intensity field in the low density material, which is used for imaging. It should be noted that these solutions assume infinite plane waves incident on the interface. In practice, however, one typically uses a finite, Gaussian laser beam, which is well approximated using these assumptions. The intensity field has the exponential form

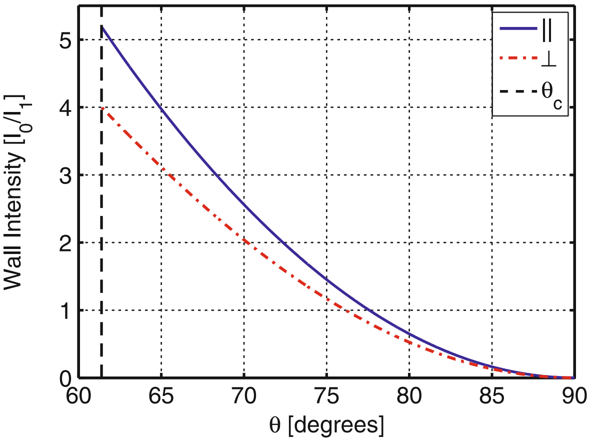
$$I(z) = I_0 e^{-z/d} , \tag{4}$$

where the decay length, d, is given by

$$d = \frac{\lambda_0}{4\pi n_1}[\sin^2\theta_1 - n^2]^{-1/2} , \tag{5}$$

and $n = n_2/n_1 < 1$. In a typical system, the substrate is a glass slide ($n_1 = 1.515$) and the interrogation medium is water ($n_2 = 1.33$), which gives $n = 0.878$. The behavior of d with respect to incident angle is shown in Fig. 3 for these conditions. For $\lambda_0 = 514$ nm (Argon Ion), the penetration depth is about $d = 140$ nm assuming an incident angle of $\theta_1 = 64.0°$. The polarization of the incident beam does not affect the penetration depth, but it does affect the amplitude of the evanescent field. For plane waves incident on the interface with intensity I_1 in the dense medium, the amplitude of the field in the less dense medium I_0 is given by

$$I_0^{\|} = I_1^{\|}\frac{4\cos^2\theta_1\left(2\sin^2\theta_1 - n^2\right)}{n^4\cos^2\theta_1 + \sin^2\theta_1 - n^2}, \tag{6}$$



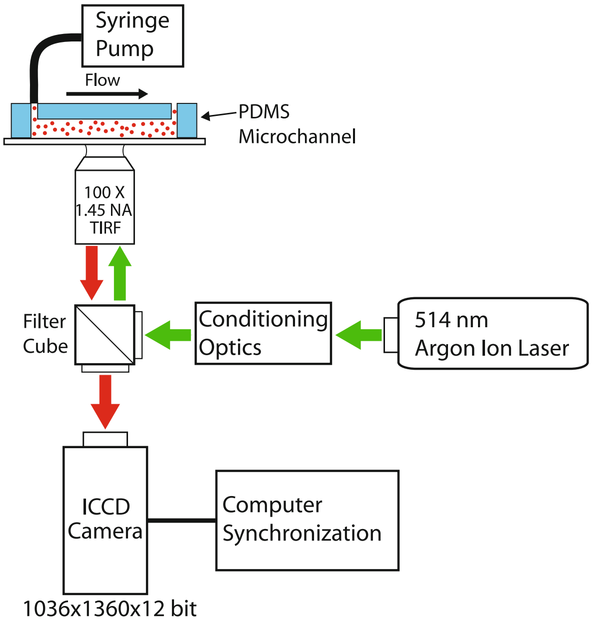
Evanescent Wave Microscopy, Figure 4 Amplitude of the evanescent field intensity at the interface in the low index material n_2 for both parallel and perpendicular polarization of the incident electromagnetic field

$$I_0^{\perp} = I_1^{\perp}\frac{4\cos^2\theta_1}{1 - n^2}, \tag{7}$$

for incident waves parallel and perpendicular to the plane of incidence, respectively, as shown in Fig. 4 [1].

Experimental Implementation

Due to the length scales involved, most interesting phenomena probed by the evanescent wave require microscope optics for imaging. In the past, several TIRM studies have been conducted using only scattering from objects in the evanescent field for imaging. More recently, fluorescence microscopy systems have become the standard imaging technique for evanescent wave microscopy



Evanescent Wave Microscopy, Figure 5 Schematic diagram of a possible TIRF system for micro- and nano-scale velocimetry using objective-base TIR illumination

(TIRF) due to superior SNR and the availability and variety of fluorescent probes. The basic components of a TIRF imaging system include: light source, illumination optics, specimen or flow cell, emission imaging optics and a camera (usually accompanied by a PC). An example of such a system is shown in Fig. 5.

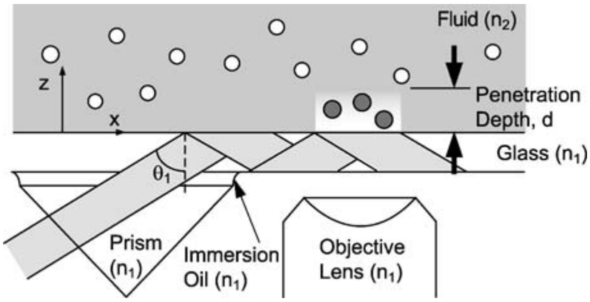
Light sources are typically continuous-wave (CW) lasers (argon-ion, helium-neon, etc.) or pulsed lasers (Nd : YAG, etc.) for their collimation and single-wavelength characteristics. Non-coherent sources (arc-lamps) are not as common in typical homemade systems, but commercial versions are available. Conditioning optics are used to create the angle of incidence necessary for TIR and are of two types, which will be discussed below. The illumination optics must be held in contact with sample substrate, which can be glass, quartz or plastics as long as the surface is reasonably smooth (standard glass slides and cover slips are adequate). Finally, flow channels are available in a wide variety of forms (both commercial and homemade), which include PDMS channels bonded to glass slide substrates, etched glass channels and commercial glass or quartz flow chambers.

Fluorescence microscopy uses fluorescent molecules (fluorophores), which absorb light energy from the evanescent field created by the light source at wavelength λ_0 and re-radiate photons at a longer wavelength λ_1. Optical filters isolate the excitation light from the emitted light, which is then collected and imaged by a camera. High magnification microscope objectives (30X to 100X) serve as the collection optics and CCD cameras are used for capturing images. Depending on the level of light emitted from the probes, cooled or intensified CCD cameras may be necessary for better sensitivity. Fluorescent probes are commercially available in several forms with varying sizes: single fluorophores (fluorescein, rhodamine laser dye), polymer micro-spheres (50 nm to several μm diameter), ►quantum dots (5 – 25 nm diameter), etc. Most dyes and particles are soluble in water for ease of use and application to biological systems. However, investigations of some interesting flow physics are possible with other materials (polymers, organics, etc.). In the case of imaging single particles, most tracers are sub-wavelength, and thus, typically limited to imaging the diffraction limited spot. However, sub-wavelength and sub-pixel resolution is possible through post-processing procedures.

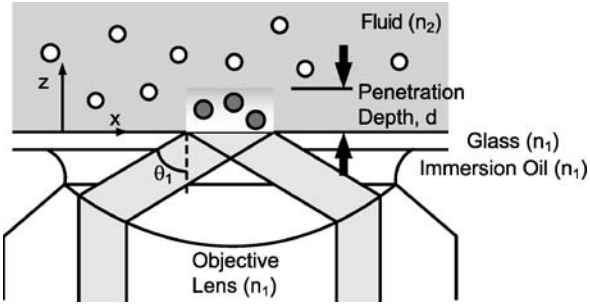
The two common types of illumination systems for creating evanescent wave illumination are prism-based systems and objective-based systems. There are several configurations for each, both of which have their own specific shortcomings, which are outlined elsewhere [1]. Two popular configurations for TIRM systems are presented below.

Prism-Based Systems Prism-based TIR illumination systems are typically home-build and low cost. A prism (triangular, square, hemispherical, etc.) is placed in contact with the sample substrate or flow channel (usually coupled to the substrate using an immersion medium). The laser beam is focused into the prism to illuminate the area of interest, then the angle is adjusted to create TIR at the interface of the sample. If the evanescent field is created on the surface of the flow channel opposite of the objective, then air, water or oil immersion objectives may be used provided they have the required working distance. Otherwise, if TIR is created on the same side as the objective, then oil immersion may not be used, since the beam will decouple from the system and fail to create an evanescent field. An example of a prism-based TIRM system is shown in Fig. 6.

Objective-Based Systems Objectives suitable for TIR are common (although expensive). They are typically limited to 60X to 100X magnification immersion objectives, and require very high numerical apertures (NA $>$ 1.4). In this method, the collimated light source is focused down onto the back focal plane of the objective to illuminate the sample. Light rays off of the optical axis are projected onto the sample interface at increasing incident angle. If the rays are localized and far enough off of the optical axis, then the full NA of the objective will be utilized and TIR



Evanescent Wave Microscopy, Figure 6 Schematic diagram illustrating the general experimental set-up for prism-based TIRM, where the beam of light is coupled into a glass slide using a prism



Evanescent Wave Microscopy, Figure 7 Schematic diagram illustrating the general experimental set-up for objective-based TIRM, where the beam of light is coupled directly into an objective. A large NA is necessary to achieve incident angles greater than the critical angle $\theta_1 > \theta_C$

will occur at the sample interface creating an evanescent wave in the sample medium as shown in Fig. 7.

Velocimetry and Tracking Techniques

With a TIRFM system in place, quantitative measurements can be made within 200 nm of the substrate surface. Typically, in fluid mechanics, a wealth of information about any given flow system can be found from the velocity field. As mentioned above, micro-PIV and micro-PTV are both well-established tools for extracting quantitative information from micro-scale fluid systems [3]. However, special care must be taken in applying these techniques to very near-wall flows with evanescent wave illumination. Both techniques require imaging the instantaneous positions of tracer particles seeded in the flow at two different instances in time to infer fluid velocities. Once a series of tracer particle images is obtained, PIV uses cross-correlations of segments from each image to determine the highest correlation for the movement of a group of particles from one image to the next and thus, the velocity of that group. PTV on the other hand, attempts to match individual tracer particles between the two images. This is performed through identification and center detection of all particles then, matching particles usually through nearest-neighbor algorithms to find the displacement and subsequently the velocity. Since there is little to no slip at the wall, two-dimensional velocimetry within the evanescent field measures the average velocity in the evanescent field weighted by the concentration profile and detectability of the tracer particles. Three-dimensional measurements are typically made by tracking algorithms and rely on the characterization of the evanescent field intensity to map tracer particle intensity to distance from the wall [5, 6].

Particle tracking algorithms have also been used successfully in two- and three-dimensional diffusion measurements and simultaneous diffusion/velocity measurements. The random, thermal motion exemplified by small particles in a surrounding fluid, (Brownian motion), is typically characterized by a diffusion coefficient. By utilizing particle tracking, diffusion coefficients can be measured by observing many thousands of individual particle motions to build an ensemble of displacement statistics. Measurements of diffusion are even more interesting near liquid–solid interfaces, accessible by TIRF, where diffusion coefficients can be anisotropic [6, 7]. In addition to the implications for interface science, these effects should be used in velocimetry algorithms by correcting observed particle displacements to account for anisotropic particle diffusion characteristics.

Near-Wall Effects

With the high resolution of the TIRM technique, one should be aware of several physical phenomena that are active on length scales comparable to the penetration depth. When an isolated particle is in the vicinity of a solid boundary, its Brownian motion is hindered due to an increase in hydrodynamic drag. The presence of the solid wall decreases the diffusion coefficient, resulting in hindered, anisotropic Brownian motion [7].

In many TIRM applications, it is important to know the concentration profile of tracer particles in the near-wall region. This is important for calculating average velocities in the evanescent field and mapping intensities to distances from the wall. Three physical phenomena may play a role of varying importance: (1) gravitational settling, (2) shear-induced lift (the Saffman effect) and (3) electrostatic attraction/repulsion. In all three cases, these effects compete with Brownian diffusion, which tends to mix the tracers into a uniform distribution throughout the fluid. The effect of gravitational settling is greatest for large particles ($2a \sim 1\,\mu$m) with density mismatch. Shear-induced migration or the Saffman effect is the migration of particles away from solid boundaries in the presence of

high shear. This becomes important for $\mathrm{Re} = 2a\rho U/\mu > 1$, where U is the mean velocity [3]. Electrostatic attraction or repulsion between tracers and the wall can also have a substantial effect on the concentration profile, depending on the relative charges of the particle and substrate. This can be suppressed by the addition of electrolytes to the fluid medium to provide charge screening.

Key Research Findings

Velocimetry with Evanescent Wave Illumination

Until recently, there were no direct experimental measurements of near-wall nano-scale flows. The development of evanescent wave velocimetry has enabled contributions in several areas. If one applies an electric field along the length of a microchannel, ions near the charged surface move, dragging the bulk fluid along and thus creating a plug-type Electro-Osmotic Flow. TIRV has been applied to characterize the two wall-parallel velocity components in EOF within 100 nm of the wall, which includes the electric double layer (EDL). Analytical and numerical studies suggesting uniform flow near the wall were verified using a nano-PIV technique with an evanescent wave, demonstrating that the EDL is much smaller than 100 nm as predicted [8].

Another research focus has been the investigation of the no-slip boundary condition between a liquid and a solid - an assumption that has been challenged by recent experimental results and molecular dynamic simulations and the subject of many recent investigations. Experimental studies have reported a wide range of slip lengths, ranging from micrometers to tens of nanometers or smaller (including no-slip). Molecular dynamics simulations, on the other hand, suggest small slip lengths, mostly less than 100 nm. The experiments have been conducted under various direct and indirect measurement techniques with varying accuracy and uncertainty Huang et al. (2006) [5] used 3D ► Total Internal Reflection Velocimetry (3D-TIRV) to make direct measurements of slip length within 150 nm of the surface. Particle tracking in the wall-normal direction was approximately 10% of the evanescent field penetration depth (about 20 nm), and they were able to show that there appears to be minimal slip over hydrophilic surfaces, while hydrophobic surfaces do appear to introduce a discernable, but small boundary slip, with a slip length of the order of 10 – 50 nm.

Given the small size of the observation region generated using evanescent wave illumination, it is desirable to minimize the size of the tracer particles for better resolution, and the use of semiconductor nanocrystals or quantum dots (QDs) has been demonstrated. QDs are single fluorophores with fluorescence lifetimes similar to traditional fluorophores. They exhibit several qualities beneficial to nano-scale velocimetry including small diameter (5 – 25 nm), narrow emission spectra and controllable surface chemistry. Although they are much brighter than traditional fluorophores, QDs have significantly lower intensity than larger, more common tracer particles measuring several hundred nanometers. Velocimetry with QDs in aqueous solutions is made possible by TIRV because of the extremely high SNR. QD tracking and velocimetry has been successfully demonstrated by several groups using nano-PTV techniques [9, 10].

Diffusion and Hindered Diffusion Measurements

When the distance h between a spherical particle of radius a and a solid boundary becomes sufficiently small ($h/a \sim 1$), hydrodynamic interactions between the particle and wall hinder the Brownian motion (diffusion) of the particle. Such effects are critical to fundamental near-wall measurements and the accuracy of micro-velocimetry techniques, which rely on the accurate measurement of micro/nano particle displacements to infer fluid velocity. By applying the 3D TIRV technique to freely suspended fluorescent particles, simultaneous observation of three-dimensional anisotropic hindered diffusion has been measured for particle gap sizes $h/a \sim 1$ with 200 nm diameter particles [6] and $h/a \ll 1$ with 3 μm diameter particles [7]. The latter results confirm the increase of hydrodynamic drag when a particle approaches a solid boundary, and such correction shall be applied to not only diffusion but also other translational motion of particles where the drag force is of concern.

Future Directions for Research

Evanescent wave microscopy has already yielded a number of contributions to the fields of micro- and nano-scale fluid and mass transport, including investigation of the no-slip boundary condition, applications to electrokinetic flows and verification of hindered diffusion. With more experimental data and improvements to TIRF techniques the accuracy and resolution these techniques are certain to improve. Improvements that will assist include the continued development of uniform, bright tracer particles (such as quantum dots), the improvement of high NA imaging optics and high sensitivity camera systems, and further development of variable index materials for better control of the penetration depth characteristics.

External Actuators

Definition

A micropump or active microvalve is said to use external actuators when the component responsible for opening or closing the valve, or moving the fluid, is added to the device after fabrication. Examples would be a separate miniature solenoid valve used to pressurize or depressurize air chambers in a pneumatic actuator, or piezoelectric patches glued to a micromachined silicon or glass membrane.

Definition

The fabrication of 3D microfluidic structures is related to the microfabrication or Micro-Electro-Mechanical Systems (MEMS) processes, which produce the micro-scale structures (or microchannels) involving or relating to three dimensions (*x*, *y* and *z*) or aspects and giving the illusion of depth, for the handling of fluids in biomedical, chemical, biological devices, etc. It is specifically referred to in the fabrication of microstructures with complex lateral contours using a 2D mask layout. These 3D microstructures may be sculpted in a bulk-substrate or created on the surface of a substrate.

Overview

3D microstructures have been highlighted in microfluidic devices and systems, and typically used to improve the properties of fluidic handling, such as micro-mixers, valves, pumps, micro total analysis systems (μ-TAS), etc. For instance, the microchannel geometry in a micromixer plays an important role in mixing, because only laminar flow is present in the straight microchannels. Well-defined three dimensional microchannels or microstructures can generate a heterogeneous mixture with a finely dispersed structure, and the diffusion of the fluid molecules in the adjacent domains produce a homogenous mixture at the molecular level. As one of the key microfluidic devices, the conventional micropump has been designed and fabricated using two dimensional or planar structures due to crystallographic orientation of the substrate. These pumps have intrinsic limitations such as dead volume, impedance mismatch in interconnects and low back pressure. The 3D fabrication technology provides a new design concept for the micropump and improves its performance. Over the last two decades, microfluidic handling and analysis have been emerging in the interdisciplinary research field of fluidics. The applications have also expanded to microarray, sample preparation, cell cultivation and detection, DNA sequencing, and environmental monitoring. Using 3D microfabrication technologies could potentially enhance the efficiency, reliability, and overall performance of various microfluidic devices. With the continually high demands of microfluidics applications, 3D microstructure fabrication technology becomes more interesting to researchers and industries.

Lithography, as a traditional pattern transfer technology, is normally the first step in top-down microfabrication. Several lithographic techniques offer intrinsic 3D structuring capabilities. For example, Electron beam lithography (EBL) can generate gray-scale profiles by controlling the exposure dose. Gray scale lithography can transfer 3D structure from a 2D gray scale mask. X-ray lithography (XRL) is capable to replicate multilevel masks by amplifying the thickness profile, and can generate complex 3D

structures with multiple exposures at tilted angles. Moreover, focused ion beam (FIB) lithography has shown the capability for direct milling and growth of hard materials. Holographic lithography can generate large volume periodic 3D structures with submicrometer resolution. However, lithographic techniques have their own peculiarities and potentialities that in many cases cannot be exploited to completely cover the entire spectrum of fabrication needs for 3D microstructures. The main disadvantages of these technologies include low speed processes and difficulty moving into mass production. On the other hand, these technologies can be used to fabricate reverse 3D microstructures in the form of molds to produce the final devices by casting, hot embossing, imprinting and soft lithography at low cost.

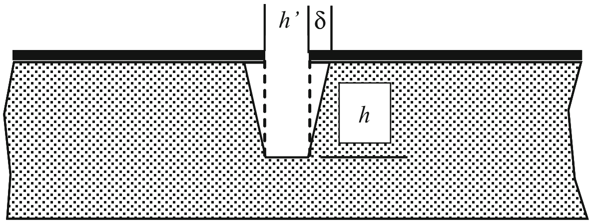
Most micromachined structures applied in MEMS are fabricated on silicon substrate. Silicon patterning with chemical and/or plasma etching has been extensively studied in the last two decades. Using wet chemical etching, one can define the 3D geometry profile into the silicon substrate by choice of mask geometry, etchant and crystallographic cutting of the substrate. Isotropic silicon etching can generate rounded sidewall profiles and anisotropic etching can produce more complicated profiles like V shape channel, square and rectangular hole, frustum of a pyramid, and other shapes. Plasma dry silicon etching makes it possible to etch controllable profiles without limitations due to crystal orientation. It also provides high etch rate and selectivity between substrate and masking material. Dry plasma etching is becoming a standard tool in microfabrication.

Recently, patterning of polymers, proteins and cells has been intensively studied for 3D polymer structure. In contrast to silicon, polymers show several major advantages that are currently not available in silicon or glass, including a wide range of material characteristics, biochemical compatibility, ease of fabrication and prototyping, and low cost. These benefits make polymers the most promising substrate materials for biomedical and biological applications. Poly(dimethylsiloxane) (PDMS), poly(methylmethacrylate) (PMMA) and SU-8 have been broadly used in microfluidic devices and systems. New technologies for polymer 3D micro/nano structure fabrication such as soft-lithography, hot embossing and different replica moldings are also developed as low-cost approaches to fabricate microfluidic devices.

Basic Methodology

Wet Chemical Etching

Wet chemical etching has its genesis in the semiconductor industry. In this process, the feature structures are sculpted



Fabrication of 3D Microfluidic Structures, Figure 1 Example of an etching profile

in bulk substrates such as silicon, quartz, SiC, GaAs, Ge and glass by orientation dependent (anisotropic) or orientation independent (isotropic) wet etchants. The first use of silicon as a substrate can be traced back to mid-1950s and early 1960s. Although this process has a long history, it is still a main conventional microfabrication technology. It is not only low cost and suitable for mass production, but also provides the ability of controlling the etching profile and the well-defined geometries of etched features.

Wet chemical etching can be considered as a sequence of three steps: transport of the reactant to the surface of substrate, reaction with the surface, and movement of reaction product into the etchant solution. Therefore, it includes three components: mask, etchant and substrate. Two important figures for the etching process are selectivity and directionality. Selectivity is the degree to which the etchant can differentiate between the masking layer and the layer to be etched. Directionality has to do with the etch profile under the mask. In isotropic etching, the etchant removes the substrate materials in all directions at the same etch rate and creates a semicircular profile under the mask. In anisotropic etching, the etch rate depends on the substrate's crystallographic orientation by which one can obtain straight sidewalls or other noncircular profiles. To describe the etching processes including wet and dry etching, the following terms are defined (Fig. 1).

Etch Rate (ER) It is the ratio of etch depth (h) and actual etching time (t).

$$ER = \frac{h}{t}$$

Selectivity (S) During the etching process, the mask layer and the substrate are both immersed in the etching media which can be a wet chemical etching bath or plasma. Although the etchant mainly reacts with the substrate, the mask layer is also attacked. The relationship between the etching of the substrate and the mask layer is the selectivity S which is given as the ratio of the etch rate of the

substrate (r) to the etch rate of the mask (r'):

$$S = \frac{r}{r'}$$

It is a critical parameter where deep etching is required.

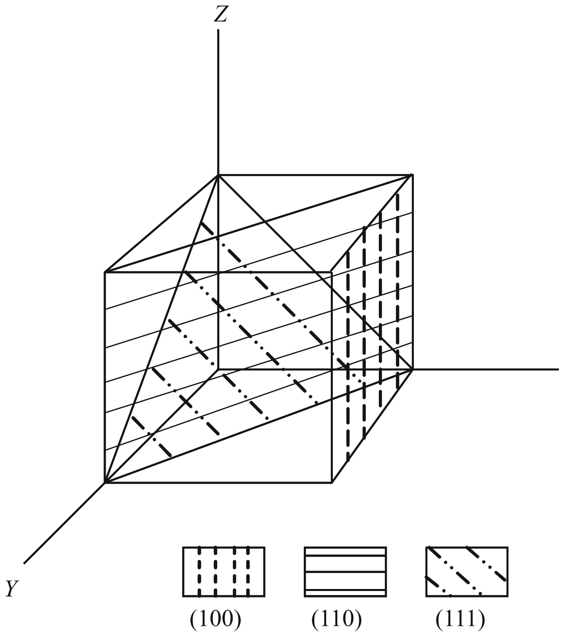
Aspect Ratio (*AR*) It is defined as the ratio of the etch depth (h) with the channel opening width (h').

$$AR = \frac{h}{h'}$$

Undercut Rate (*UR*) Undercut rate is defined as the ratio of the undercut (δ) to the etch depth (h).

$$UR = \frac{\delta}{h}$$

Since the etch rate in isotropic etching is the same in all directions, its undercut rate is ~ 1. For orientation-dependent anisotropic ►wet etching, the undercut rate is basically < 1. If the undercut rate can be controlled in the etching process, the lateral contours along the z direction will be changed and a special 3D structure can be created with a 2D mask pattern.



Fabrication of 3D Microfluidic Structures, Figure 2 Three main planes in a cubic lattice

Theory

The majority of substrate used for MEMS and microfluidic devices or systems is silicon. Crystalline silicon forms a covalently bonded structure and has the same atomic arrangement as carbon in diamond. The crystallographic orientation in crystals of the cubic class is described in terms of Miller notation [1]. Any plane in the space satisfies the equation

$$\frac{x}{a} + \frac{y}{b} + \frac{z}{c} = 1$$

Where a, b, and c are the intercepts made by the plane at the x, y, and z axes, respectively. A set of integers of h, k and l can be used and then the equation can be written as

$$hx + ky + lz = 1$$

The integer h, k, and l are called Miller indices. To identify a plane or direction, a series of three numbers are used. Figure 2 shows three planes in a cubic lattice nestled into the origin of the x, y, z coordinate system which illustrate the important planes (100), (110) and (111) in the conventional microfabrication process. Each plane is unique, differing in atom count and binding energy between the atoms. Each plane also has different mechanical, chemical and electrical properties. The etch rate is strongly affected by the crystallographic orientation of silicon. For example, the etch rate of the (100) plane is $\sim 0.6\,\mu m/min$ in 40% KOH at 70 °C while the etch rate is 1.3 $\mu m/min$ for the (110) plane and 0.009 $\mu m/min$ for the (111) plane. The (110) plane is the fastest etching primary surface. The ideal (110) surface has a more corrugated atomic structure than the (100) and (111) primary surfaces. The (111) plane is an extremely slow etching plane that is tightly packed, has a singling-bond per atom and is overall atomically flat. Table 1 lists the etch rates for some crystallographic orientations of silicon in KOH etchant with different concentrations. By understanding and using these orientation-dependent properties, 3D microstructures in a silicon substrate can be well defined.

Experimental

For wet isotropic etching of silicon, the commonly used etchant is a mixture of nitric acid (HNO_3), hydrofluoric acids (HF) and water or acetic acid (CH_3COOH). The reaction of silicon with acids suggests that chemical etching in aqueous solution occurs via the oxidation of the silicon surface by HNO_3 oxidation agent, followed by the dissolution of the silicon oxidation products in HF. The overall reaction mechanism for silicon etching in HF/HNO_3

Fabrication of 3D Microfluidic Structures, Table 1 Silicon etch rate at different crystal orientations in KOH

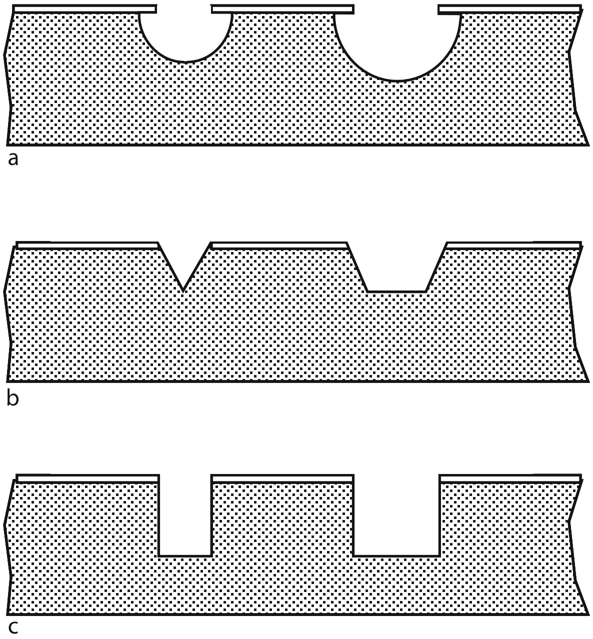
Crystallographic orientation	Etch rate at different KOH concentrations (μm/min) 30%	40%	50%
(100)	0.797	0.599	0.539
(110)	1.455	1.294	0.870
(210)	1.561	1.233	0.959
(211)	1.319	0.950	0.621
(221)	0.714	0.544	0.322
(310)	1.456	1.088	0.757
(311)	1.436	1.067	0.746
(320)	1.543	1.287	1.013
(331)	1.160	0.800	0.489
(530)	1.556	1.280	1.033
(540)	1.512	1.287	0.914
(111)	0.005	0.009	0.009

mixture is [2]:

$$Si + HNO_3 + 6HF$$
$$\longrightarrow H_2SiF_6 + HNO_2 + 2H_2O + H_2$$

The mixing weight ratio of HF to HNO_3 greatly affects the silicon etch rate. The highest etch rate is observed at the weight ratio of 2 : 1. Figure 3a shows the etching profile for this wet isotropic etching process. The etch rate is the same in all directions.

Anisotropic etchants are alkaline solutions and the etching process is characterized by a high etch rate and an excellent selectivity dominated by the substrate's crystal orientation. There are a wide variety of etchants available for anisotropic etching including KOH, NaOH, LiOH, CsOH, and RbOH. The most commonly used ones are KOH and EDP (ethylene-diamine/pyrocatechol with water). The normal etching temperature for KOH etchant is in the range of 20 – 80 °C, and it strongly influences the etch rate. Raising the etching temperature will increase the etch rate, but decrease the anisotropic degree (etching selectivity in different crystallographic directions). After several hours of the etching process at such temperatures, the concentration of the alkali solution will be changed. Therefore, closed vessels are recommended and the safety issue must be a concern. Since the photoresist will be quickly dissolved in an alkaline etching media, SiO_2 and Si_3N_4 are the common materials for mask layer. The etching selectivity ratio of silicon is ~100 to SiO_2 and > 500 to Si_3N_4. Si_3N_4 as a mask layer is necessary if an etch depth of over 200 μm is required. A SiO_2 film may be deposited on the Si_3N_4 film as a mask to pattern the Si_3N_4 film. Figure 3b illustrates the etching result for a V-groove in a (100) silicon wafer. The etching bonder at (111) planes is generally at 54.74° to the (100) surface of silicon. Figure 3c shows a straight sidewall feature using a properly aligned mask on a (110) silicon wafer.



Fabrication of 3D Microfluidic Structures, Figure 3 Etching profiles in wet chemical etching

Dry Plasma Etching

Dry etching is referred to as plasma processing, which was first introduced in the 1960s. During the past forty years, a number of plasma sources have been developed for dry etching, including reactive ion etching (RIE), sputter etching, magnetically enhanced RIE (MERIE), electron

cyclotron resonance (ECR), inductively coupled plasma (ICP), etc. It has been shown that ICP etching is the most suitable and efficient plasma source for deep anisotropic silicon etching with high etch rate and provides the capability of creating 3D microstructures.

Plasma Physics and Chemistry of ICP Etching

In general, the plasma for dry etching is produced by the dissipation of electrical power in a gaseous medium at radio frequency (RF). Electrons gain sufficient energy during oscillation in the RF field to initiate collisions with atoms and molecules to generate the etching species, and to initiate processes such as excitation, ionization and dissociation. The inductively coupled plasma can be generated by using a time-varying axial magnetic field to induce an azimuthal electrical field which effectively confines the plasma current. The current path minimizes contaminants or particles resulting from direct ICP etching and chamber wall sputtering. The highest plasma intensity region is located close to the etching chamber sidewalls and ambipolar diffusion results in a highly uniform plasma inside the chamber.

Figure 4 is a schematic diagram of a typical ICP etching system. The sample is loaded into the etching chamber via a load chamber and either mechanically or electrostatically clamped to the lower electrode. Helium or nitrogen backside cooling provides good thermal conductance between the electrode and the sample. Process gases are admitted to the etching chamber and controlled to a pressure usually in the range of 2.5 – 13 Pa. The 13.56 MHz RF power is applied to the ICP coil to generate the high-density etching plasma. The RF power is also applied to the lower electrode for independent control of substrate bias power. Unused feed gases and volatile etch products are pumped away by a backed turbo pump.

The chemistries of ICP etching mainly include fluorinated, chlorinated, or bromine-based gases. When silicon substrates are dry-processed with fluorinated chemistry, the etch rate is a combination of contributions from spontaneous or thermal reactions between fluorine and silicon, ion bombardments, and a small effect of physical sputtering. A chlorinated chemistry allows easier control of the etching profiles as compared to fluorinated chemistry due to the lack of spontaneous etching of silicon. In general, a higher silicon etch rate as well as a higher etch selectivity of substrate to masking material is expected when using fluorinated chemistry. Moreover, fluorine-based compounds cause fewer health hazards and corrosion concerns than their chlorinated and brominated counterparts.

Among the available anisotropic process schemes and recipes, the Bosch process which is named after the German company that developed and patented the technique is recognized as a standard process for ICP system. The Bosch approach is based on a variation of the teflon-film sidewall passivation technique which avoids the recombination of active species in the gas phase. The deposition and etching steps are performed subsequently to control the sidewall profile of the 3D structures. In the deposition step, the precursor gas (CF_4, C_4F_8, CHF_3, C_2F_6 or higher molecular gas) is dissociated by the plasma. The ion and radical species undergo polymerization reactions. A passivation layer of n CF_2 is deposited on the etched pattern surface. A possible reaction scheme using CF_4 as an example is

$$CF_4 + e^- \longrightarrow CF_x^+ + CF_x^- + F^- + e^-$$

$$nCF_x^- \longrightarrow nCF_{2\ \text{adsorbed}} \longrightarrow nCF_{2\ \text{film}}$$

The deposited polymer film can be removed by ion bombardment with low energy. In the etching step, the etching gas (for instance SF_6) is dissociated by the plasma, liberating high amounts of etching species. These species are necessary to remove the polymer film at the bottom of the pattern and to effectively react with the silicon. The etching reactions involve the removal of the passivation layer

$$nCF_{2\,\text{film}} + F^-(+\text{ion energy})$$
$$\longrightarrow CF_{x\,\text{adsorbed}} \longrightarrow CF_{x\,\text{gas}}$$

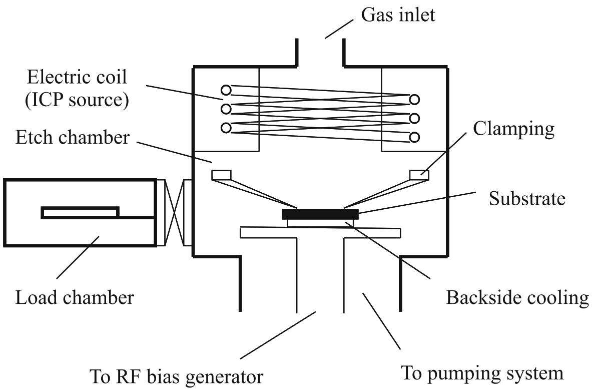
and silicon etching

$$Si + F^- \longrightarrow Si - nF + (\text{ion energy})$$
$$\longrightarrow SiF_{x\,\text{adsorbed}} \longrightarrow SiF_{x\,\text{gas}}$$

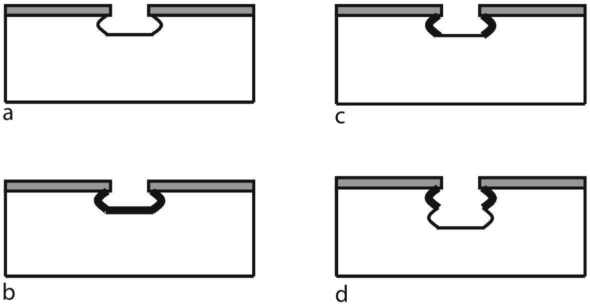
Since the bombardment and etching reaction with the passivation film on the bottom of pattern are faster than on the sidewall, the silicon surface on the sidewall can be protected by the passivation layer during the etching step. Hence a straight sidewall for the etched feature can be obtained. The kinetics of etching silicon, based on the Langmuir type surface kinetics model, in fluorocarbon discharges using ICP reactors has been developed successfully, and can be found in [3].

Time-Multiplexed Deep Etching (TMDE)

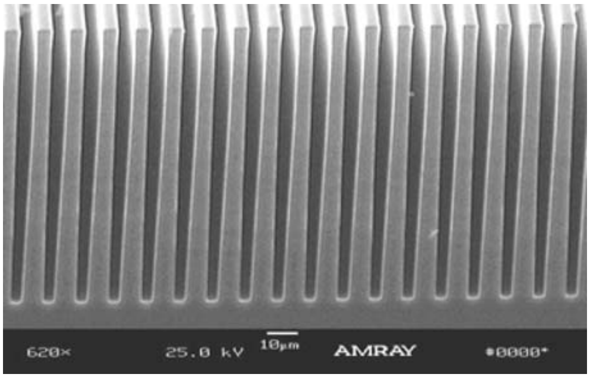
Various 3D microstructures can be created by ICP etching utilizing two gas-feeding methods, continuous etching and time multiplexing. For the continuous etching technique,



Fabrication of 3D Microfluidic Structures, Figure 4 Schematic of a typical ICP etching system



Fabrication of 3D Microfluidic Structures, Figure 5 Four process steps for time-multiplexed deep etching: (**a**) isotropic etching of silicon; (**b**) polymer passivation; (**c**) removal of formed polymer film on the horizontal surfaces; (**d**) further isotropic etching of silicon



Fabrication of 3D Microfluidic Structures, Figure 6 SEM image of microfluidic channels with high aspect ratio of 20:1 (5 μm width and 100 μm depth) fabricated using TMDE process

all gas species (passivation and etching) are flowed into the etching chamber simultaneously. The etching results depend on the presence of radicals in the glow discharge to proceed with the etching and on other radicals for protecting the sidewalls during operation.

In ►time-multiplexed deep etching (TMDE), the etching and passivation gas monomers are flowed independently one at a time during operation. First, the etch step (normally ≤ 12 s) forms a shallow isotropic trench in the silicon substrate. Second, the passivation cycle (normally ≤ 10 s) forms a protective film on all the surfaces. In the subsequent etching step, ion bombardment promotes the preferential removal of the film on the horizontal surface and further isotropic etching of silicon, allowing the profile to evolve in a highly anisotropic structure (Fig. 5).

In a typical configuration, SF_6 is the etching gas and C_4F_8 is the deposition gas for the sidewall protection. By adjusting etch parameters (such as gas flow rates and durations, plasma source power, substrate bias power, chamber pressure and substrate temperature) in each process step, etch rate, surface roughness, sidewall profile, and etch selectivity can be controlled and optimized to achieve designed 3D microfluidic structures. Figure 6 shows a scanning electron microscopy (SEM) image of microfluidic channels fabricated using TMDE process and Alcatel 601E ICP system. The feature size of the microchannels is a 5 μm width with 100 μm depth. The process recipe is source power 1800 W, bias power 50 W, SF_6 flow rate 300 sccm and pulse duration 4 s, C_4F_8 flow rate 180 sccm and pulse duration 2 s, chamber pressure 5 Pa, substrate temperature 20 °C, and process time 20 minutes.

Besides the continuous and the TMDE process, single feeding gas (such as SF_6) has been utilized in fabrication of 3D microfluidic structures with isotropic features for special applications. At the present time, commercial ICP etchers are available from Alcatel, San Jose, CA; Surface Technology Systems, Ltd. (STS), Redwood City, CA; and Plasma-Therm, Inc., St. Petersburg, FL.

Polymer-Based 3D Microstructure Fabrication

Polymer materials are widely used in the current research involving microfluidic devices because they are chemically and biologically compatible, easy to handle, and low material and manufacturing cost. The devices made by polymer materials are also disposable.

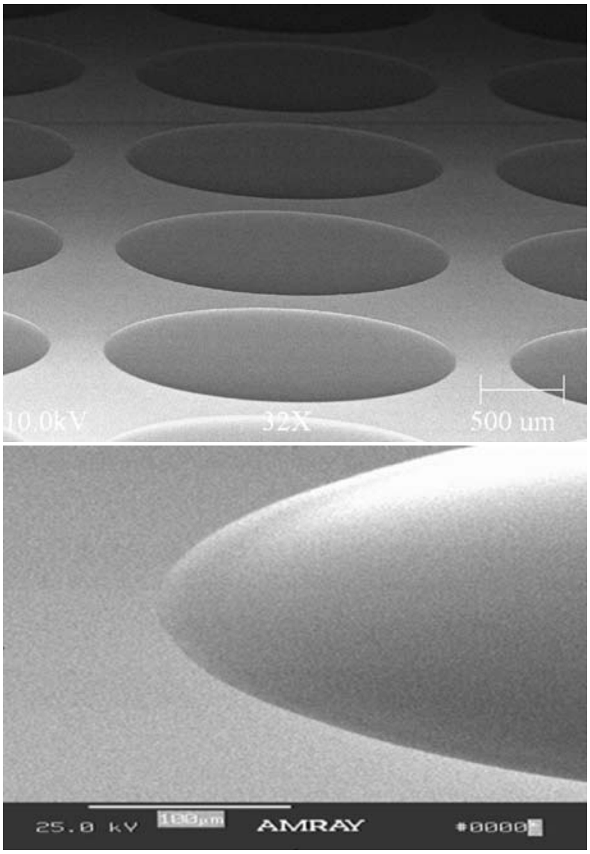
The concept of polymer-based 3D microstructure utilizes replica molding. Therefore, the key fabrication processes include 3D mold fabrication and pattern transfer. The material property is a very important factor when choosing the polymer and mold materials for special applications. For easy handling and accurate shape transfer, the mold requires smooth surface and relatively low thermal expansion coefficient since the curing of the polymer often involves heat. Nowadays, several polymer materials such as PDMS, PMMA and SU-8 are popular choices for microfluidic applications.

Replica molding is a method to reproduce the desired structures by filling the mold with the particular material. It is used to create structures on the materials that are not easy to have patterns created. It has the advantages of low cost and the capability of mass production. Replica molding involves two steps: 3D mold fabrication and mold transfer.

3D Mold Fabrication

In recent decades, a number of technologies have been developed to fabricate 3D molds. These include ► photoresist reflow, ► inkjet printing, unconventional lithography and hybrids of those methods with conventional lithography.

Photoresist Reflow Photoresist reflow is a method to generate 3D hemispheric structures for microfluidic applications. First, a photoresist will be patterned by conventional lithography to generate cylindering or rectangular bars on a substrate. Then, the photoresist pattern is thermally treated for reflowing to form the hemispheric 3D shape. When temperature is higher than the glass transition temperature of the photoresist, it begins to melt and reflows around the pattern. Due to the surface tension of the liquid resist on the substrate and the surface property of the substrate, the liquid resist always tends to form a convex shape. This method was first suggested by Popovic in 1988. Figure 7a shows the photoresist reflow result of a mold for well or cell array. A well with smooth edge is shown in Fig. 7b.



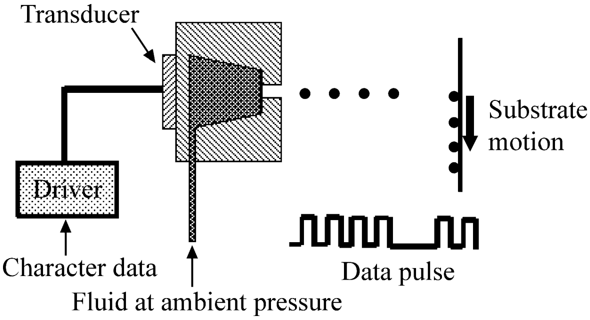
Fabrication of 3D Microfluidic Structures, Figure 7 SEM images of 3D structure of a mold fabricated by photoresist reflow: (**a**) well or cell array; (**b**) the enlarged edge of a single well mold

Inkjet Printing Inkjet printing technology is familiar to most people in the form of desktop printers. Repeatable generation of small droplets of a fluid (polymers) can be used to make 3D structures directly on a substrate for MEMS manufacturing applications.

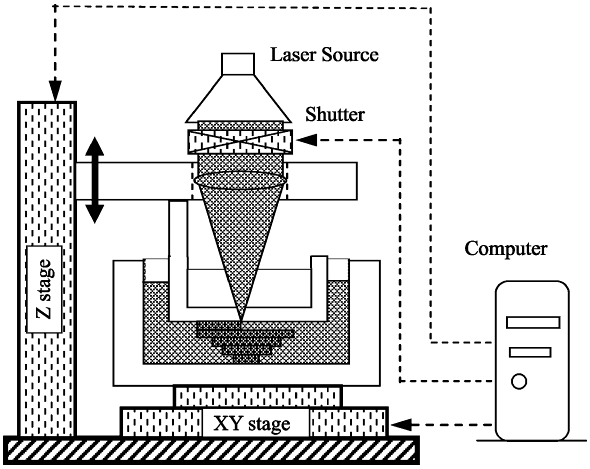
In a drop-on-demand inkjet printer, the fluid is maintained at ambient pressure and a transducer is used to create a drop only when needed. The transducer creates a volumetric change in the fluid which creates pressure waves. The pressure waves travel to an orifice, and are converted to fluid velocity, which results in a drop being ejected from the orifice. Figure 8 shows a schematic of a drop-on-demand type inkjet system which can generate 60 μm diameter drops of butyl carbitol (an organic solvent) from a device with a 50 μm orifice at 4000 drops per second. Therefore, various molds for microfluidic applications could be created by this method.

Unconventional Lithography Methods Sometimes a mold can be generated directly by unconventional lithography methods such as e-beam, grey scale and stereo laser lithography. Electron-beam direct-write lithography (EBL) has been widely used for creating masks with sub-100 nm resolution. To generate 3D structures, controlling the exposure dose during beam scanning is very important in e-beam lithography. E-beam lithography creates patterns by serially exposing the resist beam spot by the beam spot. The differential levels of exposure dose determine the pattern depth of the exposed area after developing. By adjusting the dose of each exposed spot, lateral contours can be controlled and 3D structures can be created.

► Gray-scale lithography utilizes locally modulated exposure doses to develop 3D structures in photoresist. Differentially exposed doses lead to multiple depths of exposed photoresist across the surface. This is due to the ultraviolet (UV) light energy being absorbed by the photoactive compound as it travels in the depth of the photoresist. From the differentially exposed doses, a gradient height photoresist structure corresponding to the designed silicon structure will remain once the resist is developed.



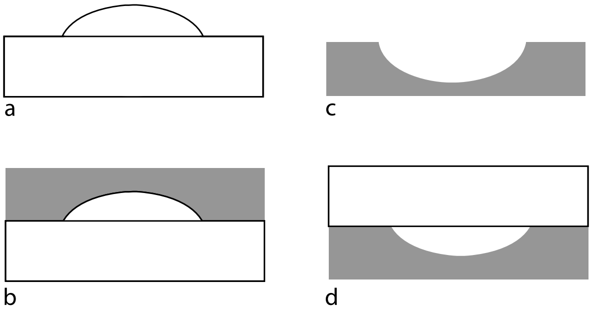
Fabrication of 3D Microfluidic Structures, Figure 8 Schematic of a drop-on-demand type inkjet system



Fabrication of 3D Microfluidic Structures, Figure 9 Schematic of a micro stereo lithography system

There are two primary techniques to generate an optical mask capable of modulating the UV intensity passing through to the photoresist surface. One such method uses a high-energy-beam sensitive glass as an optical mask, in which the UV light transmission of the glass is changed by an e-beam direct write system. Thus, when using this mask to expose the photoresist, the exposed pattern will form 3D structures due to the different exposure levels. The second method utilizes projection lithography to induce diffraction by using a conventional chrome-on-glass (COG) mask.

Micro stereo lithography is a rapid prototyping method to generate 3D molds. It is a maskless process with layer-by-layer fabrication of microstructures via the projection of sliced images of 3D objects, as shown in Fig. 9. A laser beam directs to the photocurable resin which can be classified as an epoxy, vinylether, or acrylate. The 3D structure or mold is built on a platform which can be controlled by an XYZ positioner. When one layer is complete, the platform drops lower into the vat of resin, fresh resin washes over the part, and the laser proceeds to build the next layer. The 3D microstructure is built up in this additive process. When all layers are complete, the part is cleaned and post-cured. The major drawback of this technique is the considerable capital investment. Also, only photocurable resins can be used which can be a limitation if a special material is required.



Fabrication of 3D Microfluidic Structures, Figure 10 Direct casting process: (**a**) making a 3D mold; (**b**) casting a polymer structure; (**c**) peeling off the 3D polymer structure; (**d**) bonding to form sealed microfluidic structure

Mold Transfer

After generating a mold, the next step is to transfer the 3D structure from the mold into the polymer. There are several technologies available.

Direct Casting The direct method is to cast the polymer material onto the mold and then peel off the 3D structure after the material is polymerized. Figure 10 illuminates this simple process. The reverse 3D structure is first prepared by microfabrication techniques as a mold. Then, a prepolymer with crosslink is cast onto the mold. After the polymer is well cured by heat or UV, the 3D polymer structure is produced by peeling off the polymer structure from the mold. To construct a microfluidic device, bonding the 3D polymer structure with a substrate is the next step to seal the fluidic channels and reservoirs.

Soft Lithography Soft lithography represents a non-photolithographic strategy based on self-assembly and replica molding for carrying out micro and nanofabrication [4]. It has been mostly developed in recent years. It is a favorable process for researchers to build nanometer scale structures. It includes the following techniques:

Replica Molding (REM) A PDMS stamp is cast against a conventionally patterned master. Polyurethane is then molded against the secondary PDMS master. In this way,

multiple copies can be made without damaging the original master. The technique can replicate features as small as 30 nm.

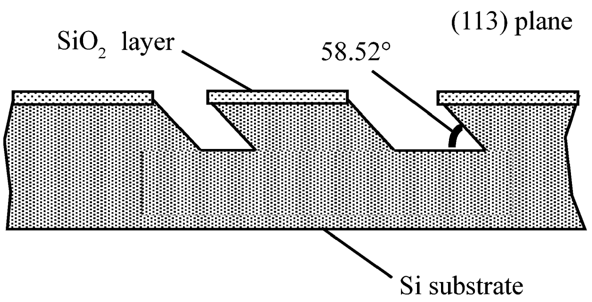
Micromolding in Capillaries (MIMIC) Continuous channels are formed when a PDMS stamp is brought into conformal contact with a solid substrate. Capillary action fills the channels with a polymer precursor. The polymer is cured and the stamp is removed. MIMIC is able to generate feature sizes as small as 1 μm.

Microtransfer Molding (μTM) A PDMS stamp is filled with a prepolymer or ceramic precursor and placed on a substrate. The material is cured and the stamp is removed. The technique is able to create multilayer systems and features as small as 250 nm.

Solvent-Assisted Microcontact Molding (SAMIM) A small amount of solvent (e.g., methanol, ethanol, or acetone) is spread on a patterned PDMS stamp which is placed on a polymer, such as photoresist. The solvent swells the polymer and causes it to expand to fill the surface relief of the stamp. Feature size as small as 60 nm can be reached.

Microcontact Printing (μCP) An ink of alkanethiols is spread on a patterned PDMS stamp. The stamp is then brought into contact with a substrate, which can range from coinage metals to oxide layers. The thiol ink is transferred to the substrate where it forms a self-assembled monolayer that can act as a resist against etching. Features can be made as small as 300 nm in this method.

Hot Embossing Hot embossing is essentially the stamping of a pattern into a polymer that is softened by raising the polymer's temperature just above its glass transition temperature. Some parameters such as loading pressure, demolding force and temperature play important roles in quality of the molded parts. Hot embossing often requires high loading pressure to stamp the polymer material in a vacuum chamber. However, the pressure should be controlled within a limit to avoid damaging the mold. And at the end of hot embossing, the demolding process requires fast release without damaging the stamped pattern. The surface roughness of the mold affects the demolding and the roughness of the stamped pattern as well. The stamp used to define the pattern in the polymer can be made in a variety of ways including micromachining from silicon, LIGA, and the methods that have been discussed above. A wide variety of polymers have been successfully hot embossed including polycarbonate and PMMA. The feature size can be in micro- or submicro-scale. This



Fabrication of 3D Microfluidic Structures, Figure 11 Wet etch profile in a (113) silicon wafer

technique is used primarily for defining microchannels and wells for microfluidic devices. The benefits of this approach are the ability to take advantage of the wide range of the properties of polymers, as well as the potential to economically mass produce parts with micron-scale features.

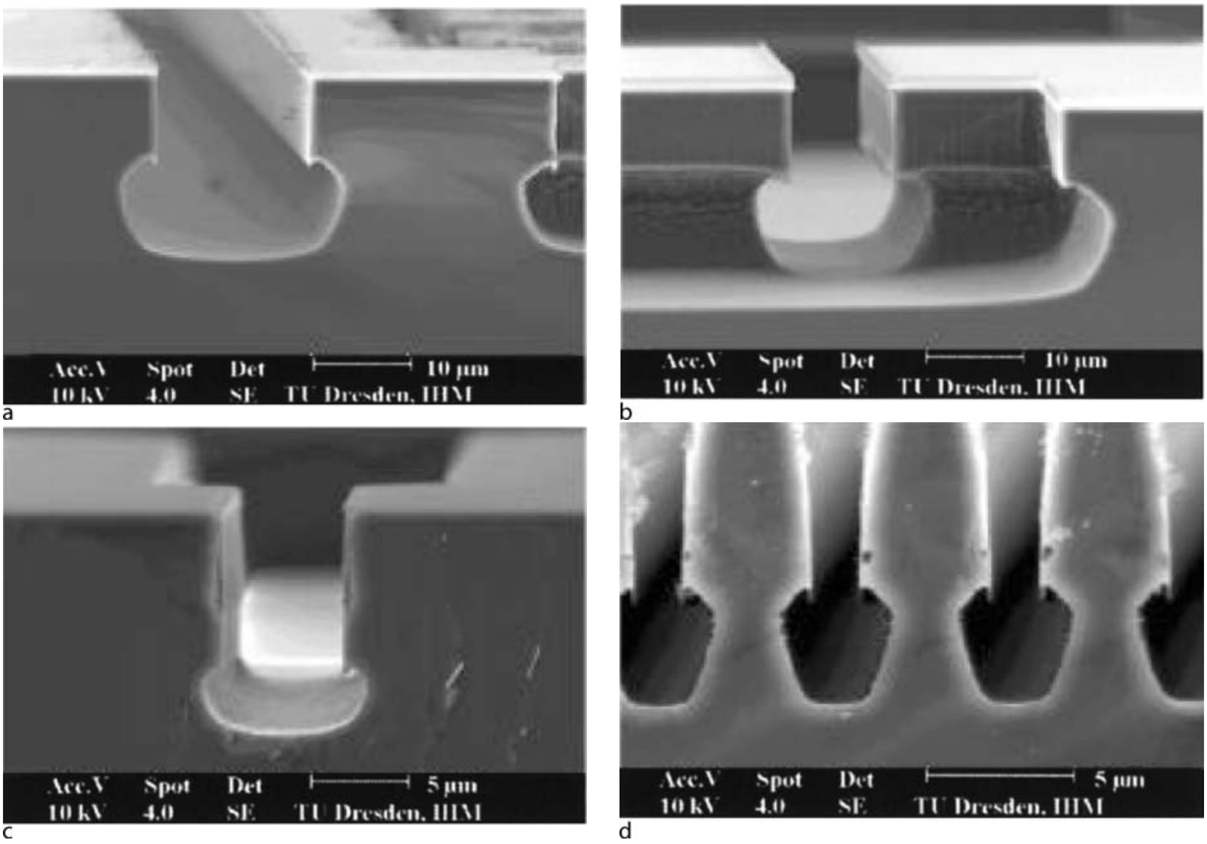
Key Research Findings

Figure 11 shows the possible wet etching profile with (113) crystallographic orientation of a silicon wafer. The mask pattern is parallel stripes and aligned at an angle φ, relative to the substrate crystallographic orientation. The angle φ was estimated from the geometrical relationship including the inclination of the $(h\,k\,l)$ plane in relation to the (110) plane, equal to $(90° - \alpha)$. The angle of α represents the angle of inclination of $(h\,k\,l)$ planes toward the (100) plane.

$$\varphi = \arctan\left[0.707 \cos\left(90° - \alpha\right)\right]$$

The substrate used in this experiment was (113) silicon wafer with 1 μm SiO_2 layer. The SiO_2 was used to be the mask material for silicon wet etching. The first step was to use optical lithography and buffered HF wet etching to pattern the SiO_2 layer with a mask and an align angle $\varphi = 16.78°$. Then the silicon etching was carried out in 10 M KOH solution at 75 °C to create an anisotropic 3D structure [5].

The complex 3D structures with desired cross-section for special microfluidic applications can be realized by modifying three classes of ICP etching processes [6]. Figure 12 shows the resulting profiles of the 3D structures. The first patterning was carried out using an anisotropic continuous etching process (SF_6+ polymer-forming gas, high density plasma, and intensive ion bombardment). Afterwards, a polymer layer was deposited under the same conditions of the deposition step in a TMDE process. The deposition rate is $\sim$ 85 nm/min, and the uniformity of the thickness is $\sim$ 4%. After deposition of the polymer, isotropic silicon



Fabrication of 3D Microfluidic Structures, Figure 12 SEM images of the composed etching profiles: (**a**), (**b**) patterns realized by anisotropic silicon etching, deposition of passivation polymer layer and isotropic silicon etching; (**c**), (**d**) patterns etched like (**a**) and (**b**), passivation with polymer and additional Si_3N_4 layer (5). (With permission from Elsevier)

etching using SF_6 plasma was carried out. The minimum pattern created in this way has a lateral width of 11 µm (Figs. 12a, b).

In addition to realize smaller patterns with the same cross-sectional area, a silicon nitride layer was deposited on the surface after anisotropic etching of the deep trenches. The polymer was then deposited and the silicon was etched by the isotropic process (only SF_6). The results are shown in Figs. 12c, d. In this case, the patterns with a minimum lateral width of 5 µm are realized.

The combination of conventional photolithography and photoresist reflow is an effective method to smoothly integrate microfluidic chambers with microchannels. To fabricate a PDMS 3D microstructure joined with the microchannel by mold transfer, a master mold is needed. The photoresist reflow method was adopted to make the master mold for the 3D chambers and a negative photoresist SU-8 was used to generate the microstructure master mold for the microchannels. Since SU-8 is an epoxy-based photoresist and has good chemical stability with stands temperatures up to 200 °C, the channel pattern can not be damaged during the whole processing. The processing schematic is shown in Fig. 13. First, negative photoresist SU-8 was used to form high bars for the microchannels' mold. Photoresist cylinders were then separately built by conventional lithography. In order to achieve large fluidic volume, thick photoresist AZ100XT was chosen and its patterned cylinders on the substrate were thermally treated on a hot plate. The reflow occurred at 120 °C in a period of 60 s. Sometimes, the organic solvent vapor surrounding the photoresist pattern can promote the reflow process. Figure 14a shows the SEM image for the photoresist mold, which smoothly joins hemispherical structure 2200 µm in diameter and 167 µm in depth with the microchannel.

After completing the mold, the next step was to transfer from the photoresist microstructure to PDMS by casting. The PDMS, Dow Corning Sylgard 184 silicone, was chosen as the casting material because of its high-dimensional accuracy and easy fabrication. After the PDMS substrate was cured in a vacuum oven for 2 h at 5 mTorr of pres-

sure at 75 °C, it was then peeled off from the photoresist mold. The PDMS substrate consists of 3D structure joined smoothly together with the microchannel as shown in Fig. 14b.

Future Directions for Research

3D microfabrication being one of the most promising areas of microfabrication technologies has been extensively studied and developed over the last two decades. New technologies have been discovered and developed to design and fabricate a variety of microfluidic devices and systems [7, 8]. The demand for high-precision 3D microfluidic devices and efficient manufacturing technologies is rapidly growing in recent years, particularly in the application areas of drug discovery and delivery, diagnostics, biotelemetry, and genomics. It creates an obvious need for modular, non-silicon approaches to build inexpensive, disposable and biocompatible sensors and systems. To continually explore 3D fabrication methods using the extremely developed lithography technologies, new materials are expected, which are photosensitive, wet or dry etchable and biocompatible. To precisely control 3D microstructures, it is highly desirable to develop the analog 3D fabrication technologies or tools which can produce complex 3D structures without masks. Most microfluidic devices need to be sealed in order to perform certain liquid handling functions. Packaging for sealing a device with a lid or bonding with an additional layer is always a challenging issue in the fabrication of polymer-based microfluidic devices. New technologies and materials which are suitable to integrate 3D fabrication and sealing or bonding will promote rapid prototyping and commercialization for microfluidic devices and systems.

Nanorods; Nanocatalyst; Nanostructures

Definition

A nanocatalyst is a material which performs the role of chemical catalysis while confined to a physical size of 10 to 1000 nm. More important, the nanometer size of the catalyst material affords these materials access to unique physical and chemical properties which makes them capable of delivering enhanced catalytic performance. Most nanostructures are obtained as a result of self-assembly, governed by the physical and chemical nature of the material systems.

Overview

A catalyst is a material entity which participates in a chemical reaction in such a way as to reduce the activation energy required to change one chemical species, *reactants*, into a second chemical species, *products*. Ideally the catalyst material can emerge at the end of the desired chemical reaction unaltered after performing this function. If the catalyst material is in a different phase than the reactants (e. g. a gas-phase reaction occurring on a solid-state surface), the solid is characterized as a heterogeneous catalyst. From an economical point of view there is a desire to use catalyst materials that are not consumed in the planned chemical reaction. The performance of a catalytic material will improve when:

- The surface area exposed to the reacting species is large.
- The catalyst material is specifically suited to perform a desired chemical reaction.

The emergence of nanotechnology offers potential enhancement in both criteria. One of the fundamental advantages of a nanocatalyst is that it offers a large potential surface area of catalyst per mass of material. Prior to the advent of nanotechnology a large surface area could always be realized through the use of a finely divided powders or meshes. In a heterogeneous reactor environment the act of reclaiming the catalytic material would, however, impose certain difficulties. With regards to the specificity of a chemical catalyst, this ability relies on chemical and physical phenomena that can best be described as depending on the steric and/or quantum mechanical nature of the catalyst. Nanotechnology permits one to design physical structures endowed with specific geometric and electronic properties. There is currently great interest in growing nanostructured materials, attached to a substrate, into structures that are commonly referred to as nanorods, nanoribbons, quantum dots, etc. These intriguing structures occur as the result of processing conditions used to form these materials with a variety of physical and chemical processes. The act of formation of these material structures is referred to as self-assembly. As an example, in Fig. 1 GaSb crystalline droplets are formed on the surface of Si wafer, as a result of surface tensions produced because of lattice constant differences between the two materials. These dot-like structures have been given the name of quantum dots, because the physics which describes electronic behavior in these structures requires a quantum mechanical treatment. Self-assembly is also credited with building more complicated structures such as nanorods and ribbons; again the physics and chemistry of atomic assembly produce these structures governed by minimum energy.

Within the specific context of micro- and nanofluidics, the fabrication of self-assembled nanostrucures can represent an enabling technology for novel engineering applications. One such application – and the specific motivation for this article – lies in the creation of catalytic nanostructures for micro-/nanoscale reacting flow systems. A specific example is the catalyzed chemical decomposition of monopropellant fuels for the purposes of small satellite micropropulsion [1] (Fig. 2). Here, the size and density of nanorod formations naturally provide the high surface area-to-volume ratios desirable for efficient catalysis in microscale geometries. Certainly other important applications exist, including those that leverage nanotechnology to produce *clean* energy and/or reduce emission of greenhouse gases. Some specific, high-profile applications include: fuel cell electrode fabrication, pollution control, hydrogen production and chemical reagent production. For example, platinum (Pt) nanocrystalline layers are used in proton exchange membrane (PEM) fuel cells to catalyze the reduction of oxygen and oxidation of hydrogen on the cathodes and anodes, respectively. The current challenge is that the Pt nanostructured layer has been found to degrade through normal use owing to a number of factors such as fouling by fuel impurities, Pt dissolution, and nanoparticle coalescence and agglomeration [2]. Research efforts are targeted at identifying new alloy combinations with Pt that might overcome or mitigate these issues.

Fabrication of Self-Assembled Catalytic Nanostructures, Figure 2
A photograph of a prototype monopropellant-based microthruster developed for miniaturized satellite applications (*nanosats*) by NASA/Goddard Space Flight Center in collaboration with the University of Vermont [1]. This device utilizes the catalyzed decomposition of hydrogen peroxide as the energy source for propulsion. The catalytic structures in this device are not self-assembled, but rather consist of a three-dimensional array of MEMS-fabricated pillar-type structures coated with a silver catalyst. For reference of scale, the entire catalytic array is ~1 mm wide and 2 mm long

Basic Methodology

Scientist are developing an ability to use nanofabrication techniques to make artificially structured catalyst arrays that can drive a chemical reaction to products with dramatically improved energy efficiency and chemical specificity. In general, nanorod structures have been demonstrated in a growing number of solid-state materials; a non-exhaustive, but illustrative, list includes the following: Si, InP, SiC, ZnO, CdS, GaN, and RuO_2 [3–8]. Currently it is not possible to predict with certainty what will be the best catalyst material for a specific chemical reaction. Research is proceeding both experimentally and theoretically to develop a deeper understanding of these materials and processes that one day will make this possible.

Much of the initial work in the overall area of nanotechnology involved ZnO; this is a result of the fact that this material has a combination of physical and chemical properties which makes it ideal for the fabrication of complex nanostructures [4–9]. These properties have given ZnO a ubiquitous role in the nanotechnology world. Once nucleated, the growth of single-crystal ZnO nanostructures (nanorods) is possible. The epitaxial growth of single-crystal ZnO as a thin film is preferred in its *c*-axis along the (0001) direction. Further, from energetic considerations, crystal growth proceeds by maximizing the areas of its sidewall facets, oriented in the (2110) and (0110) directions. These growth mode constraints result in the formation of tall hexagonally shaped nanorod structures. It has been shown by Wang et al. [7] that the addition of elemental impurities can affect the final nanostructure of the grown material. Another interesting concept for the purposes of this application and nanotechnology in general is the continued growth of additional materials onto the sidewalls of existing ZnO or other nanorods. Norton et al. [4] reported on the epitaxial growth of a Mg-doped ZnO layer on the

sidewall of an existing ZnO nanorod. The process used to grow the additional layer on the ZnO nanorod structure in that study was molecular beam epitaxy (MBE).

There are a number of experimental techniques used to fabricate self-assembled nanostructures from ZnO and other materials. These techniques include the following: vapor–liquid–solid; metalorganic chemical vapor deposition; template-assisted; chemical reaction; molecular beam epitaxy; and reactive sputtering. In this section we provide a brief overview of these techniques.

Vapor–Liquid–Solid (VLS) Technique

In the VLS method, a thin layer (70 Å) of metal such as Au, Ag, Pt, Pd, Cu, or Ni is deposited on the substrate surface. The substrate is then annealed at high temperature (500 °C for Au) to form nanodots of the metal catalyst, which provide the preferential site for the adsorption of gas-phase reactants. For the case of ZnO nanorods, the substrate is placed in a furnace containing ZnO powder and a source of carbon. When heated to 700 °C, the ZnO and carbon react to produce CO_2 and Zn. The gaseous Zn is dissolved to supersaturation in the metal dot and crystal growth occurs from the substrate side of the metal dot. The growth continues as long as the conditions for growth remain sufficient, such as reactant concentration and the proper temperature for growth. The method has been used to form a variety of nanowires such as InP, GaN, CdS, and Si [6]. Several groups have repeated the process with variations such as the substrate used for growth and the reactor design.

Metalorganic Chemical Vapor Deposition (MOCVD)

To date the greatest success in growing straight, tall, and well-aligned rod-shaped structures has been with an MOCVD growth process. This approach relies typically on the use of chemical precursors (e. g. diethylzinc and oxygen in the case of ZnO growth). It appears that the chemical nature of this process technique encourages the growth of exceptionally straight nanorods. Different metalorganic precursors are used as the starting materials for different inorganic nanorod materials [8].

Template-Assisted Growth

This technique can use several different variations to achieve the growth of nanostructured materials. In one version, a metal catalyst is deposited and/or patterned into a desired layout. From these metal catalyst locations the nanorods materials are assembled to the finished length or size. Another approach can involve the actual growth of a different material inside or on an existing nanostructed material such a carbon nanotube. This technique can be used to grow nanostructured materials with chemical compositions that have not been fabricated into nanostructures [10].

Solution-Based Approaches

These methods are, in theory, the least technically challenging procedures for the fabrication of nanometer-sized structures of a given composition. The techniques of hydrothermal and solvothermal production are included under this general heading of solution-based approaches. These methods all involve the dissolution of a targeted nanorod material (e. g. TiO_2) in a basic solution (e. g. NaOH in water). This solution is raised to a temperature and pressure above standard temperature and pressure and held for several hours. The resulting nanostructure precipitates are freestanding and need to be collected from a liquid solution by filtration. The precipitate in this example would be $Ti(OH)_x$, and would require further processing called calcination. Calcination is performed at a temperature of about 700 °C removing the H species from the nanorod material.

Modifications of this process have resulted from the use of different basic solutions that have reduced the required process temperatures or pressures. An example would be the formation of Eu_2O_3 nanorods [11]. These are formed by dissolving $Eu(NO_3)_3$ in a cyclohexamine base solution. The resulting precipitate is calcinated at 700 °C for one hour and nanorods with a length of 300 nm and diameter of 20 – 30 nm are obtained.

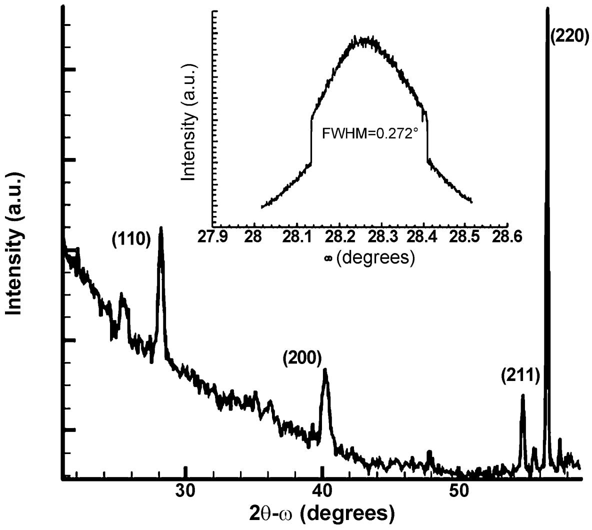
These solution-based approaches have the benefit of producing a large volume of material with an inexpensive process. A downside is that the catalyst material is freestanding, and to be used in a heterogeneous reactor will require additional process complications.

Molecular Beam Epitaxy (MBE)

This technique is prized for the high level of control that is possible, in terms of both the control of desired (the materials which constitute the nanorods) and undesired species fluxes (contaminants, e. g. water and oxygen) at the growth surface. This technique has been successfully used to grow a wide variety of semiconductor nanostructures. Due to high capital cost and cost of operation, it is not expected that this technique will prove capable of producing catalyst materials on a large scale.

Reactive Sputtering

Deposition of metal oxide nanorods has been achieved by reactive sputtering. As an example of this deposition



Fabrication of Self-Assembled Catalytic Nanostructures, Figure 3
The X-ray diffraction pattern of RuO_2 nanorods grown on a Si substrate for 10 min at 600 °C. The inset is an omega scan of (220) peak. Major peaks indicate particular crystal orientation of the atoms in the nanorods

approach, RuO_2 nanorods have been obtained by sputtering on a Si/SiO_2 surface [12]. In this particular case, these structures were used as the starting substrate for the further growth of TiO_2. Sputtering is a process that has been used in large-volume manufacturing such as the automotive industry; therefore it is possible to envision its use in the manufacture of heterogeneous catalyst layers.

Key Research Findings

The scientific literature has shown that self-assembled nanorod structures have been grown from a large number of materials and for a wide variety of engineering applications. For illustrative purposes, in this article we focus on the fabrication and growth characteristics of ruthenium oxide nanorods; the target application lies in the catalyzed decomposition of hydrogen peroxide for small satellite micropropulsion (e. g. Fig. 2). The findings reported here, while case specific, are nonetheless reflective of broader phenomena and considerations associated with the growth of self-assembled nanostructures.

Our laboratory at the University of Vermont has successfully grown RuO_2 nanorods by reactive sputtering on Si wafer substrates with a variety of pre-existing surface conditions. Proof of a crystalline structure has been obtained by X-ray diffraction. A sample X-ray diffraction spectrum of the deposited nanorods is shown in Fig. 3. Each of the major peaks in Fig. 3 corresponds to a single crystal orientation of the nanorods. Although each nanorod is single crystal, each nanorod is randomly oriented relative to another, thus displaying the random pattern observed under scanning electron microscopy (SEM) imaging (Fig. 4).

Experimental Apparatus

The reactor used in this investigation is shown in Fig. 5. The samples were prepared by sputtering from a 1.5 inch diameter Ru metal target, operated at 13.56 MHz and a power level of 50 W. The reactor ambient was obtained by flowing 100 sccm of a 5/95% O_2/Ar gas mixture, throttled to a pressure of 15 mtorr. The samples were heated radiatively from behind with a resistive boron nitride-coated pyrolitic graphite heater. Silicon wafer substrates with three different surface preparations were used: Si with a native oxide layer; Si with the oxide layer removed by hydrofluoric acid (HF) treatment leaving a hydrogen passivated surface; and Si with Au dots nucleated on the sur-

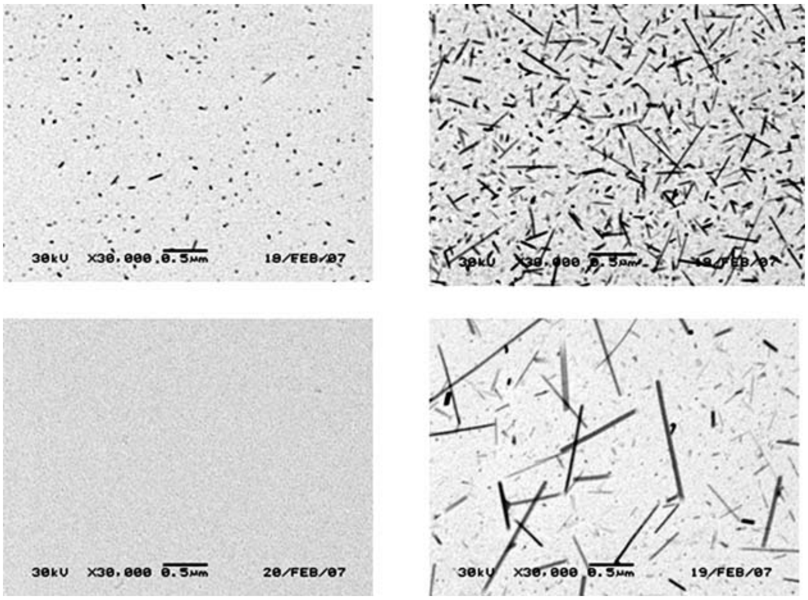
face. Nanorod growth was obtained to varying degrees on all surface preparations, as can be observed in Fig. 6.

Temperature Dependence of Growth

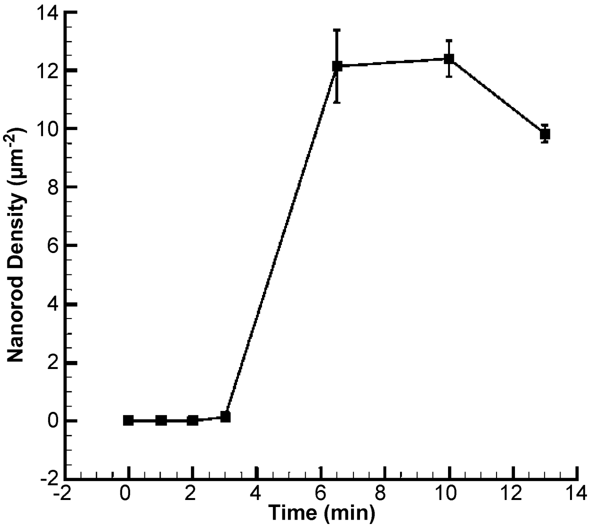
Ruthenium oxide nanorods were found to form on all samples independent of pre-existing surface preparation, yet not at all substrate temperatures. Initially the effect of substrate temperature on the growth of RuO_2 nanorods was investigated. SEM images of samples prepared at varying substrate temperatures are shown in Fig. 7 for the case of RuO_2 grown on Si covered with Au nucleation sites. The RuO_2 layer was prepared by exposing the Si surface to the sputtered Ru flux at substrate temperatures of 400, 500, 600, and 700 °C for a period of 5 minutes. At a substrate temperature of 400 °C, short, sparse RuO_2 nanorods formed. There is also the appearance of randomly scattered dots on the surface, assumed to be composed of RuO_2 deposited on a continuous island-like thin-film structure. Increasing the substrate temperature to 500 °C resulted in conditions that caused these nucleation sites to develop into nanorods again rising above a continuous cauliflower-like film. From a plan view SEM image such as seen in Fig. 7, the nanorods appear to be randomly oriented. Measuring the average length of the nanorods from this vantage point is not possible because of the nanorod's angular projection from the Si surface. It is more significant to simply measure the length of the longest nanorods for a given set of process conditions and compare these to those obtained for different growth conditions. Considering that the number of rods sampled in a field of view is large (approximately 6 μm^{-2}), the measured rod length is an accurate representation of the maximum rod length. At a substrate temperature of 400 °C, 0.18 μm tall nanrods were observed. The conditions of a 500 °C substrate temperature produced nanorods with a maximum length of 0.6 μm. When the temperature was increased further to 600 °C, the maximum length of the nanorods has grown to 1.3 μm. Finally when a substrate temperature of 700 °C is used, growth of the nanorods is not obtained past the formation of RuO_2 dots.

Axial Growth Rate

To further understand the mechanism which governs the growth of RuO_2 nanorods in a radiofrequency sputtering process, a series of runs were made under identical process conditions and were terminated after increasingly longer periods of time, following which characterization was carried out. The process conditions used in this sequence of runs were similar to those in the temperature investigation, but in this case a substrate temperature of 600 °C was used. The periods of growth were 2, 3, 6.5, 10 and 13 min. From the plot in Fig. 8, one can observe that the density of nanorods increases with time. The maximum nanorod length for these depositions is approximately 1.3 μm and this value does not change with time.



Fabrication of Self-Assembled Catalytic Nanostructures, Figure 7 SEM images (shown in negative tone) of RuO_2 nanorods. Nanorods were deposited on Au dots for 5 min. Shown clockwise from top left are substrate temperatures of 400, 500, 600, and 700 °C



Fabrication of Self-Assembled Catalytic Nanostructures, Figure 8 Plot of a RuO_2 nanorod density at varying deposition times. Nanorods were deposited at 600 °C

Relative to the growth rate of nanorods presented in the literature, using different processing techniques, the rate of growth observed herein is relatively fast. In the time evolution study described above, the nucleation of nanorods is very fast, and short relative to the time increments investigated. In the time period from 3 to 6.5 min, the density of nanorods increases at a rate of 5.41×10^6 cm^{-2} s^{-1}. The Rutherford backscattering spectrometry (RBS) analysis of a film deposited at room temperature can be used to calculate a measured flux of Ru atoms to be 7.08×10^{-10} mol cm^{-2} s^{-1}. The diameter of the nanorods grown after a time of 10 min was observed by SEM to be approximately 100 nm. Assuming a final rod diameter of 100 nm and that all of the sputtered flux of Ru adatoms are successfully incorporated into the nanorods structure, a simple mass balance can be performed to estimate the average length of the nanorods. Using this assumption and the measured Ru flux and density of nanorods formed, a nanorod length of 0.32 µm is estimated. This value is comparable with the values obtained from the cross-sectional SEM view shown in Fig. 4.

Radial Growth Rate

The growth of nanorods in the vertical direction is very fast once nucleated. After viewing all SEM images it is interesting to note that for varying periods of growth, the nanorods grew to a maximum length and then virtually stopped. There seems to be no apparent explanation for the cessation of vertical growth. Under closer examination, the SEM images of RuO_2 nanorods grown under identical conditions, but after different periods of growth (5, 15, 25, and 60 min), were examined (Fig. 9). It is first observed that the nanorods actually have a square profile. It is further observed that the square profile of the nanorods is also increasing with time. The nanorod radial growth rate is

estimated to be 1.9 nm min^{-1}. It is proposed that the further axial growth is halted as a result of the consumption of Ru adatoms used in the radial growth process. The axial reaction rate constant is assumed to be large relative to the radial growth constant, and the axial growth dominates initially. As the cross-section of the square rod increases, the density of surface states dominates the consumption of Ru adatoms and axial growth is halted.

In this article, a brief overview of fabrication techniques and issues associated with the growth of nanostructures made of catalytic materials has been given. Illustrative research findings were also presented for the specific case of RuO_2 nanostructures.

Future Directions for Research

To date, much of the research in this area can best be categorized as phenomenological. As such, there are many important areas for future research. We close this article by identifying three key areas for immediate research:

- *Growth mechanisms.* Observations on the growth mechanisms of RuO_2 nanorods have been reviewed. In particular, the dependence of the length of nanorods on substrate temperature and the width of nanorods on deposition time has been described. Further studies are required to fully develop a theoretical model for the growth mechanism of these structures and to gain a better understanding of the limiting factors of growth.
- *Mechanical characterization.* For the application of catalytic nanostructures, these nanorods may experience significant forces due to the flow of liquid and gas around them. The mechanical robustness of the nanorod structures as well as the connection to the substrate must be evaluated. Techniques such as manipulation via an atomic force microscope may be used to determine the strength of these structures. Theoretical modeling will also contribute to this effort.
- *Device application and integration.* It is clear that self-assembled nanostructures hold great promise for future applications. Nanorod structures have been studied for nearly a decade now; however, very little progress has been made in the implementation of these structures into/as devices. Further work is required in order to integrate these structures into devices. Future work in our laboratory will study the catalytic efficiency of RuO_2 nanorods in a microthuster device.

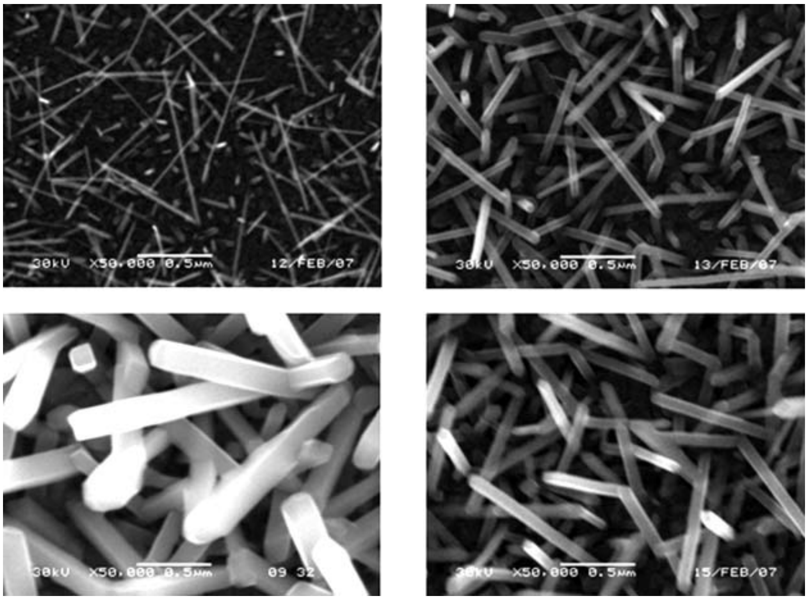
Fabry-Perot Optical Filter

Synonyms

Optical narrow passband filter



Fabrication of Self-Assembled Catalytic Nanostructures, Figure 9 SEM images of RuO_2 nanorods. Nanorods were deposited on HF-dipped Si at 460 °C. Shown clockwise from top left are deposition times of 5, 15, 25, and 60 min

Definition

A Fabry-Perot optical filter consists of two flat highly-reflective and parallel mirrors spaced a well-defined distance apart, with the reflecting part facing each other. The space in between the mirror surfaces is essentially a resonance cavity. The incident light suffers multiple reflections between the coated surfaces that define the cavity. When the cavity width is equal to an odd multiple of a half wavelength of the incident light, the reflected beams interfere constructively and the optical transmission is maxim. At other cavity widths, the reflected beams interfere destructively and the optical transmission can be reduced toward to zero. Therefore, this device acts as a passband filter that transmits certain wavelengths. To perform high reflectivity and high transmittance, dielectric mirrors are used instead of metallic mirrors.

Feedback

Definition

The cycle of observing a dynamic system (sensing), making a decision (control computation), implementing that decision by actuators (actuation), and then observing the new dynamics at the next time instant. This cycle of sensing → computation → actuation is what is meant by the term feedback. Feedback is routinely used in complex systems ranging from electronic systems, to airplanes and cars, chemical plants, and is ubiquitous in biological systems (living cells use feedback to control all aspects of their operation).

mntnguyen@ntu.edu.sg

Synonyms

Magnetic fluid; Liquid magnet; Dispersed magnetic nanoparticles

Definition

A ferrofluid is a liquid consisting of ferromagnetic nanoparticles suspended in a nonmagnetic carrier fluid, typically water or oil. The ferromagnetic nanoparticles are coated with a surfactant such as oleic acid to prevent their agglomeration. The magnetic particles have typical diameters on the order of 5 – 15 nm and a volume fraction of about 5 – 10%.

Chemical and Physical Principles

Although certain pure substances such as liquid oxygen also behave as magnetic liquids, ferrofluids are commonly understood as colloidal ferrofluids (Fig. 1). The fluid is composed of a carrier fluid and ferromagnetic nanoparticles, usually magnetite, hematite, or some other compound containing iron in the 2+ or 3+ state. These nanoparticles are solid, single-domain magnetic particles. The particles are coated with a monolayer of surfactant molecules to prevent them sticking to each other. Because these particles are so small, Brownian motion is able to disperse them homogeneously in the carrier fluid. The dispersion is sufficiently strong that the solid particles do not agglomerate or separate even under strong magnetic fields. A typical ferrofluid is opaque to visible light. It should be noted that the term *magnetorheological fluid* (MRF) refers to liquids similar in structure to ferrofluids but different in behavior. The particle sizes of MRFs are on the order of micrometers and are 1 – 3 orders of magnitude larger than those of ferrofluids. MRFs also have a higher volume fraction of particles, on the order of 20 – 40%. Exposing an MRF to a magnetic field can transform it from a light viscous fluid into a thick solid-like material.

The ferromagnetic nanoparticles can be fabricated using size reduction through ball milling, chemical precipitation, or thermophilic iron-reducing bacteria. In ball milling, a magnetic material with a particle size of several micrometers such as magnetite powder is mixed with the carrier liquid and the surfactant. The ball-milling process takes approximately 1000 h. Subsequently, the product mixture undergoes centrifuge separation to filter out oversized particles. The purified mixture can be concentrated or diluted to obtain the final ferrofluid.

Synthesis by chemical precipitation is a more common approach, in which the particles precipitate out of solution during chemical processes. A typical reaction for magnetite precipitation is

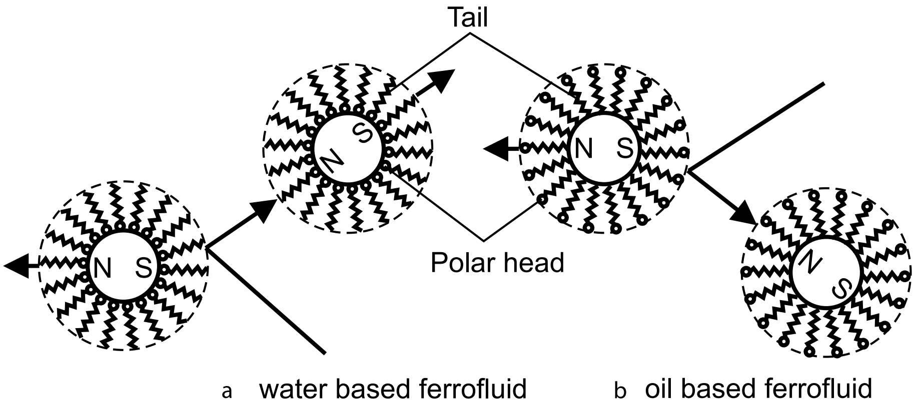
$$5NaOH + 2FeCl_3 + FeCl_2 \rightarrow Fe_3O_4 + 5NaCl + 4H_2O \quad (1)$$

The reaction product is subsequently coprecipitated with concentrated ammonium hydroxide. Next, a peptization process transfers the particles from the water-based phase to an organic phase such as kerosene with a surfactant such as oleic acid. The oil-based ferrofluid can then be separated by use of a magnetic field.

Another approach to the fabrication of ferrofluids is based upon thermophilic bacteria that reduce amorphous iron oxyhydroxides to nanometer-sized iron oxide particles. Thermophilic bacteria are able to reduce a number of different metal ions. Thus, this approach allows other compounds, such as Mn(II), Co(II), Ni(III), and Cr(III) compounds, to be incorporated into magnetite. Varying the composition of the nanoparticles can adjust the magnetic, electrical, and physical properties of the substituted magnetite and, consequently, of the ferrofluid. Ferromagnetic particles with an extremely low Curie temperature can be designed with this method. For instance, $Mn_xFe_{1-x}Fe_2O_4$ nanoparticles may have Curie temperatures between 75 °C and 325 °C. Most of the particle materials commonly used in ferrofluids have much higher Curie temperatures. The temperature dependence of the magnetic properties depicted in Fig. 2 can be used in microfluidic applications.

Key Research Findings

At the typical channel size of microfluidics (about 100 μm), ferrofluid flow in a microchannel can be described as a continuum flow. The governing equations are based on conservation of mass and conservation of momentum. In case of temperature-dependent magnetic



Ferrofluids in Microchannels, Figure 1 Colloidal model of magnetic nanoparticles and schematic representation of an elastic collision between particles: (**a**) water-based ferrofluid, (**b**) oil-based ferrofluid

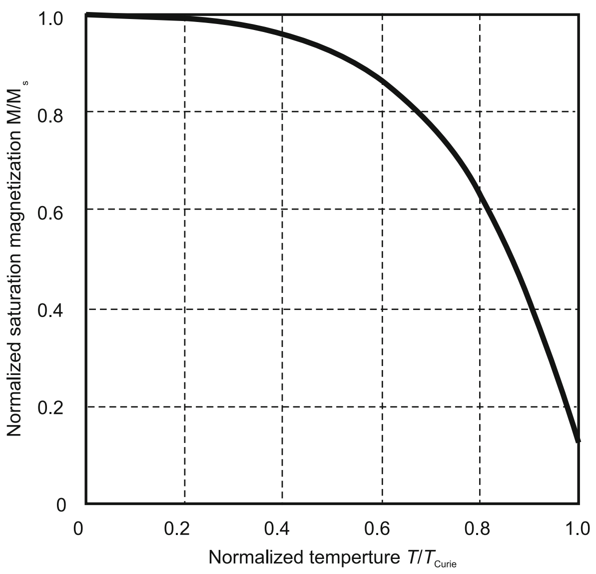
properties, conservation of energy may be needed for calculating the temperature field.

The continuity equation has the general form

$$\frac{\mathrm{D}\rho}{\mathrm{D}t} + \delta \operatorname{div} \nabla = 0 \,, \tag{2}$$

where ∇ is the nabla operator and $\mathrm{D}\rho/\mathrm{D}t$ is the substantial (or total) derivative operator:

$$\frac{\mathrm{D}}{\mathrm{D}t} = \frac{\partial}{\partial t} + u\frac{\partial}{\partial x} + v\frac{\partial}{\partial y} + w\frac{\partial}{\partial z} = \frac{\partial}{\partial t} + (\boldsymbol{v} \cdot \nabla) \,. \tag{3}$$



Ferrofluids in Microchannels, Figure 2 Temperature dependence of magnetization

Newton's second law formulates the conservation of momentum:

$$\begin{aligned} \rho\frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} &= \sum \boldsymbol{f}_i = \boldsymbol{f}_{\text{pressure}} + \boldsymbol{f}_{\text{viscous}} + \boldsymbol{f}_{\text{gravity}} + \boldsymbol{f}_{\text{magnetic}} \\ \rho\frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} &= -\nabla p + \eta\nabla^2\boldsymbol{v} + \rho\boldsymbol{g} + \boldsymbol{f}_{\text{magnetic}} \end{aligned} \tag{4}$$

Compared with a nonmagnetic fluid, the Navier–Stokes equation (4) for ferrofluid flow in a microchannel has an additional term for the magnetic force [1]:

$$\mathbf{f}_{\text{magnetic}} = -\nabla \left[\mu_0 \int_0^H \left(\frac{\partial M\upsilon}{\partial \upsilon} \right)_{H,T} \mathrm{d}H \right] + \mu_0 M \nabla H \tag{5}$$

where $\mu_0 = 4\pi \times 10^{-7}\,\mathrm{H\,m^{-1}}$ is the permeability of free space, M is the intensity of magnetization, υ is the specific volume, and H is the magnetic field strength in A/m. The magnetic pressure can be grouped together with the static pressure to form an apparent pressure. Thus the conservation of momentum can be reduced to the conventional Navier–Stokes equation. Since the magnetic force is a body force, the flow of a ferrofluid in a microchannel should have the same velocity distribution as a pressure-driven flow. The first term in Eq. (5) shows that the magnetic force is a body force, which is proportional to the volume. According to the scaling law, or the so-called *cube–square law*, the magnetic force will be dominated by the viscous force on the microscale. However, the second term in Eq. (5) may have advantages on the microscale owing to the high magnetic-field gradient ∇H that is achievable

with integrated microcoils. As mentioned above, ferrofluids with a low Curie temperature are readily available. Using the temperature dependence of the magnetization shown in Fig. 2, the magnetization can be adjusted by varying the temperature from room temperature to an acceptably low Curie temperature. The temperature dependence of the magnetization can be implemented in the first term of Eq. (5); the magnetic force then has the form [2]

$$\mathbf{f}_{\text{magnetic}} = \frac{1}{2}\mu_0 \left(H \frac{\partial M}{\partial T} \right) \nabla T + \mu_0 M \nabla H \qquad (6)$$

It is clear from Eq. (6) that the high temperature gradient ∇T that can be achieved on the microscale can be another advantage when one wishes to drive a ferrofluid in a microchannel.

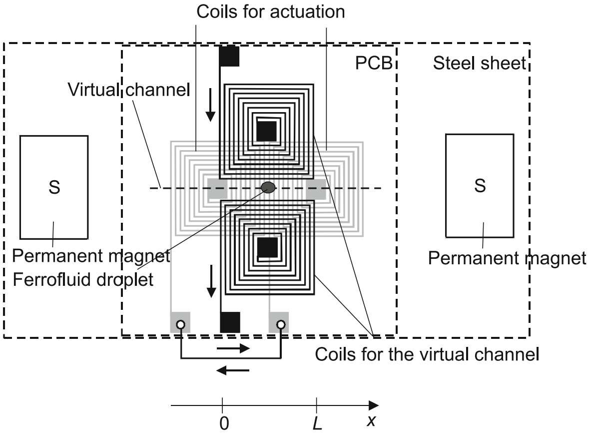
Examples of Applications

The following examples present the utilization of the high magnetic gradient and temperature gradient on the microscale for pumping ferrofluids.

Manipulation of Ferrofluid Microdroplets

The magnetic force is proportional to both the magnetic moment and the gradient of the magnetic field. At a constant temperature below the Curie point, the magnetic moment is proportional to the volume. The disadvantage of volume-based actuation on the microscale can be compensated by the high magnetic-field gradient achievable with microcoils. Since the magnetic nanoparticles in a ferrofluid have a diameter on the order of a few nanometers, the random movement of the particles is larger than the effects of magnetic and gravitational forces. Thus the dispersion of these particles is stable even under a strong magnetic field. Nanoparticles polarized by an external magnetic field cause a ferrofluid droplet to act as a liquid magnet. This unique feature allows a ferrofluid droplet to be controlled by an external magnetic field. A controlled ferrofluid microdroplet can potentially be used as a reaction platform for handling samples in Lab-on-a-Chip applications.

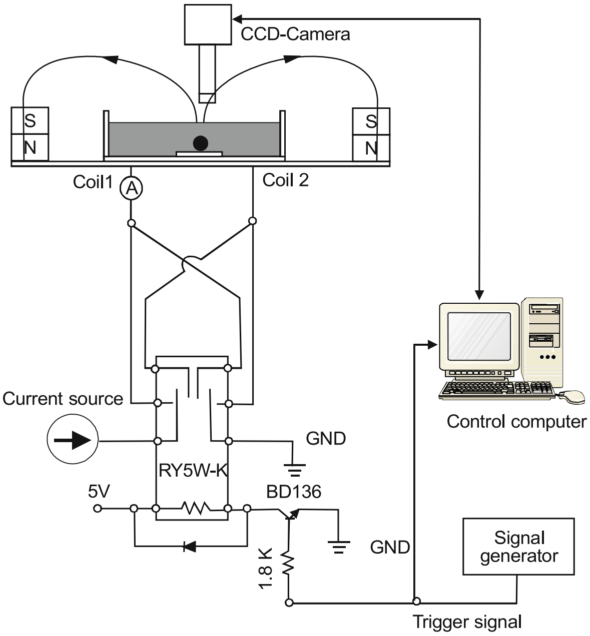
Figure 3 shows the basic setup for controlling a ferrofluid microdroplet [3]. The main part of the setup is a double-sided printed circuit board (PCB). Two planar coils are etched on each side of the PCB, as depicted. The black and gray lines represent coils on the front and the back, respectively, of the PCB. Two permanent magnets (NdFeB) are placed on a soft magnetic steel sheet, which carries the PCB device. The permanent magnets induce a large uniform magnetic field perpendicular to the



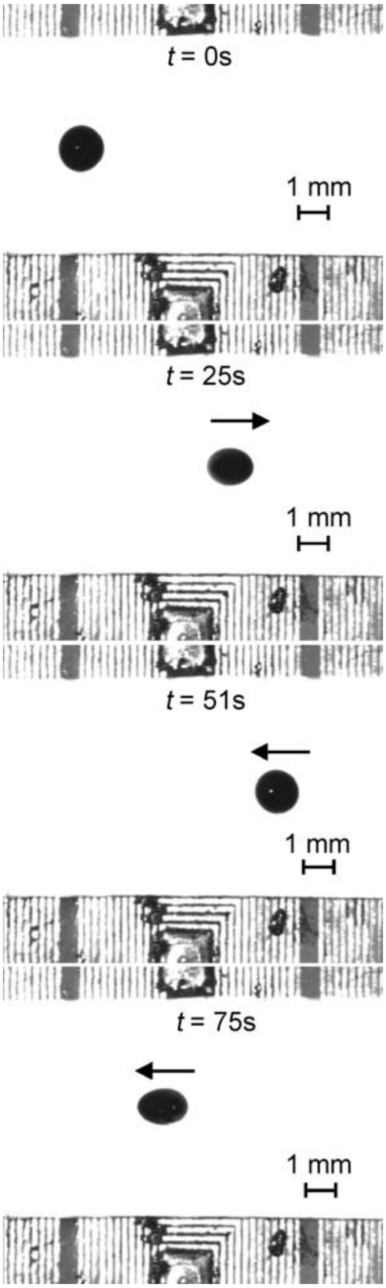
Ferrofluids in Microchannels, Figure 3 Experimental setup for controlling ferrofluid droplets. The coils are etched on a double-sided printed circuit board. The gray coils are on the back of the PCB. The PCB is placed on a soft magnetic steel sheet with two permanent magnets at either side. The magnetic field of the two permanent magnets polarizes the magnetic particles in the ferrofluid droplet

direction of motion x of the ferrofluid droplet, and consequently polarize the magnetic particles in the ferrofluid. The fields generated by the two front coils (black in Fig. 3) are permanent and have the same sign. These fields form a potential valley between the coils, where the gradient in the y-direction is zero. Thus, these fields work as a *virtual channel* for the ferrofluid droplet. The ferrofluid droplet is confined in this *virtual channel* and can move only in the x-direction. This *virtual channel* can be replaced by a real microchannel in the x-direction. In this case, only two driving coils are needed. The two coils on the back of the PCB are connected in series, so that their fields always have opposite signs. The field gradients between the two coils have the same sign, allowing the droplet to move in a prescribed direction. The direction of motion can be changed if the current in the coils is reversed. The switching circuit for changing the current direction is shown in Fig. 4.

The carrier liquid of the ferrofluid used in the experiment (APG S10n, Ferrotec) was a synthetic ester oil which was immiscible in silicone oil. The viscosity η, density ρ, and surface tension σ of the ferrofluid at 25 °C were 0.406 kg/ms, 1330 kg/s, and 32×10^{-3} N/m, respectively. The saturation magnetization and the initial susceptibility χ of this ferrofluid were 44 mT and 1.6, respectively. Two silicone oils with different viscosities were used to investigate the effect of viscous friction: $[-\mathrm{Si(CH_3)_2O}-]_n$, with a kinematic viscosity of $\nu = 50$ cSt, and $[-\mathrm{C_7H_8OSi}-]$, with a kinematic viscosity of 100 cSt. Both oils had approximately the same surface tension of 2.03×10^{-7} N/m and a density of 960 kg/m^3. In the experiments, the ferrofluid droplet was surrounded



Ferrofluids in Microchannels, Figure 4 Switching circuit and optical setup



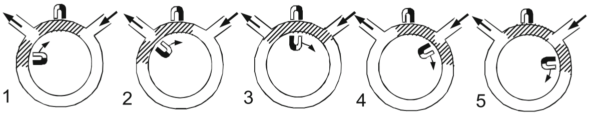
Ferrofluids in Microchannels, Figure 5 Recorded motion of a ferrofluid microdroplet

by the silicone oil. The higher density of the ferrofluid ensured that the droplet remained on the bottom surface of a 0.5 mm thick Teflon sheet. The hydrophobic surface of the Teflon sheet allowed the droplet to keep its spherical shape. The two virtual-channel coils were supplied with a constant current of 750 mA. The direction of the current in the driving coils was switched using the control circuit shown in Fig. 4. The periodic motion of the ferrofluid droplet was captured with a CCD camera. The camera was synchronized with the switching signal to record the position of the droplet at given time instants. Figure 5 shows an example of a recorded image sequence from this experiment. It is apparent that the droplet elongates under the induced magnetic force. Since the driving magnetic force is a body force, a larger droplet will have a better volume-to-surface ratio, or a larger ratio between the magnetic force and the drag force. A larger droplet can accelerate faster and reach its final position in a shorter time.

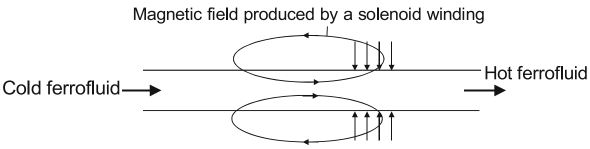
This actuation concept can be used for transport and sorting applications in droplet-based microfluidics. The results show the potential use of ferrofluid droplets as both a vehicle and a microreaction platform for droplet-based Lab-on-a-Chip applications.

Ferrofluid as an Actuator

The above example shows that a ferrofluid droplet or plug in a microchannel can function as an actuator. The actuating force is induced by an external magnetic field. The external magnetic field can be generated either by a microcoil, as demonstrated in the previous example, or by a moving magnet. In this concept, a ferrofluid plug is suspended in the channel. An external permanent magnet controls the position of the ferrofluid plug. Moving the permanent magnet pushes the ferrofluid plug in the



Ferrofluids in Microchannels, Figure 6 Concept of a ferrofluidic micropump



Ferrofluids in Microchannels, Figure 7 Concept of magnetocaloric pumping

desired direction. While moving in the microchannel, the ferrofluid plug pushes the surrounding liquid on one side and pulls it on the other side. The effect causes a pumping effect. If the magnet stops, the magnetic field holds the plug at its current location and prevents the pumped liquid from moving back. This sealing property means that a ferrofluid plug can also work as an active valve. The pumping power depends on the gradient of the external magnetic field and the magnetization of the ferrofluid. The field strength can be adjusted by the external permanent magnet, and so the pump design becomes independent of the type of liquid pumped.

Magnetic pumping using a ferrofluid has been implemented on a microscale by Hatch et al. [4]. The pump was fabricated in silicon and glass. The channel structure was etched in silicon and bonded anodically to a borosilicate glass plate. Two permanent magnets were used, as a valve actuator and a plug actuator. The working principle of this rotary concept is explained in Fig. 6. A fixed permanent magnet creates a stationary ferrofluid plug between the inlet and the outlet (1). First, a moving permanent magnet merges a second plug with the stationary plug (2). After complete merging has occurred, the large plug blocks both the inlet and the outlet (3). When the large plug is separated into one stationary and one moving plug, the fluid is sucked into the inlet and pushed out of the outlet (4). The design of the pump is similar to the concepts of a rotary pump and a check valve pump. However, this design is a pure magnetic micropump because no mechanical moving parts are involved. This micropump is able to deliver a maximum flow rate of 70 mL/min and a maximum back pressure of 1.3 kPa.

Ferrofluids in Microchannels, Table 1 Curie Temperature and saturation magnetization of various ferromagnetic solids

Substance	Curie temperature (°C)	$\mu_0 M_S$ (T)

Iron	770	2.18
Magnetite	585	0.56
Nickel	358	0.64

Continuous Pumping of Ferrofluid in a Microchannel Using a Temperature Gradient

According to Eq. (6), a temperature gradient can cause a magnetic force. This actuation concept has been termed magnetocaloric pumping by Love et al. [2]. Figure 7 shows a simple configuration for this. A magnetic field is induced by a coil or a permanent magnet. A temperature gradient along the flow direction causes a gradient in the magnetization, which in turn results in a net force that pumps the ferrofluid. The relationship between magnetization and temperature shown in Fig. 2 indicates that the closer the heating temperature is to the Curie temperature of the magnetic nanoparticles, the larger the force and the higher the flow rate. The ideal particle would have a Curie temperature close to the maximum expected thermal-cycling temperature. Table 1 lists the Curie temperatures of a number of ferrous materials. Most commercial-grade ferrofluids are based on magnetite particles and have a relatively high Curie temperature of 585 °C. Thus, almost all liquids will evaporate before this pumping concept works. The solution to this problem is the use of magnetic materials with Curie temperatures below the boiling point or any other critical temperature of the liquids used in the microfluidic system.

Fiber Optic Cables

Definition

Fiber optic cables are flexible tubes which allow user-friendly transportation of light; thus positioning and handling of a light beam or spot is possible without using a complex system of mirrors and lenses. Fiber optic cables consist of a bundle of tiny glass fibers or they are filled with a transparent liquid. A clever exploitation of total reflectance and interference at the inner surface of the fiber leads to lossless channeling of the light.

Control volume method; Control volume based finite difference method; Computational fluid dynamics (CFD)

Definition

The present article briefly discusses two of the basic discretization techniques commonly used for computational fluid dynamics (CFD) analysis of systems involving fluid flow, heat transfer and associated phenomena such as chemical reactions. These mathematical tools, however, are generalized enough to address other transport processes occurring in electrical, magnetic or electromagnetic systems as well.

Overview

In order to simulate fluid flow, heat transfer, and other related physical phenomena over various length scales, it is necessary to describe the associated physics in mathematical terms. Nearly all the physical phenomena of interest to the fluid dynamics research community are governed by the principles of continuum conservation, and are expressed in terms of first or second order partial differential equations that mathematically represent these principles (within the restrictions of a continuum-based framework). However, in case the requirements of continuum hypothesis are violated altogether for certain physical problems (for instance, in case of high Knudsen number rarefied gas flows), alternative formulations in terms of the particle-based statistical tools or the atomistic simulation techniques need to be resorted to. In this article, we shall only focus our attention to situations in which the governing differential equations physically originate out of continuum conservation requirements, and can be expressed in the form of a general differential equation that incorporates the unsteady term, the advection term, the diffusion term and the source term, to be elucidated as follows.

Finite Volume and Finite Difference Methods for Modeling and Simulation, Table 1 Conservation equations in the general form

Equation	Φ	Γ	S
Continuity	1	0	0
Momentum	$\boldsymbol{V}$	μ	$-\nabla p + \boldsymbol{F}$
Energy	T	k/c_p	$\dot{Q}/C_p$

A generic form of the general conservation principle for any dependent variable, ϕ, can be expressed as

$$\underbrace{\frac{\partial}{\partial t}(\rho\phi)}_{\text{transient term}} + \underbrace{\nabla\cdot(\rho \boldsymbol{V}\phi)}_{\text{advection term}} = \underbrace{\nabla\cdot(\Gamma\nabla\phi)}_{\text{diffusion term}} + \underbrace{S}_{\text{source term}}. \quad (1)$$

The well known equations of mass, momentum and energy conservation can all be cast in the above general form, with the expressions for ϕ, Γ (general diffusion coefficient) and S (general source term) being the sole distinctive features of one equation from another. This issue is summarized in Table 1, for convenience. In Table 1, μ denotes the viscosity, p denotes the pressure, $\boldsymbol{F}$ denotes the body force per unit volume, T denotes the temperature, k denotes the thermal conductivity, c_p denotes the specific heat, and $\dot{Q}$ denotes the rate of heat generation per unit volume.
In many situations, the complicated and/or coupled nature of the governing differential equations makes it difficult, if not impossible, to solve them analytically. Keeping that in view, it has always been a challenging task to the research community to develop efficient numerical techniques for solving the general transport equations. Fundamental to the development of a numerical method for solving these differential equations is the idea of discretization. Although an analytical solution to a partial differential equation gives us the value of the variable ϕ as a continuous function (in the absence of any continuum-level discontinuities in the problem domain) of the independent variables (namely, the spatial and temporal variables), the numerical solution aims to provide us with values of ϕ at a *discrete* number of points in the domain. These points are typically called as *grid points*, or equivalently, as the *nodes* or the *cell centroids*, depending on the specific numerical method being employed. The process of converting the governing transport equation into a set of equations for the discrete values of ϕ is called the *discretization process* and happens to be one of the key aspects of the numerical solution strategy. The specific methods employed to bring about this conversion are called as the *discretization methods*. The finite different and the finite volume methods are two of the common discretization methods often employed for fluid flow analysis, and will be briefly discussed here. The other commonly used methods, such as the finite element method, the boundary element method, the meshless method, etc. fall beyond the scope of this article and will not be discussed here. It however, needs to be kept in mind that all these discretization methods share one common philosophy: their only goal is to convert the governing differential equation into a system of discretized algebraic equations (the number of algebraic equations being same as the number of scalar unknowns considering the discrete grid points (or the nodal points) at which these variables are to be solved). It is the methodology and philosophy of this discreization technique in which one numerical method differs from the other.

Basic Methodology

Finite Difference Method

The finite difference methods approximate the derivatives in the governing differential equation using the truncated Taylor series expansions, for the purpose of discretization [1]. The starting point of formulating a finite difference scheme is to discretize the domain into a number of grid points and to express the derivatives at those grid points in terms of the nodal values of the function itself. The grid points can be numbered by a number of free indices (depending on the dimensionality of the problem), provided that the grid-system is a structured one. For illustration, let us express the value of a variable in the vicinity of the grid point i, in the form of Taylor series, as

$$\begin{aligned}\phi(x) = \phi(x_i) + (x-x_i)\left(\frac{\partial\phi}{\partial x}\right)_i \\ + \frac{(x-x_i)^2}{2!}\left(\frac{\partial^2\phi}{\partial x^2}\right)_i \\ + \frac{(x-x_i)^3}{3!}\left(\frac{\partial^3\phi}{\partial x^3}\right)_i \\ + \dots \\ + \frac{(x-x_i)^n}{n!}\left(\frac{\partial^n\phi}{\partial x^n}\right)_i + H\end{aligned} \quad (2)$$

where H means the *higher order terms*. By replacing x by x_{i+1} or x_{i-1} in Eq. (1), one may obtain the expressions for the values of the variable ϕ at these points, in terms of the values and derivatives at the point x_i. Executing this exercise, the first order derivative of at the point x_i can be

written in any of the following ways (Eq. (3a), (3) or (3c)):

$$\left(\frac{\partial\phi}{\partial x}\right)_i = \frac{\phi_{i+1}-\phi_i}{x_{i+1}-x_i} - \frac{x_{i+1}-x_i}{2}\left(\frac{\partial^2\phi}{\partial x^2}\right)_i - \frac{\left(x_{i+1}-x_i\right)^2}{6}\left(\frac{\partial^3\phi}{\partial x^3}\right)_i + H \tag{3a}$$

where $\phi_i \equiv \phi\,(x = x_i)$.

$$\left(\frac{\partial\phi}{\partial x}\right)_i = \frac{\phi_i-\phi_{i-1}}{x_i-x_{i-1}} - \frac{x_i-x_{i-1}}{2}\left(\frac{\partial^2\phi}{\partial x^2}\right)_i - \frac{\left(x_i-x_{i-1}\right)^2}{6}\left(\frac{\partial^3\phi}{\partial x^3}\right)_i + H \tag{3b}$$

$$\left(\frac{\partial\phi}{\partial x}\right)_i = \frac{\phi_{i+1}-\phi_{i-1}}{x_{i+1}-x_{i-1}} - \frac{\left(x_{i+1}-x_i\right)^2-\left(x_i-x_{i-1}\right)^2}{2\left(x_{i+1}-x_{i-1}\right)}\left(\frac{\partial^2\phi}{\partial x^2}\right)_i - \frac{\left(x_{i+1}-x_i\right)^3+\left(x_i-x_{i-1}\right)^3}{6\left(x_{i+1}-x_{i-1}\right)}\left(\frac{\partial^3\phi}{\partial x^3}\right)_i + H \tag{3c}$$

All three of the above expressions are exact if all terms in the right hand side are retained. However, the terms involving the higher derivatives can be neglected in case the distance between the successive grid points is small enough, except for the typical situations in which the magnitudes of the higher order derivatives are locally very large. The truncation of the Taylor series upto the first term in the right hand side of the Eqs. (3a), (3), (3c) leads to the following approximations of the first order derivative:

$$\left(\frac{\partial\phi}{\partial x}\right)_i \approx \frac{\phi_{i+1}-\phi_i}{x_{i+1}-x_i} \tag{4a}$$

$$\left(\frac{\partial\phi}{\partial x}\right)_i \approx \frac{\phi_i-\phi_{i-1}}{x_i-x_{i-1}} \tag{4b}$$

$$\left(\frac{\partial\phi}{\partial x}\right)_i \approx \frac{\phi_{i+1}-\phi_{i-1}}{x_{i+1}-x_{i-1}}\,. \tag{4c}$$

Expressions (4a), (4b) and (4c) correspond to the so-called *forward difference scheme*, *backward difference scheme* and *central difference scheme*, respectively. The error incurred in truncating the infinite Taylor series upto a finite number of terms for the calculation of the derivatives is known as the *truncation error*. Since the higher order terms are expected to be smaller (as they vary with higher powers of the small grid spacing), the first truncated term is usually the principle source of truncation error. The order of the truncation error, therefore, is usually estimated by the order of this term. For an equally spaced grid arrangement (such that $x_{i+1} - x_i = x_i - x_{i-1} = \Delta x$ (say)), the forward difference and the backward difference schemes for evaluating the first order derivatives are $O\,(\Delta x)$, whereas the central difference scheme for the same is $O\left(\Delta x^2\right)$. It is, however, possible to derive higher order versions of these schemes, by using higher order polynomial interpolations as approximations for evaluating the functional derivatives, instead of going through the direct route of Taylor series approximations.

Analogous to the first derivative, the second order derivatives can also be approximated by going through the route of Taylor series expansions. For example, one can approximate the second order derivative in terms of a central difference of the first order derivatives, as

$$\left(\frac{\partial^2\phi}{\partial x^2}\right)_i \approx \frac{\left(\frac{\partial\phi}{\partial x}\right)_{i+1} - \left(\frac{\partial\phi}{\partial x}\right)_i}{x_{i+1}-x_i}\,. \tag{5}$$

Good choices of points for evaluation of the first order derivatives appearing in the above expression may be the points that are located midway between x_i and x_{i+1} and x_{i-1} and x_i. Central difference approximations for these derivatives are as follows:

$$\left(\frac{\partial\phi}{\partial x}\right)_{i+\frac{1}{2}} \approx \frac{\phi_{i+1}-\phi_i}{x_{i+1}-x_i}\,, \quad \left(\frac{\partial\phi}{\partial x}\right)_{i-\frac{1}{2}} \approx \frac{\phi_i-\phi_{i-1}}{x_i-x_{i-1}} \tag{6}$$

The above leads to a simplified expression of Eq. (5), for equidistant grid spacings, as

$$\left(\frac{\partial^2\phi}{\partial x^2}\right)_i \approx \frac{\phi_{i+1}-2\phi_i+\phi_{i-1}}{(\Delta x)^2} \tag{7}$$

Equation (7) is a well-known expression for a second order accurate estimation of the second order derivatives using the central difference scheme.

One of the disadvantages associated with the finite difference method is that the physical principle of conservation is not automatically enforced in the scheme, unless special care is taken. Moreover, the implementation of this method is often restricted to simple geometries, since this method

cannot be implemented with convenience on unstructured grids.

Finite Volume Method

Starting point of the finite volume method is the integral form of the governing conservation equations [2]. This is achieved by first sub-dividing the problem domain into a number of contiguous control volumes of finite dimensions, and then integrating the governing differential equation over each of these elemental control volumes. The representative value of the variable to be solved for each control volume may be taken as the value of the variable at the geometric centre of the control volume. For evaluating the integrals, suitable profile assumptions for the dependent variable can be taken (giving rise to approximating quadrature formulae for the surface and the volume integrals), without violating the constraints of physical consistency and overall balance. However, once the integrals have been evaluated, the history of the profile assumption is essentially lost. This gives the analyst a freedom to adopt different profile assumptions for the same variables appearing in different terms of a governing equation. Integrations with respect to time can be carried out with the following linear interpolation formula:

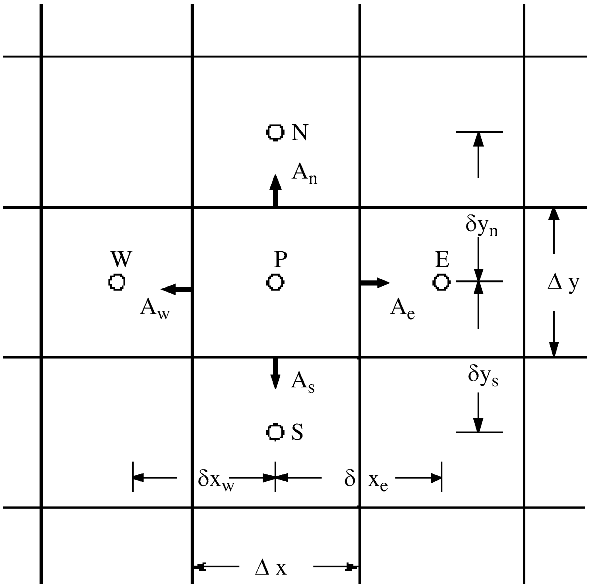
$$\int_{t}^{t+\Delta t} \phi \, \mathrm{d}t = \left[f\phi^{t+\Delta t} + (1-f)\,\phi^{t} \right] \Delta t\,, \quad 0 \leqslant f \leqslant 1 \tag{8}$$

The special cases of $f = 0$, $f = 0.5$ and $f = 1$ give rise to the *explicit scheme*, *Crank Nicholson scheme* and the *implicit scheme*, respectively. The integration with respect to the temporal and the spatial variables eventually results in a system of algebraic equations (one for each control volume), which can be solved by standard numerical techniques.

For a simple illustration of the finite volume discretization methodology, one may consider a two-dimensional rectangular control volume with the grid point P at its geometric centre, as depicted in Fig. 1. The neighboring grid points for the point P are the points E, W, N and S (symbolizing the 'east', 'west', 'north' and 'south' neighbors). The locations of the four faces of the control volume containing the point P are denoted by the corresponding lowercase alphabets. If we take the two-dimensional transient heat conduction equation as a prototype example, in the form

$$\rho c_{\mathrm{P}} \frac{\partial T}{\partial t} = \frac{\partial}{\partial x}\left(k\frac{\partial T}{\partial x}\right) + \frac{\partial}{\partial y}\left(k\frac{\partial T}{\partial y}\right) + S \tag{9}$$

then an implicit time-discretization, piecewise linear temperature profile assumption between consecutive grid



Finite Volume and Finite Difference Methods for Modeling and Simulation, Figure 1 A generic finite volume discretization stencil in two dimensions

points for the diffusion terms, and a piecewise constant temperature profile within each control volume for the source term give rise to a discretized version of the control volume-integral of Eq. (9) in the following form:

$$a_{\mathrm{P}} T_{\mathrm{P}} = a_{\mathrm{E}} T_{\mathrm{E}} + a_{\mathrm{W}} T_{\mathrm{W}} + a_{\mathrm{N}} a T_{\mathrm{N}} + a_{\mathrm{S}} T_{\mathrm{S}} + a_{\mathrm{P}}^{0} T_{\mathrm{P}}^{0} + b \tag{10}$$

where $a_{\mathrm{E}} = k_{\mathrm{E}} \Delta y/\delta x_{\mathrm{e}}$, $a_{\mathrm{W}} = k_{\mathrm{w}} \Delta y/\delta x_{\mathrm{w}}$, $a_{\mathrm{N}} = k_{\mathrm{n}} \Delta x/\delta y_{\mathrm{n}}$, $a_{\mathrm{S}} = k_{\mathrm{s}} \Delta x/\delta y_{\mathrm{s}}$, $a_{\mathrm{P}}^{0} = \rho c_{\mathrm{p}} \Delta x \Delta y/\Delta t$, $b = S_{\mathrm{c}} \Delta x \Delta y + a_{\mathrm{P}}^{0} T_{\mathrm{P}}^{0}$, $a_{\mathrm{P}} = a_{\mathrm{E}} + a_{\mathrm{W}} + a_{\mathrm{N}} + a_{\mathrm{S}} + a_{\mathrm{P}}^{0} - S_{\mathrm{P}} \Delta x \Delta y$. Here the superscript '0' symbolizes the value at a time instant of t and the superscript is omitted to symbolize the value at a time instant of $t + \Delta t$. Further, the source term is linearized in the form $S = S_{\mathrm{c}} + S_{\mathrm{P}} T_{\mathrm{P}}$, to arrive at the above discretization. In general, for executing the finite volume discretization of heat conduction problems, the following important points may be taken into account [2]:

- The profile assumption should be consistent with the requirements of the continuity of fluxes at the control volume faces.
- All coefficients in the discretized algebraic equation should be of the same sign.
- The interfacial value of thermal conductivity can be best interpolated by invoking a harmonic mean approximation, based on values of the same at the adjacent grid points.

- The explicit scheme gives rise to a system of discretized algebraic equations that are not mathematically coupled. However, the cost that one might have to pay against this simplification is that the scheme is conditionally stable. On the other hand, the implicit scheme requires a coupled system of linear algebraic equations to be solved, but is unconditionally stable (the issues of 'stability' in the context of discretized equations will be elaborated later).

Key Research Findings

Convection–Diffusion Problems

The finite volume formulation for diffusion type problems can be extended for solving the convection–diffusion types of problems, in which additional advection terms appear in the governing differential equations. Assuming that the velocity field is already obtained from a separate solution module, various discretization strategies can be formulated for solving the convection–diffusion problem, based on the 'cell Peclet number' (P), which is nothing but the ratio of the advection to diffusion strengths, based on control volume specific length scales. Considering the following generic form of a two-dimensional unsteady state convection–diffusion equation as an illustrative example:

$$\frac{\partial}{\partial t}(\rho\phi) + \frac{\partial}{\partial x}(\rho u\phi) + \frac{\partial}{\partial y}(\rho v\phi) = \frac{\partial}{\partial x}\left(\Gamma\frac{\partial \phi}{\partial x}\right) + \frac{\partial}{\partial y}\left(\Gamma\frac{\partial \phi}{\partial y}\right) + S \quad (11)$$

one can arrive at a discretization equation as

$$a_P\phi_P = a_E\phi_E + a_W\phi_W + a_N\phi_N + a_S\phi_S + a_P^0\phi_P^0 + b \quad (12)$$

where $a_E = D_eA(|P_e|) + \max(-F_e, 0)$, $a_W = D_wA(|P_w|) + \max(F_w, 0)$, $a_N = D_nA(|P_n|) + \max(-F_n, 0)$, $a_S = D_sA(|P_s|) + \max(F_s, 0)$, $a_P^0 = \rho_P^0\Delta x\Delta y/\Delta t$, $b = S_c\Delta x\Delta y + a_P^0\phi_P^0$, $a_P = a_E + a_W + a_N + a_S + a_P^0 - S_P\Delta x\Delta y$. Here, $D_e = \Gamma_e\Delta y/\delta x_e$, $D_w = \Gamma_w\Delta y/\delta x_w$, $D_n = \Gamma_n\Delta x/\delta y_n$, $D_s = \Gamma_s\Delta x/\delta y_s$, $F_e = (\rho u)_e\,\Delta y$, $F_w = (\rho u)_w\,\Delta y$, $F_n = (\rho v)_n\,\Delta x$, $F_s = (\rho v)_s\,\Delta x$, $P_e = F_e/D_e$, $P_w = F_w/D_w$, $P_n = F_n/D_n$, $P_s = F_s/D_s$.

The function $A(|P|)$, as appearing in the above equation, depends on the specific interpolation scheme chosen to discretize the convection–diffusion terms. Appropriate expressions of the same, for different schemes, are given in Table 2. Regarding the choice of a suitable scheme, certain important considerations can be noted [2]:

- The central difference scheme can give rise to physically inconsistent solutions, in case $|P| > 2$.
- The upwind scheme does not suffer from the above limitation, but tends to overpredict diffusion.
- Although the exponential scheme gives a reasonably accurate estimation of the profile variation of ϕ, it involves costly computation of exponential terms.
- The hybrid scheme is a piecewise linearlization of the exponential scheme, and therefore, retains a correct physical behaviour. However, it tends to set the diffusion effects to zero as soon as $|P| > 2$.
- The Power law scheme is essentially a curve-fitting of the exponential scheme that attempts to eliminate the above-mentioned discrepancy.
- The upwind scheme had been identified by many researchers as a common source of 'numerical diffusion' or 'false diffusion', which means an 'overprediction' of the diffusion strength as a numerical artifact. However, a different (and possibly, more logical) viewpoint is that the false diffusion is not so much attributable to the specific convection–diffusion scheme chosen (since, the best portrayed scheme for overcoming false diffusion, namely the central difference scheme, itself ceases to work at high values of cell Peclet number), but can be associated with the obliquity of the flow directions with respect to the grid lines that form the discretized space. Higher order upwind schemes, for example, the QUICK (quadratic upstream interpolation scheme for convective kinetics) differencing scheme [3], have been suggested as alternative remedies to overcome false diffusion effects. Such alternative schemes, however, also suffer from certain shortcomings in the sense that these are conditionally stable.

Discretization of Fluid Flow Equations

So far, we have discussed the solution of general transport equations, by assuming the velocity field to be known. In principle, the equations governing the velocity field (namely, the continuity and the momentum conservation equations) are also of a general conservative nature (see

Finite Volume and Finite Difference Methods for Modeling and Simulation, Table 2 convection–diffusion discretization schemes

Scheme	$A(\|P\|)$
Central difference	$1-0.5\|P\|$
Upwind	1
Exponential	$\|P\|/(\exp\|P\|-1)$
Hybrid	$\max(0, 1-0.5\|P\|)$
Power law	$\max(0, (1-0.5\|P\|)^5)$

Table 1), and ideally, should have been solvable by the standard convection–diffusion discretization methodologies discussed as earlier. In reality, however, the strategy does not work in that way and additional considerations need to be invoked. This is because of the fact that the momentum equation source terms contain pressure as an additional scalar variable, although there is no separate explicit governing differential equation for pressure. Early efforts in solving the fluid flow equations were mainly based on the stream function-vorticity approach, in which the pressure gradient terms from the momentum conservation equations are eliminated by cross-differentiating the two components of the momentum conservation equation (in case of a two-dimensional flow-field) and subtracting one from the other, giving rise to the following two coupled equations:

$$\frac{\partial \zeta}{\partial t} + u\frac{\partial \zeta}{\partial x} + v\frac{\partial \zeta}{\partial y} = \frac{\mu}{\rho}\left(\frac{\partial^2 \zeta}{\partial x^2} + \frac{\partial^2 \zeta}{\partial y^2}\right) \tag{13}$$

$$\frac{\partial^2 \psi}{\partial x^2} + \frac{\partial^2 \psi}{\partial y^2} = -\zeta \tag{14}$$

where $\boldsymbol{\zeta}$ is the vorticity vector ($\boldsymbol{\zeta} = \nabla \times \boldsymbol{V}$) and ψ is the stream function ($u = \partial\psi/\partial y,\ v = -\partial\psi/\partial x$). These two coupled equations can be discretized in the same manner outlined as above, and the pressure field can subsequently be computed by solving for the following Poisson equation:

$$\frac{\partial^2 p}{\partial x^2} + \frac{\partial^2 p}{\partial y^2} = 2\rho\left[\frac{\partial^2 \psi}{\partial x^2}\frac{\partial^2 \psi}{\partial y^2} - \left(\frac{\partial^2 \psi}{\partial x \partial y}\right)^2\right] \tag{15}$$

The apparently-elegant stream function vorticity approach, however, suffers from certain shortcomings, as follows [2]:

- The vorticity at the wall may be difficult to specify for many practical problems.
- The pressure can be required as an intermediate outcome for updating the density values through the equation of state, so that a complete elimination of pressure might not always be desirable.
- Most importantly, the method cannot be extended to three dimensions in which the stream function is not defined.

In order to overcome such shortcomings, the primitive variable based methods have been suggested as better alternatives in the literature. The challenges associated with the primitive variable methods are not to elimininate the pressure, but to convert the indirect information in the continuity equation into a direct algorithm for the calculation of pressure. However, a straight forward discretization of the pressure gradient terms in the momentum conservation equation, based on the linearly-interpolated values of pressure from the adjacent grid points may give rise to certain anomalies, leading to a condition in which a zigzag pressure field could be numerically interpreted as a uniform one. As a remedy, the concept of 'staggered' (displaced) grids has been introduced, according to which the velocity components are calculated for the points that lie on the faces of the control volumes (see Fig. 2). Advantages of such kinds of grid arrangement are mainly twofold [2]:

- The discretized continuity equation would contain the differences of the adjacent velocity components, so that wavy velocity fields are not wrongly predicted as outcomes of the continuity equation for cases in which a uniform velocity field is expected to physically exist.
- The pressure difference between two adjacent grid points becomes the natural driving force for the velocity variations between these grid points, so that unrealistic predictions of the pressure field are ruled out.

It is important to mention here that the use of staggered grids is not always a compulsion. In case special pressure interpolation schemes are employed to overcome the difficulties associated with the non-staggered grids mentioned as earlier, the staggered grid arrangement might not be necessary. In such cases, the same grid arrangement can be employed for solution of the velocity field and the other scalar variables, which is commonly referred to as a 'co-located grid'.

Several algorithms do exist in the literature for numerical computation of fluid flow problems on the basis of primitive variables, in a finite volume framework. One of the most commonly used algorithms of this kind is the SIMPLE (semi implicit method for pressure linked equations) algorithm [2]. With reference to a generic staggered control volume for solution of the momentum equation for u (see Fig. 3) and with similar considerations for the other velocity components, major steps of the SIMPLE algorithm can be summarized as follows:

(i) Guess the pressure field, p^*.

(ii) Solve the discretized momentum conservation equations, to be cast in the following forms:

$$a_e u_e^* = \sum a_{nb} u_{nb}^* + b + (p_P^* - p_E^*)A_e\ ;$$

$$a_n v_n^* = \sum a_{nb} v_{nb}^* + b + (p_P^* - p_N^*)A_n\ ;$$

$$a_t u_t^* = \sum a_{nb} w_{nb}^* + b + (p_P^* - p_T^*)A_t\ ,$$

where the subscript 'nb' refers to the neighbouring grid points.

(iii) Substitute a 'velocity correction' formula, expressed in terms of 'pressure corrections' at the main grid points in the discretized continuity equation (discretized over the main control volume, not the staggered one), to get the pressure correction equation in the following form (with 'T' and 'B' denoting the 'top' and 'bottom' grid points relative to the point P in a three-dimensional space):

$$a_P p'_P = a_E p'_E + a_W p'_W + a_N p'_N + a_S p'_S + a_T p'_T + a_B p'_B + b \quad (16)$$

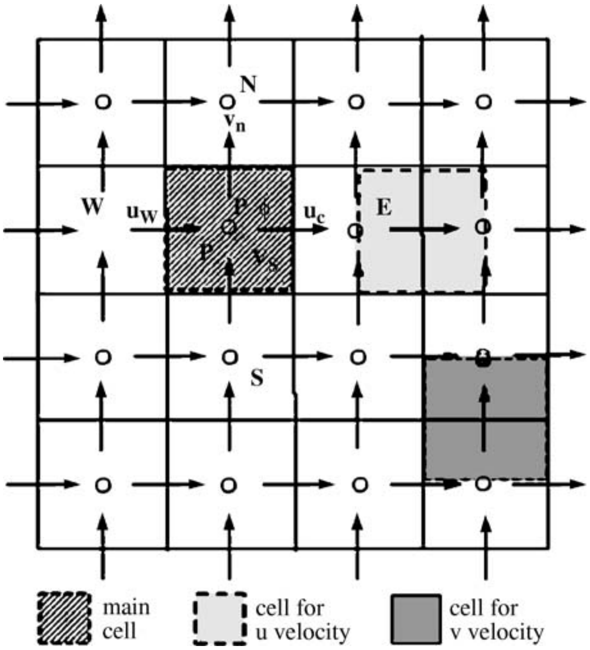
where $a_E = \rho_e d_e \Delta y \Delta z$ (where $a_E = A_e / a_e$), $a_W = \rho_w d_w \Delta y \Delta z$, $a_N = \rho_n d_n \Delta x \Delta z$, $a_S = \rho_s d_s \Delta x \Delta z$, $a_T = \rho_t d_t \Delta x \Delta y$, $a_B = \rho_b d_b \Delta x \Delta y$, $a_P = a_E + a_W + a_N + a_S + a_T + a_B$, and

$$b = \frac{(\rho_P^0 - \rho_P)\Delta x \Delta y \Delta z}{\Delta t} + \left[(\rho u^*)_w - (\rho u^*)_e\right]\Delta y \Delta z + \left[(\rho v^*)_s - (\rho v^*)_n\right]\Delta x \Delta z + \left[(\rho w^*)_b - (\rho w^*)_t\right]\Delta x \Delta y$$

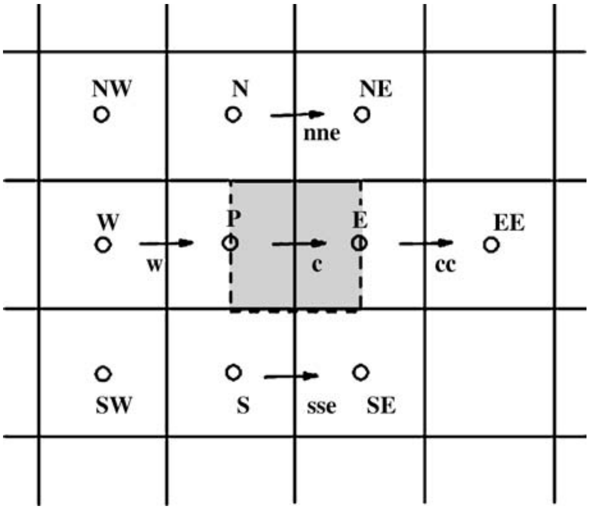
(iv) Correct the pressure field as $p = p^* + p'$.
(v) Correct the velocity field as $u_e = u_e^* + d_e\left(p'_P - p'_E\right)$, and similarly for the other velocity components.
(vi) GOTO step (ii) with the corrected value of p obtained from step (iv) ad the new p^*.
(vii) Repeat the loop until convergence.

With regard to the SIMPLE algorithm outlined as above, certain important points can be carefully noted:

- No attempt is made for the direct solution of momentum equations. In the velocity correction expression, i. e., $u'_e = \sum a'_{nb} u'_{nb} + b + \left(p'_P - p'_E\right) A_e$, the first term in the right hand side is essentially dropped, which enables one to cast the pressure correction equation in a general conservative form.
- The algorithm is called as *semi implicit* to acknowledge the dropping of the term $\sum a'_{nb} u'_{nb}$. This term essentially represents an indirect or implicit influence of the pressure correction on velocity. Although pressure corrections at nearby locations can alter the neighbouring velocities and thus can cause a velocity correction at the point under consideration. This influence is not considered in the SIMPLE algorithm. However, it needs to be noted here that this semi-implicit nature has nothing to do with any possible implicit or explicit nature of the time-discretization scheme.
- On convergence, all the velocity and pressure corrections tend to zero. This implies that no error is incurred on dropping the $\sum a'_{nb} u'_{nb}$ term, once the convergenced solution has been obtained, with an understanding that the term 'b' in Eq. 15, which is essentially a mass source term for the discretized continuity equation, should tend to zero once the mass conservation is satisfied. The sole emphasis here is to obtain a pressure



Finite Volume and Finite Difference Methods for Modeling and Simulation, Figure 2 Staggered grid arrangement for the solution of momentum equations



Finite Volume and Finite Difference Methods for Modeling and Simulation, Figure 3 A generic staggered control volume for discretization of the x-momentum equation

field that satisfies the continuity equation. The dropping of the $\sum a'_{\text{nb}} u'_{\text{nb}}$ term, however, is related to the rate at which the convergence is obtained.

- For highly compressible flows, the pressure correction formula should also accommodate the provision of a density correction term.
- The pressure is a relative variable, as an outcome of this algorithm, and not an absolute quantity.
- The approximation introduced in the derivation of the pressure correction equation by dropping the term $\sum a'_{\text{nb}} u'_{\text{nb}}$ leads to a rather exaggerated pressure correction. Because of the omission of the neighbouring velocity corrections, the pressure correction carries the entire burden of correcting the velocities, which results in a rather severe pressure correction field. Thus, although the pressure correction equation does a fairly good job in correcting the velocities, it does a poorer job in correcting the pressure. Taking this into consideration, a revised version of the SIMPLE algorithm, namely, the SIMPLER algorithm [2] has later been proposed, in which a separate pressure equation is formulated (by discretizing the continuity equation) to solve for the pressure field, and the pressure correction is solely employed to correct the velocity field but not the pressure field. This leads to a faster convergence, although a slightly increased overhead of solving another scalar equation (namely, the pressure equation).
- Other variants of the SIMPLE algorithm have also been proposed in the literature. For example, Van Doormal and Raithby [4] developed the SIMPLEC (SIMPLE-Consistent) algorithm, which follows similar steps as that of the SIMPLE algorithm, with the sole difference that the momentum equations are manipulated so that the modified velocity correction formulae omit terms that are less significant than those omitted in the SIMPLE algorithm. Issa [5] introduced the PISO (Pressure Implicit with Splitting of Operators) algorithm for the non-iterative computation of unsteady compressible flows. This algorithm involves one predictor step and two corrector steps, as an extension of the SIMPLE algorithm. The SIMPLEC and the PISO algorithms have been found to work as efficiently as the SIMPLER algorithm in many cases, although it cannot be convincingly concluded their relative superiorities, which strongly depend on the extent of coupling between the velocity field and the other scalar fields, and often on the strategy of solving the system of discretized algebraic equations.

Issues of Consistency, Stability and Convergence

Irrespective of the discretization method chosen, the success of the numerical scheme depends heavily on certain factors, associated with the terminologies such as consistency, stability and convergence. A numerical scheme is said to be consistent if it produces systems of algebraic equations that can be demonstrated as equivalent to the original governing differential equation, in the limit as the grid spacings tend to zero. In more technical terms, the truncation error must tend to zero with limitingly thin grid spacings. In general, the truncation error can be numerically assessed by obtaining the numerical solutions over two different grid spacings (h and $2h$, say). Let the corresponding numerical solutions be $\phi_h$and ϕ_{2h}, respectively. It can also be noted that for sufficiently fine grids, the truncation error is proportional to the leading order term in the Taylor series, i. e., $T.E \approx \alpha h^p + H$, where α depends on the derivatives at a given point but is independent of h, and H stands for the higher order terms. Thus, one can write

$$\phi_{\text{exact}} = \phi_h + \alpha h^p + H = \phi_{2h} + \alpha\,(2h)^p + H \tag{17}$$

so that the truncation error for the grid size of h can be estimated as

$$(T.E)_h \approx \frac{\phi_h - \phi_{2h}}{2^p - 1} \tag{18}$$

Equation (16) forms the basis of the Richardson extrapolation formula [6] commonly used in Numerical analysis, for improving the accuracy of the numerical solutions by accommodating for the truncation error estimates.

Another important factor for the successful performance of a discretization scheme is its stability. In simple terms, a numerical solution method is said to be stable if it does not magnify the errors that appear in the course of a numerical solution process. For unsteady problems, stability guarantees that the numerical method yields a bounded solution provided that the solution of the original governing differential equation is also bounded. For iterative methods, the iterations act as *virtual* time steps, and the meaning of stability has analogous physical implications. Classically, the stability of a discretization scheme is assessed by employing the von Neumann analysis. For non-linear problems, stability might be rather difficult to investigate by adopting this method. Here, we outline the stability analysis of a linear problem in which explicit method of time discretization is used, for the sake of illustration. For simplicity, let us consider a one-dimensional diffusion problem with constant thermophysical properties and no source terms, numerically solved by employing uniform grids and an explicit time-discterization scheme. In this special case, the discretization equation takes the form of

$$a_{\text{P}}\phi_{\text{P}} = a_{\text{E}}\phi^0_{\text{E}} + a_{\text{W}}\phi^0_{\text{W}} + \left(a^0_{\text{P}} - a_{\text{E}} - a_{\text{W}}\right) x\phi^0_{\text{P}} \tag{19}$$

where $a_E = \Gamma_e/\delta x_e$, $a_W = \Gamma_w/\delta x_w$, $a_P^0 = \rho \Delta x/\Delta t$ and $a_P = a_P^0$. Let Φ represent a solution of the discretized equations (not the original governing differential equation) using infinite computational precision. With practical computing systems, however, there would definitely be some round-off error, given as $\varepsilon = \phi - \Phi$. Using this definition in Eq. (19) and noting that Φ satisfies this equation exactly, one obtains

$$a_P \varepsilon_P = a_E \varepsilon_E^0 + a_W \varepsilon_W^0 + \left(a_P^0 - a_E - a_W\right) \varepsilon_P^0 \qquad (20)$$

In order to assess whether the round-off error gets amplified with time, one may expand the error in an infinite series as

$$\varepsilon(x,t) = \sum_m e^{\sigma_m t} e^{i\lambda_m x}, \quad m = 0, 1, 2, \ldots, M \qquad (21)$$

where σ_m is either real or complex, and $\lambda_m = m\pi/L$, $m = 0, 1, 2, \ldots, M$; L being the width of the problem domain. If σ_m is real and greater than zero, then the error grows with time, wheres if σ_m is real and less than zero then the error is damped out with time. If σ_m is complex, the solution is oscillatory. In particular, the nature of evolution of the error can be estimated from the amplification factor, $a = \varepsilon(x, t + \Delta t)/\varepsilon(x,t)$. If the magnitude of a is greater than unity then the error grows with the time-step, whereas if a is less than unity then the error is damped out with the time-step so that the scheme can be predicted as stable. In order to assess this factor for the special case under consideration, one may exploit the linearity of the equation and just examine the stability consequences of a single error term in Eq. (21), rather than the summation. Substituting a single term from Eq. (21) in Eq. (20), one can obtain an expression for a as

$$a = e^{\sigma_m \Delta t} = 1 - \frac{4\Gamma \Delta t}{\rho (\Delta x)^2} \qquad (22)$$

The above gives rise to the conditional stability criterion of the explicit scheme, as

$$\Delta t \leqslant \frac{\rho (\Delta x)^2}{2\Gamma} \qquad (23)$$

Analogous stability analyses can be executed for the other time-discretization schemes as well. It is important to note here that although the von Neumann stability analysis yields a limiting time-step estimate to keep the round-off errors bounded, it does not preclude the occurrence of an *bounded* but *unphysical* solutions. A classical example is the Crank-Nicholson scheme, which from the von Neumann viewpoint is unconditionally stable, but can give rise to bounded unphysical solutions in case all the coefficients of the discretization equation do not happen to be of the same sign [2].

Closely associated with the concepts of consistency and stability is the idea of convergence. A numerical scheme is said to be convergent if the solution of the discretized equations tends to the exact solution of the governing differential equation as the grid spacing tends to zero. For linear initial value problems, both consistency and stability are the necessary and sufficient conditions of convergence as per the Lax equivalence theorem [6], which states "given a properly posed linear initial value problem and a finite difference approximation to it that satisfies the consistency condition, stability is the necessary and sufficient condition for convergence". For non-linear problems, however, consistency and stability are only the necessary conditions for convergence but not sufficient.

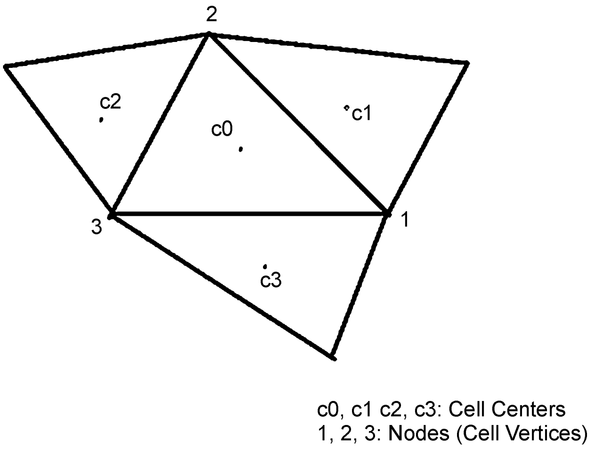
Concepts of Discretization in Unstructured Meshes

The use of unstructured meshes [7] for solving fluid flow and other transport problems has become increasingly popular over the past few decades, because of its elegant capability of discretizing complicated and irregular-shaped geometries. Although the finite volume method was originally developed for structured grids (as outlined in the preceding discussions), it has been subsequently adapated to accommodate the features of unstructured meshes. A conceptual distinguishing feature between the structured and the unstructured meshes is that an unstructured mesh has the provision of having a variable number of neighboring cell vertices (although it might not exploit this feature always), whereas in a structured mesh each cell vertex has a fixed number of neighbouring cell ver-



Finite Volume and Finite Difference Methods for Modeling and Simulation, Figure 4 A triangular shaped control volume (with cell centre at c0) and three of its neighbouring control volumes

tices (except for the boundary cells). Since the fluxes calculated at the cell faces in unstructured meshes need not necessarily be aligned with the direction joining the neigbouring grid points, special considerations are necessary to formulate the discretization equations. In this context, it needs to be recognized that in case of unstructured grids, it is possible to have a hybrid mesh composed of polygons with different shapes. Although the discretization policy, in principle, is similar for all polygonal shapes, precise forms of the discretization equations strongly depend on the specific shape of the control volume under consideration. Here, for the sake of illustration, we only outline the discretization methodology for unstructured triangular meshes. A typical triangular control volume with three neighbouring triangular cells is depicted in Fig. 4. Here, we illustrate a prototype discretization of the steady version of the x-momentum equation. The first step is to integrate the governing differential equation over the triangular control volume, to yield

$$\underbrace{\int_{CV} \nabla\cdot(\rho \boldsymbol{V} u)\,\mathrm{d}\forall}_{\text{term 1}} = \underbrace{-\int_{CV} \frac{\partial p}{\partial x}\,\mathrm{d}\forall}_{\text{term 2}} + \underbrace{\int_{CV} \nabla\cdot(\mu\nabla u)\,\mathrm{d}\forall}_{\text{term 3}} \quad (24)$$

The various terms appearing in Eq. (24) can be simplified by applying the divergence theorem, so as to convert the volume integrals into equivalent surface integrals, to obtain

$$\text{term 1} = \int_{CV} \nabla\cdot(\rho \boldsymbol{V} u)\,\mathrm{d}\forall = \int_{CS} (\rho \boldsymbol{V} u)\cdot \mathrm{d}\boldsymbol{A}$$

$$= \sum_{i=1}^{\substack{\text{number}\\ \text{of edges (3)}}} (\rho u_{\mathrm{f}})_i\,(\boldsymbol{V}\cdot \mathrm{d}\boldsymbol{A})_i\,,$$

or equivalently,

$$\text{term 1} = \sum_{i=1}^{3} (\rho u_{\mathrm{f}})_i\, U_{\mathrm{f},i} = \sum_{i=1}^{3} F_i U_{\mathrm{f},i}\,,$$

say, where

$$\boldsymbol{U} = \boldsymbol{V}\cdot \mathrm{d}\boldsymbol{A} = u\,\mathrm{d}A_{\mathrm{x}} + v\,\mathrm{d}A_{\mathrm{y}}$$

is the contravariant velocity vector, the subscript ‘f’ refers to a cell face and F symbolizes the advection strength.

$$\text{term 2} = \int_{CV} -\frac{\partial p}{\partial x}\,\mathrm{d}\forall = \int_{CS} -\left(p\hat{i}\right)\cdot \mathrm{d}\boldsymbol{A}$$

$$= -\sum_{i=1}^{3} (p\,\mathrm{d}A_{\mathrm{x}})_i\,,$$

or equivalently,

$$\text{term 2} = -\sum_{i=1}^{3} p_i \Delta y_i$$

$$= -\big[(p_{c1} - p_{c0})\,\Delta y_1 + (p_{c2} - p_{c0})\,\Delta y_2 + (p_{c3} - p_{c0})\,\Delta y_3\big]\,.$$

Here, Δy_i represents the difference of the y-coordinates of the two vertices of the edge ‘i’, the vertices being taken in a specific (positive oriented, as a convention) order for the evaluation of this parameter, for all edges.

$$\text{term 3} = \int_{CV} \nabla\cdot(\mu\nabla u)\,\mathrm{d}\forall = \int_{CS} (\mu\nabla u)\cdot \mathrm{d}\boldsymbol{A}$$

$$= \sum_{i=1}^{3} \mu_i \left[\frac{\partial u}{\partial x}\Delta y - \frac{\partial u}{\partial y}\Delta x\right]_i\,.$$

The partial derivatives appearing in this expression can be evaluated by choosing auxiliary control volumes surrounding an edge ‘i’, for the evaluation of integrals associated with that edge. For example, for evaluation of the integrals over the edge $1-2$, one can construct an auxiliary control volume with the bounding edges as $1 - c1 - 2 - c0 - 1$. As an illustration, the term $(\partial u/\partial x)_i$ can be evaluated as follows:

$$\left(\frac{\partial u}{\partial x}\right)_i = \frac{\int_{A_i} \frac{\partial u}{\partial x}\,\mathrm{d}A}{A_i} = \frac{\int_{C} u\,\mathrm{d}y}{A_i}\,,$$

where C is a closed contour that forms the surface of the auxiliary control volume. This contour integral can be numerically approximated by employing the Trapezoidal rule, so that one can write

$$\left(\frac{\partial u}{\partial x}\right)_1 = \frac{\big[(u_{c1} - u_{c0})\,\Delta y_1 + (u_1 - u_2)\,\Delta y_{c1-c0}\big]}{A_1}\,,$$

where $\Delta y_1 = y_2 - y_1$ and $\Delta y_{c1-c0} = y_{c1} - y_{c0}$. Analogous considerations can be made for the other integrals to be

evaluated for term 3, as well. The discretized form of term 3, therefore, becomes

$$\text{term } 3 = \underbrace{\sum_{i=1}^{3} D_i \left(u_{ci} - u_{c0}\right)}_{\text{orthogonal diffusion flux}} + \underbrace{D_{n1}\left(u_1 - u_2\right) + D_{n2}\left(u_2 - u_3\right) + D_{n3}\left(u_3 - u_1\right)}_{\text{non-orthogonal diffusion flux}},$$

where

$$D_i = \frac{\mu_i}{2A_i}\left[(\Delta x)^2 + (\Delta y)^2\right]_i,$$

$$D_{ni} = \frac{\mu_i}{2A_i}\left[(\Delta x)_i (\Delta x)_{ci-c0} + (\Delta y)_i (\Delta y)_{ci-c0}\right].$$

For numerical implementation, the orthogonal diffusion flux may be treated implicitly, whereas the non-orthogonal diffusion flux may be treated explicitly by clubbing the same together with the source term. The discretized forms of the three terms can finally be assembled together to obtain the discretized x-momentum equation for the triangular control volume in the following form:

$$a_P u_{c0} = A_1 u_{c1} + A_2 u_{c2} + A_3 u_{c3} + S \qquad (25)$$

where $A_i = \left[D_i A(|Pe|_i) + \max(\pm F_i, 0)\right]$ (F_i is taken to be positive if the cell is to the left of edge i, otherwise it is taken as negative), $A_P = A_1 + A_2 + A_3$, and $A(|Pe|_i)$ depends on the chosen interpolation scheme for representing the convection–diffusion phenomenon (see Table 2). Similar considerations can be made for discretization of other equations as well.

Future Directions of Research

CFD has now become a somewhat mature field, in which the basics of algorithm development associated with the finite difference and finite volume methodologies have been relatively well established. However, there are certain issues yet to be well resolved, on which future directions of research related to these topics can be based:

- Efficient parallelization of the solution strategies
- Embedding the aspects of multi-scale physics in the discretization techniques
- Establishing hybrid simulation strategies with coupled molecular and continuum based discretizations.

Flexible Shear Stress Sensor

Synonyms

Smart skin

Definition

Fluid shear stress information is of great interest for many fluidic dynamic monitoring/diagnostics applications. For example, oscillatory shear stress plays an important role in the biological activities of vascular endothelial cells, which may lead to atherosclerosis. The emergence of Micro-Electro-Mechanical Systems (MEMS) technology provides us with the miniaturization of shear stress sensors with perfect spatial and temporal resolutions. The conventional MEMS sensors are based on the fabrication with the rigid silicon substrate, which limits the application to

only on the flat surface. In vivo biomedical applications demand the deployment of the sensors on the curved and non-planar surface, which will maximize the measurement precision and minimize the disturbance due to intruding the sensor. Scientists have combined the silicon technology with the polymer process to fabricate the sensor skin, which can conformally coat the non-flat surface and precisely measure the microfluidic parameters, such as shear stress, temperature and pressure.

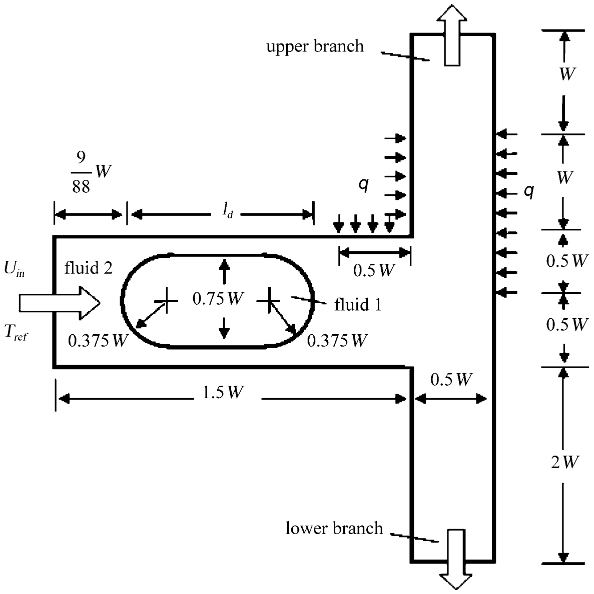
T-junction; Bifurcating microchannel

Definition

Flow bifurcation in microchannels is discussed in this article. In this article, flow bifurcation refers to geometrical bifurcation. Specifically, the transport of droplets in microchannel where a mother branch bifurcates into two daughter branches with thermocapillary effects is examined.

Overview

Microchannel bifurcations have been employed in manipulating droplets. These manipulations include but are not limited to droplet fusion and splitting. Fusing of droplets has been demonstrated using a microchannel with three bifurcating branches [1]. A bifurcating T-junction can be employed to split a droplet into two daughter droplets of smaller size [2]. The relative size of the two daughter droplets is determined by the length of the branches. A longer branch creates larger resistance to flow and therefore creating smaller daughter droplet. In the extreme case where one of the branches is sufficiently long, the droplet does not break but is switched into the other branch. Such a passive geometrical control is limited in terms of its versatility. A more versatile active control utilizing thermocapillary effects [3] is presented in this study. The focus is on unequal splitting and switching the droplet into a desired branch at a T-junction.



Flow Bifurcation in Microchannel, Figure 1 Schematic of a droplet in a micro T-junction

Basic Methodology

Problem Description

Figure 1 shows a fluid 1 droplet of length in a micro T-junction. Fluid 2 at temperature T_{ref} flows into the micro T-junction with a fully developed velocity profile of u_{in} at the inlet. This corresponds to a mean velocity of u_{m}. As fluid 2 flows, it carries the droplet.

An asymmetric temperature field is induced in the T-junction by applying a heat flux q at the selected locations. The remaining walls of the channel are properly insulated. As a result, the temperature dependent surface tension $\sigma(T)$ varies along the droplet interface. σ is assumed to vary linearly with temperature, i. e.

$$\sigma = \sigma_o + \frac{\mathrm{d}\sigma}{\mathrm{d}T}(T - T_{\mathrm{ref}}) \qquad (1)$$

where σ_o is the surface tension at temperature T_{ref}. The variation of σ induces an additional interfacial (thermocapillary) force on the droplet at the interface. This suggests that the net force on the droplet, and thus its motion,

can be controlled by adjusting the heater power.
Driven by the pressure gradient and the thermocapillary force, fluid 2 together with the droplet flows out of the domain via either the upper or the lower branch. It is possible that the droplet splits at the T-junction. The two outlets are maintained at the same pressure with a fully developed temperature profile.

Governing Equations

The level-set method [4] is used to capture the droplet interface. The level-set function ξ is defined as the signed distance function from the interface. Obviously, the value of ξ at the interface is zero. In the present study, the value of ξ for fluid 2 (the carrier fluid) is assigned negative. The distance function ξ for fluid 1 (the droplet) is positive. As a result, ξ can be expressed as

$$\xi(\boldsymbol{x}, t) = \begin{cases} < 0\,, & \text{if } \boldsymbol{x} \in \text{fluid 2} \\ = 0\,, & \text{if } \boldsymbol{x} \in \text{interface} \\ > 0\,, & \text{if } \boldsymbol{x} \in \text{fluid 1} \end{cases} \tag{2}$$

With the knowledge of ξ, any property of the fluid α (e. g. the density, viscosity, thermal conductivity or other properties of interest) in the domain at any given time t can be calculated conveniently as

$$\alpha = (1 - H)\,\alpha_1 + H\alpha_2 \tag{3a}$$

where subscripts 1 and 2 refer to fluid 1 and 2 respectively. The smoothed Heaviside function H is given by [6]

$$H(\xi) = \begin{cases} 0\,, & \xi < -\varepsilon \\ \frac{\xi+\varepsilon}{2\varepsilon} + \frac{1}{2\pi}\sin\left(\frac{\pi\xi}{\varepsilon}\right)\,, & |\xi| \leqslant \varepsilon \\ 1\,, & \xi > \varepsilon \end{cases} \tag{3b}$$

The Heaviside function is smoothed over a finite thickness of 2ε. The parameter ε is related to the grid size and is usually taken as a factor of the grid spacing. In this article, ε is set to one control volume thickness.
The conservation equations, i. e. continuity, incompressible Navier-Stokes, energy equations, can now be written for the whole domain. These are expressed as

$$\nabla \bullet \boldsymbol{u} = 0 \tag{4}$$

$$\frac{\partial(\rho\boldsymbol{u})}{\partial t} + \nabla \bullet (\rho\boldsymbol{u}\boldsymbol{u}) = -\nabla p + \nabla \bullet \left[\mu\left(\nabla\boldsymbol{u} + \nabla\boldsymbol{u}^T\right)\right] + \boldsymbol{f}_F \tag{5}$$

$$\frac{\partial(\rho cT)}{\partial t} + \nabla \bullet (\rho c\boldsymbol{u}T) = \nabla \bullet (k\nabla T) \tag{6}$$

where $\boldsymbol{u}$, p, ρ, μ, T, c and k are the velocity vector, pressure, density, viscosity, temperature, specific heat and thermal conductivity respectively. Viscous dissipation is neglected in the energy equation.
In the Eq. (5), the surface tension force $\boldsymbol{f}_F$ is modeled using the Continuum Surface Force model [7]. It is reformulated as an equivalent body force acting within a band of 2ε at the interface using a smeared-out Dirac delta function $D(\xi)$. The surface tension force can be expressed as

$$\boldsymbol{f}_F = -\kappa\sigma\boldsymbol{N}_F D(\xi) + (\boldsymbol{N}_F \times \nabla\sigma) \times \boldsymbol{N}_F D(\xi) \tag{7a}$$

where $D(\xi)$, $\boldsymbol{N}_F$ and κ are defined respectively as

$$D(\xi) \equiv \begin{cases} \frac{1+\cos(\pi\xi/\varepsilon)}{2\varepsilon} & |\xi| < \varepsilon \\ 0 & \text{otherwise} \end{cases} \tag{7b}$$

$$\boldsymbol{N}_F \equiv \frac{\nabla\xi}{|\nabla\xi|} \tag{7c}$$

$$\kappa \equiv \nabla \bullet \boldsymbol{N}_F \tag{7d}$$

The first and the second terms on the right side of Eq. (7a) represent the capillary and the Marangoni effects respectively. The capillary force is induced by the curvature of the interface and acts perpendicular to the interface. However, the Marangoni force is generated by a variation of surface tension along the interface and acts tangentially along the interface. For the present situation, since the variation of surface tension is caused by temperature gradient, the Marangoni force is referred to as thermocapillary force.
The interface is convected by the velocity field. The evolution of the interface is governed by

$$\frac{\partial\xi}{\partial t} + \boldsymbol{u} \bullet \nabla\xi = 0 \tag{8}$$

To ensure that ξ remains a distance function, i. e. satisfying $|\nabla\xi| = 1$, redistancing is performed. This is achieved by solving for the "steady-state" solution of a second distance function ψ given by

$$\frac{\partial\psi}{\partial\bar{t}} = \text{sign}(\xi)\,(1 - |\nabla\psi|) \tag{9}$$

where $\bar{t}$ is a pseudo time for the variable ψ. The "initial" condition for Eq. (13) is $\psi(\boldsymbol{x}, 0) = \xi(\boldsymbol{x})$. Even with proper redistancing, mass might not be conserved. To overcome this, a global mass correction [5] is employed. The "steady-state" solution to a third distance function ψ' that

F

ensures proper mass conservation is solved. This is written as

$$\frac{\partial \psi'}{\partial t'} = \text{sign}\,(\xi_{\text{ref}})\,\frac{M_{\text{d}} - M_{\text{c}}}{M_{\text{d}}} \tag{10a}$$

where M_{d} and M_{c} are the desired mass and the most current mass of the reference phase respectively. The mass of the reference phase can be calculated as

$$M = \begin{cases} \sum \rho_{\text{ref}} H \Delta V & H_{\text{ref}} = 1 \\ \sum \rho_{\text{ref}}\,(1 - H)\,\Delta V & H_{\text{ref}} = 0 \end{cases} \tag{10b}$$

The summation is performed over the whole solution domain. The desired mass of the reference phase is calculated as the initial mass of the reference phase. In Eq. (10a), t' is a pseudo time. The term sign (ξ_{ref}) refers to the sign of ξ for the reference phase. The droplet is chosen as the reference phase in this article. The "steady-state" values of ψ gre used as the "initial" condition for Eq. (10a).

Boundary Conditions

In this article, the normal and tangential velocities at the inlet are specified as u_{in} and zero respectively. No slip condition is used at all walls. The two outlets are set to the same pressure. For the energy equation, the temperature at the inlet is specified and zero-gradient is applied at both outlets. All walls are insulated except the locations where the heat fluxes are applied. For the level-set functions, $|\nabla \xi| = 1$ is imposed at all boundaries.

Solution Procedure

The solution procedure can be summarized as:

1. Specify the locations of the interface at time $t = 0$ and construct ξ for all nodes.
2. Set $t = t + \Delta t$.
3. Specify the properties for all nodes using Eqs. (3).
4. Solve the continuity and momentum equations (Eqs. (4) and (5)) for $\boldsymbol{u}$ and p at $t + \Delta t$.
5. Solve the energy equation (Eq. (6)) for T at $t + \Delta t$.
6. Solve for ξ (Eq. (8)), perform redistancing (Eq. (9)) and mass correction (Eq. (10)).
7. Repeat Steps 3 to 6 until the solution converges.
8. Repeat Steps 2 through 7 for all time steps.

Numerical Method

The continuity (Eq. (4)), Navier–Stokes (Eq. (5)), energy (Eq. (6)), level-set (Eqs. (8), (9) and (10a)) equations are special cases of a general transport equation

$$\rho \frac{\partial \phi}{\partial t} + \rho u_j \frac{\partial \phi}{\partial x_j} = \frac{\partial}{\partial x_j}\left(\Gamma \frac{\partial \phi}{\partial x_j}\right) + S \tag{11}$$

where ϕ, ρ, Γ, and S are the dependent variable, density, diffusion coefficient and source term respectively. The finite-volume method of Patankar [8] is used to solve the transport equation given in Eq. (11). A staggered grid with the scalar variables stored at the centers of the control volumes (CVs) and the velocities located at the CVs is employed. In this article, the power-law of Patankar [8] is used to model the combined convection-diffusion effect in the momentum equations. The CLAM scheme [9] is used to model the convection of the level-set equations. The SIMPLER algorithm is used to resolve the velocity-pressure coupling. The fully implicit scheme is used to discretize the transient term. The resulting algebraic equations are solved using the TriDiagonal Matrix Algorithm.

Key Research Findings

The present problem is governed by a total of 8 dimensionless numbers: droplet length to channel width ratio (l_{d}/W), density ratio (ρ_1/ρ_2), viscosity ratio (μ_1/μ_2), thermal diffusivity ratio (α_1/α_2), Prandtl number (Pr), Reynolds number (Re), Capillary number (Ca) and Marangoni number (Ma). Pr, Re, Ca and Ma are defined respectively as

$$\text{Pr} = \frac{\mu_2}{\rho_2 \alpha_2} \tag{12}$$

$$\text{Re} = \frac{\rho_2 u_m W}{\mu_2} \tag{13}$$

$$\text{Ca} = \frac{u_m \mu_2}{\sigma_o} \tag{14}$$

$$\text{Ma} = \frac{|d\sigma/dT|\,\Delta T}{\mu_2 u_m} \tag{15a}$$

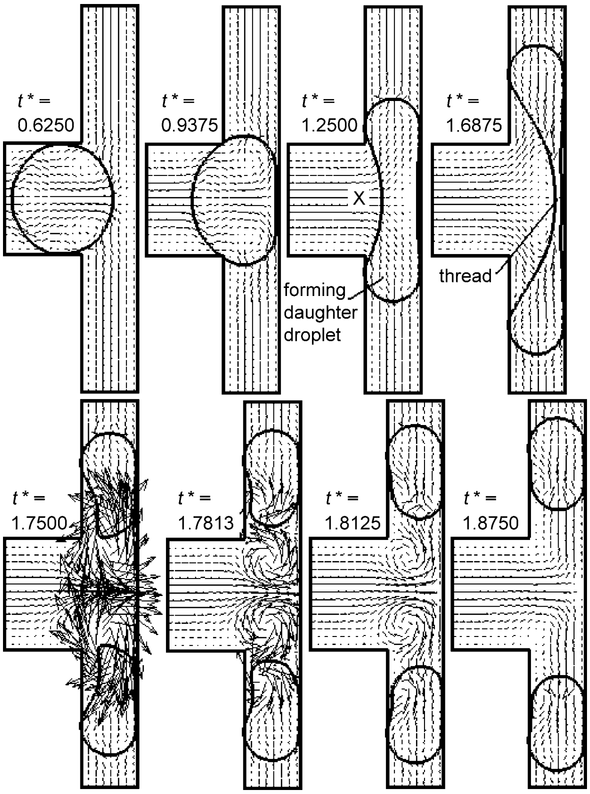
The Marangoni number represents the ratio of the thermocapillary force to the viscous force. The driving temperature difference ΔT is created by the applied heat flux q. For the purpose of non-dimensionalization, the applied heat flux q is assumed to increase the fluid 2 temperature flowing out at the upper outlet by ΔT. With this, ΔT can be expressed in terms of q as

$$\Delta T = \frac{6q}{\rho_2 u_m c_{p2}} \tag{15b}$$

The dimensionless time t^* and temperature T^* are given by

$$t^* = \frac{t u_m}{W} \tag{16}$$

$$T^* = \frac{T - T_{\text{ref}}}{\Delta T} \tag{17}$$



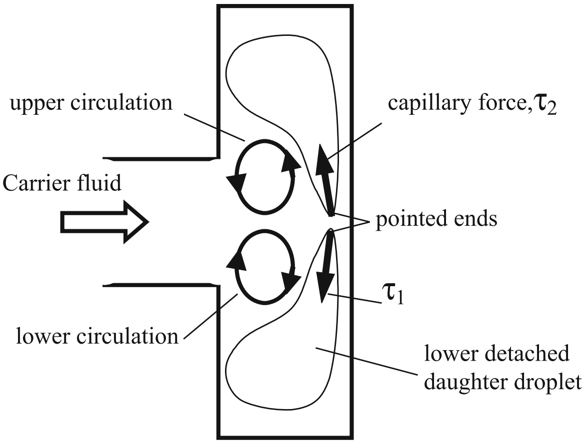
Flow Bifurcation in Microchannel, Figure 2 Evolution of a droplet in a T-junction for Ma = 0

Computations were made for a micro T-junction of $W = 400\,\mu$m. The dimensionless numbers are set to $l_d/W = 1.1$, $\rho_1/\rho_2 = 1.0961$, $\mu_1/\mu_2 = 0.0192$, $\alpha_1/\alpha_2 = 1.1078$, $Pr = 441.9882$, $Re = 0.0175$ and $Ca = 0.00625$. Of the 8 dimensionless numbers, only variation of Ma is considered as the effect of the thermocapillary force on the droplet motion is of interest. Results for the case of Ma = 0, 40 and 80 are presented. Validations of the solution procedure were presented in [5] and will not be repeated here.

The Case of Ma = 0

Figure 2 shows the evolution of a droplet in the T-junction for the case where the heater is switched off, i. e. Ma = 0. Only the portion of the T-junction containing the droplet is depicted. To avoid over-crowding the figure, only one in every two velocity vectors is shown. Although not shown, a mesh of 63 × 150 CVs with a time step of $\Delta t^* = 1.5625 \times 10^{-4}$ is sufficient to achieve grid independent solution. Therefore, all subsequent computations were made with this mesh and time step size.

The droplet is much larger than either of the branches. When it arrives at the T-junction ($t^* = 0.9375$), it blocks



Flow Bifurcation in Microchannel, Figure 3 Formation of vortices as the two daughter droplets detach

the T-junction and consequently creates an upstream pressure build-up. The pressure build-up squeezes the droplet into the shape of a dumbbell. The two forming daughter droplets at the two ends of the mother droplet are joined by a fluid 1 thread ($t^* = 1.2500$). These two forming daughter droplets further block the flow of carrier fluid into the branches. With the increase in the pressure build-up, the forming daughter droplets are pushed further into the branches and results in a thinning of the thread ($t^* = 1.6875$). The fluid 1 thread breaks eventually. The two forming daughter droplets detach from each other and become two smaller daughter droplets.

The velocity field just after the breaking off of the fluid 1 thread is highly complicated with vortices forming adjacent of the daughter droplets. For the ease of explanation, a schematic of the two daughter droplets just after the thread breaks is shown in Fig. 3.

Upon detachment, a pointed tail forms at the rear of each daughter droplet from the broken fluid 1 thread. Such a sudden creation of pointed interfaces with large curvature generates strong capillary forces instantly. The sudden availability of these strong capillary forces has a profound effect on the flow field. Given the symmetric of the flow field, the effect of the capillary forces on the lower forming daughter droplet only is discussed. τ_1 is the capillary force acting on lower daughter droplet at the pointed tail. It acts to pull the pointed tail towards the center of lower daughter droplet, effectively shortening the tail in the process. τ_1 is so large that the tail is able to drag along the particles of the carrier fluid adjacent to it and simultaneously increases the carrier fluid velocity dramatically. This can be seen from the suddenly increase in the carrier fluid velocity around the detached daughter droplets. However, the lower daughter droplet is still blocking branch B. This

drives the fluid particles of the carrier fluid to circulate at the T-junction, generating the lower circulation. As the tail of the droplet is shortened, it becomes more rounded off, thus possesses a smaller curvature. The decrease in curvature is accompanied by decreasing capillary force. It follows that the circulation dies down as the capillary force at the tail is no longer strong enough to sustain it. Similar phenomenon occurs to the upper daughter droplet resulting in the formation and decay of the upper circulation.

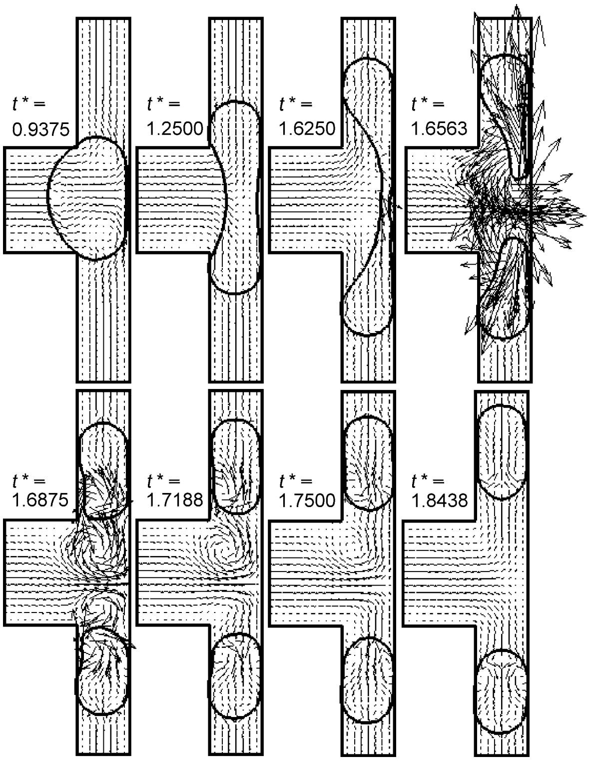
The daughter droplets become more and more circular as they travel downstream under the influence of surface tension ($t^* = 1.8750$). The two daughter droplets are of equal size. This is expected given the symmetry of the flow field. Each of these daughter droplets leaves the T-junction via one of the branches.

From the above observation, a mother droplet of size smaller than the branch does not break for it fails to create the required pressure build-up for splitting. It can only flow into one of the channel at the T-junction depends on the flow conditions in these branches.

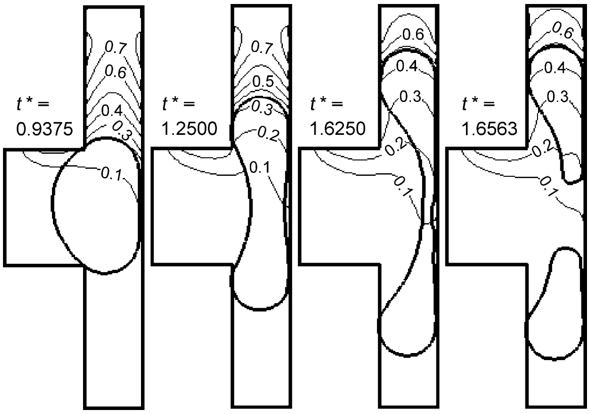
The Case of Ma = 40

The heater is now switched on. A non-zero heat flux q, corresponding to $\mathrm{Ma} = 40$, is generated. The induced asymmetric dimensionless temperature field is shown in Fig. 4. A strong temperature gradient is induced in the upper branch. This gives a larger variation of surface tension and results in a larger thermocapillary force. However, given the location of the applied heat flux, the temperature gradient along branch B is minimal. As a result, the variation of surface tension and the thermocapillary force are both smaller. The evolution of the droplet is shown in Fig. 5.

The droplet is asymmetrically split with a larger daughter droplet formed in the upper branch. The detachment of the daughter droplets occurs earlier ($t^* = 1.6563$) than that in the case of $\mathrm{Ma} = 0$ ($t^* = 1.7500$). To explain these, Fig. 6, illustrating the flow induced by the thermocapillary forces, is constructed.

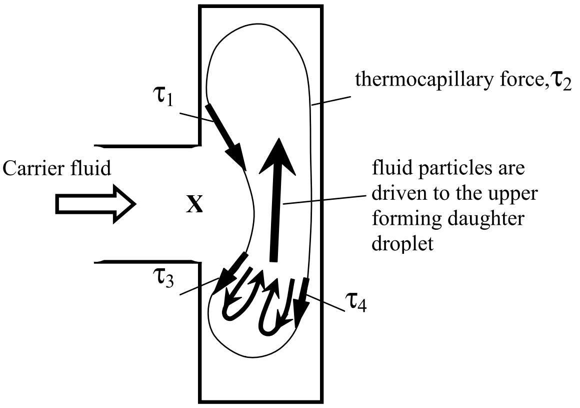


Flow Bifurcation in Microchannel, Figure 5 Unequal splitting of a droplet in a T-junction for Ma = 40

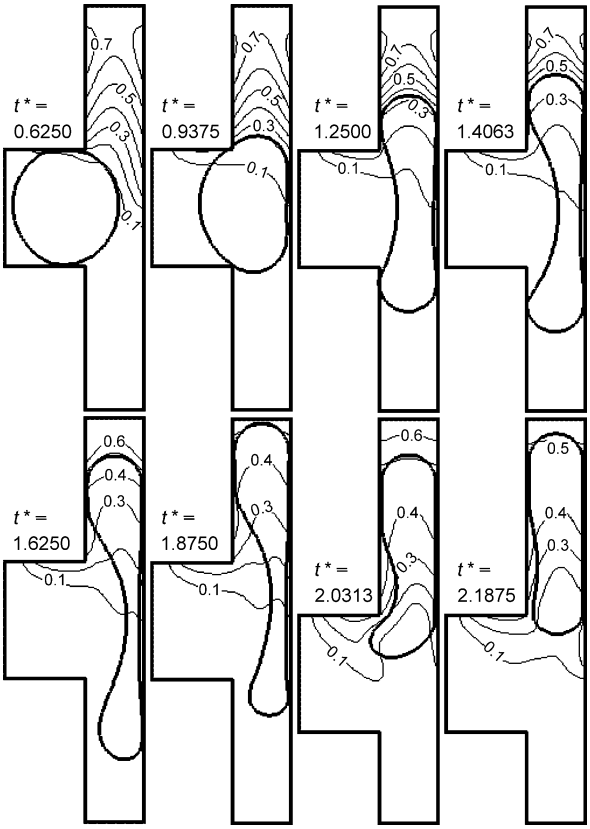


Flow Bifurcation in Microchannel, Figure 4 Dimensionless temperature field in a T-junction for Ma = 40

Figure 6 shows the thermocapillary forces, τ_1, τ_2, τ_3 and τ_4, acting at different locations of the droplet interface. These forces, downwardly directed, induce a secondary flow within the droplet of the following nature. The thermocapillary forces drive the fluid 1 particles adjacent to the interface downwards into the lower forming daughter droplet. This has the effect of depleting the fluid 1 thread and accelerates its thinning. The accumulation of the fluid 1 particles in the lower forming daughter droplet tends to inflate it. It should be noted that the magnitude of the surface tension in lower branch is larger than that of the upper branch given the lower temperature in the lower branch. Creating larger interfacial area at the tip of the lower forming daughter droplet to accommodate additional fluid 1 is not favorable as more energy is required. The fluid 1 particles then turn and flow upwards into the upper forming daughter droplet via the center of the fluid 1 thread. When these particles reach the tip of the upper forming daughter droplet, larger interface can be favorably created as the surface tension is smaller and thus less



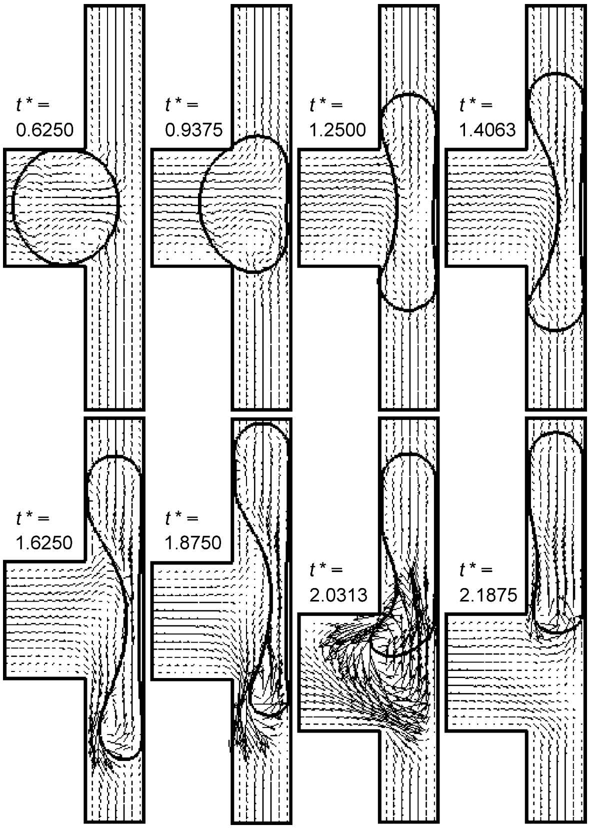
Flow Bifurcation in Microchannel, Figure 6 Thermocapillary forces acting on a droplet at a T-junction



Flow Bifurcation in Microchannel, Figure 7 Dimensionless temperature field in a T-junction for Ma = 80

energy is required. As a result, more fluid 1 particles accumulate in the upper forming droplet. Upon the detachment of the two daughter droplets, the upper daughter droplet is naturally larger.

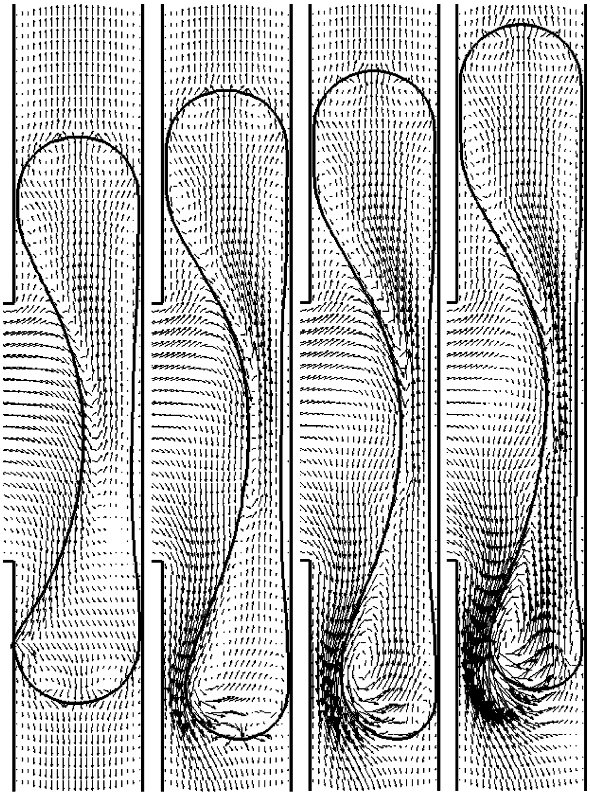
The mechanism in generating the circulations is similar to the case of Ma = 0. However, since now the interfacial forces (the resultant of capillary and thermocapillary forces) at the pointed tails of the detached daughter droplets are no longer of the same magnitude, the strength of the induced circulations is different. Although the capillary force at the tip of the upper detached droplet is smaller, it is compensated by a much stronger thermocapillary force. With this, the upper circulation is stronger and dies down slower.



Flow Bifurcation in Microchannel, Figure 8 Switching of a droplet in a T-junction for Ma = 80

The Case of Ma = 80

The heat flux is further increased to achieve Ma = 80. Figure. 7 shows the induced dimensionless temperature field. The dimensionless temperature field exhibits a similar trend to that of the case Ma = 40. It should be noted that the actual temperature and its gradient are twice of the case with Ma = 40 as a larger q is used in obtaining the dimensionless temperature. The thermocapillary effect should therefore be twice as strong. The thermocapillary force is so strong that the droplet becomes asymmetric as early as $t^* = 0.9375$. The corresponding velocity field during the evolution of the droplet is given in Fig. 8. In this



Flow Bifurcation in Microchannel, Figure 9 Circulations in the lower forming daughter droplet

case, the droplet no longer splits but switches entirely into the upper branch.

To obtain a clearer picture of the switching mechanism, a more detailed flow field is required. Figure 9 shows the evolution of the droplet from $t^* = 1.4063$ to $t^* = 1.7813$ with all the velocity vectors plotted. For the present case, the secondary flow induced by the thermocapillary forces is much stronger. The induced secondary flow of a circulatory nature (as in the case of Ma = 40) within the upper forming daughter droplet is obvious ($t^* = 1.4063$). It increases significantly the flow of fluid 1 particles into the upper forming daughter droplet. The asymmetrical shape of the droplet is obvious with a larger upper forming daughter droplet. Since temperature gradient induced in the lower branch is minimal, no obvious circulatory motion is observed.

Although the lower forming droplet is smaller, it is still sufficient to block the lower branch at $t^* = 1.4063$. Pressure does build up. The pressure build-up pushes the two forming daughter droplets into the respective branch. This is accompanied by a thinning of the fluid 1 thread. However, given the different size in the forming daughter droplet, the ability to withstand the pressure build-up is different. The smaller lower forming droplet fails to withstand further pressure build-up eventually and the pressure forces the creation of a small gap between the lower forming droplet and the wall ($t^* = 1.5625$). The sudden release of pressure accelerates the carrier fluid into the lower branch via the gap ($t^* = 1.5625$). This generates a large shear stress, downwardly directed, on the interface of the lower forming daughter droplet, creating two circulations within it. The stronger circulation accelerates the fluid particles in the lower forming daughter droplet upwards into the upper forming daughter droplet. The lower forming daughter droplet becomes smaller ($t^* = 1.7813$). The fluid 1 thread does not break for (1) there is no further pressure build up thinning it and (2) the flow of the fluid 1 particles from the lower daughter droplet to the upper daughter droplet replenishes it. As a result, the lower forming daughter droplet does not detach but merges with the upper forming daughter droplet instead. In the process, the whole mother droplet is switched into the branch A.

The two cases of non-zero Ma suggest that a temperature gradient can be used to (1) split a droplet or droplet into two daughter droplets of controllable sizes and (2) switch a droplet into a desired branch in a bifurcating microchannel.

Future Directions for Research

Controllable splitting and switching of a droplet into a desired branch at a bifurcating T-junction with thermocapillary effects has been demonstrated numerical. The relative size of the two daughter droplets, strongly dictated by the Marangoni number, is a parameter of interest and requires further investigation. Occasionally, the droplet carries non-fluid particles, e. g. cells or bioparticles, in the form of encapsulation. These particles may break out from the encapsulation during splitting or switching. Therefore, effect of having these encapsulated particles needs to be examined.

Flow Boiling Instability

DAVID BRUTIN
Poytech Marseille, IUSTI Laboratory, Marseille, France
david.brutin@polytech.univ-mrs.fr

Synonym

Two-phase flow instability; Liquid–vapor instability

Definition

When two-phase flow phase change occurs in a channel with a small hydraulic diameter compared with the capillary length, *flow boiling instabilities* may arise. As in classical-sized channels, the instabilities can be static or dynamic; however their intensity is higher in microchannels due to the higher rate of volumic generation of vapor which induces considerable pressure drops.

Overview

Between 1985 and 2006, 1247 papers were published on Sciencedirect® on the subject of boiling, of which only 49, i. e., about 4%, deal with mini or microchannels. Four of these 49 papers report flow instabilities. Even if flow boiling is a well-developed research subject, flow boiling in microchannels, not to mention instabilities which occur in these microchannels, have not been discussed or reported to any considerable extent in the literature. In Table 1 a few studies dealing with *flow boiling instabilities* in microchannels are listed. We will discuss some of these studies below.

Wu and Cheng [1] conducted experiments using 8 parallel silicon microchannels heated from the bottom. They observed water flows with large-amplitude or long-period oscillating boiling modes as a function of heat flux and mass flux depending on whether the water outlet is at saturation temperature or superheated.

Qu et al. [2] found evidence of two kinds of unsteady flow boiling for 21 parallel microchannels measuring 231 × 713 µm. They observed in their parallel microchannel array either a global fluctuation of the whole two-phase zone for all the microchannels (Fig. 1) or chaotic fluctuations of the two-phase zone (Fig. 2): over-pressure in one microchannel and under-pressure in another. The individual microchannel mass flow rate was not controlled.

Hetsroni et al. [3] created an experimental setup to study liquid–gas and liquid–vapor flow in parallel triangular microchannels with diameters of 103 to 161 µm. They used a fast video camera coupled with a microscope through a Pyrex plate to record the flow patterns. They showed the influence of the injection method (plenum shape) and found evidence for the same inlet conditions,

Rect.: rectangular / Tri.: triangular

i. e., mass flow rate and heat flux, different flow patterns (annular flow, bubbly flow, etc.). The random nature of this flow in the parallel microchannels results from the inlet mass flow rate, which is not constant but depends on the pressure drop in each microchannel.

Peles [4] made a micro heat exchanger using photolithography processes on a silicon substrate. The micro heat exchanger was based on multiple parallel triangular microchannels. The results obtained using pressure measurements and fast video recording of flow boiling evidence various flow regimes such as *rapid bubble growth*, *complete bubble flow*, *bubbly flow* and *annular flow*. The first two regimes described by the author are presented as specific at the microscale. Flow instabilities are observed such as temperature and pressure fluctuations at a frequency which decreases with increasing mass flow rates (high peristaltic pump frequency).

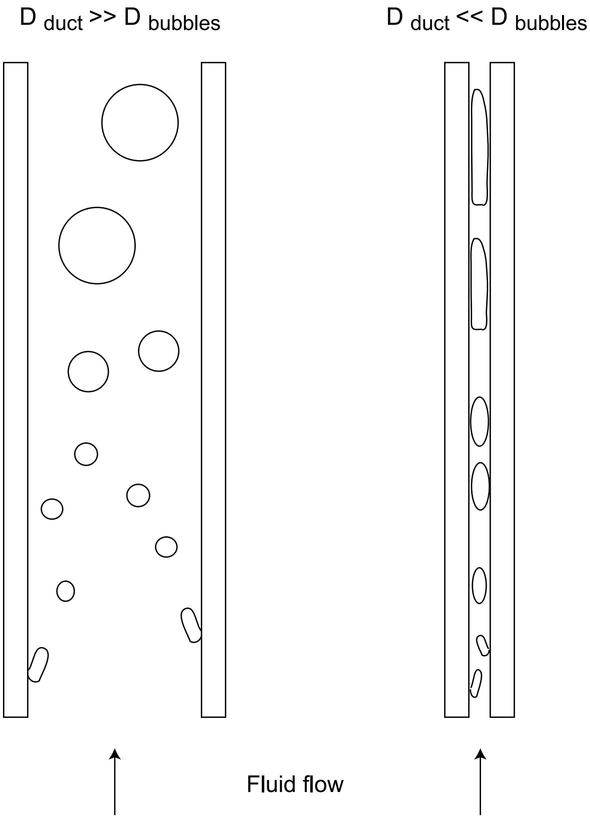
As for flow boiling instabilities in classical channels, several types of instabilities have been observed and reported by different authors. Table 2 summarizes these instabilities and their physical consequences on the fluid flow. We also show in the following table which publications reported these instabilities in microchannels. This classification is based on the one proposed for channels by Bergles in 1976 [5] and is divided into two categories:

- static instabilities induce a shift of the equilibrium point to a new steady-state point: Ledinegg instability, boiling crisis, bumping, geysering or chugging are all static instabilities since they can be analyzed using only stationary models;
- dynamic instabilities are driven by the inertia of the system; the stationary state is not sufficient to predict the destabilization threshold of theses instabilities such as acoustic waves, pressure drop oscillations or thermal oscillations.

Basic Methodology

Influence of Confinement on Flow Boiling

The confinement effect on boiling appears through the influence of the wall on the flow. In a large tube, boiling is not influenced by the wall of the duct and the flow is free to structure itself and evolve inside. In our minichannel, dimensions are such that the bubble growth from a nucleation site is modified by the proximity of the wall (Fig. 3). One criterion is to verify whether the theoretical diameter of the bubbles is larger than the diameter of the duct. We estimate the bubble detachment diameter using the correlation of Fritz [6] which takes into account nucleation surface orientation for *n*-pentane. Equation (1) is used where θ is the wetting angle expressed in degrees. This relation is based on the balance between surface tension and buoy-



Flow Boiling Instability, Figure 3 Wall influence on flow boiling behavior

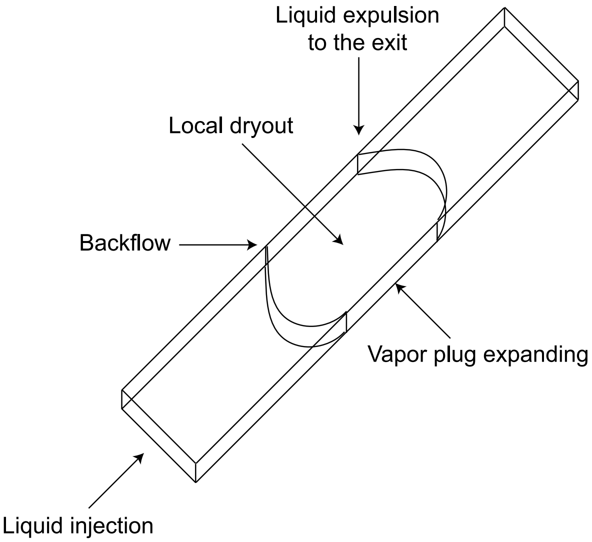
Flow Boiling Instability, Table 2 Classification of flow instabilities (based on [5])

Class	Type	Characteristics	Observed by
Static	Ledinegg instability	Flow undergoes sudden, large amplitude excursion to a new stable operating condition	[3, 7]
Static	Boiling crisis	Wall temperature excursion and flow oscillation	[3, 7]
Static	Flow pattern transition instability	Cyclic flow pattern transition and flow rate variations	[8]
Static	Bumping, geysering or chugging	Period process of super-heat and violent evaporation with possible expulsion and refilling	[7]
Dynamic	Acoustic oscillations	High frequencies related to time required for pressure wave propagation in system	-
Dynamic	Density wave oscillation	Low frequencies related to transmit time of a continuity wave	-
Dynamic	Thermal oscillations	Occur in film boiling	-
Dynamic	Coupling instabilities	Strong only for a small fuel time constant and under low pressures	[3, 7]
Dynamic	Pressure drop oscillations	Very low frequency periodic process	[2, 7]

ancy forces. We obtain a bubble detachment diameter of 600 μm, which means that inside our minichannel with a thickness of 500 μm the proximity of the wall influences the evolution of the bubble. Thus it is reasonable to think that wall confinement influences the vapor bubble behavior and coalescence in the minichannel.

$$D_{\text{bubbles}} = 0.0208\,\theta \sqrt{\frac{\sigma}{g(\varrho_L - \varrho_G)}} \qquad (1)$$

We can consider that one degree of freedom has been removed. The consequence is that bubbles grow along the other two axes (width and length). Whereas bubbles are supposed to be spherical without the influence of any wall, here they are compressed. This modification of shape induces an increase in wall friction. Confinement increases bubble coalescence by reducing the volume of the channel for a given heating surface; the volumic density of the bubbles grows quickly and thus bubbles group together to form slugs. Due to the proximity of the wall, wall friction for the evolution of bubbles and slugs is increased. When vapor slugs flow through the minichannel, this induces overheating of the wall due the reduction of heat transfer associated with the vapor phase (Fig. 4 and 5). These periodical slugs become more and more numerous as the heat flux increases or the liquid mass flow rate decreases.



Flow Boiling Instability, Figure 4 Local dryout due to a vapor slug

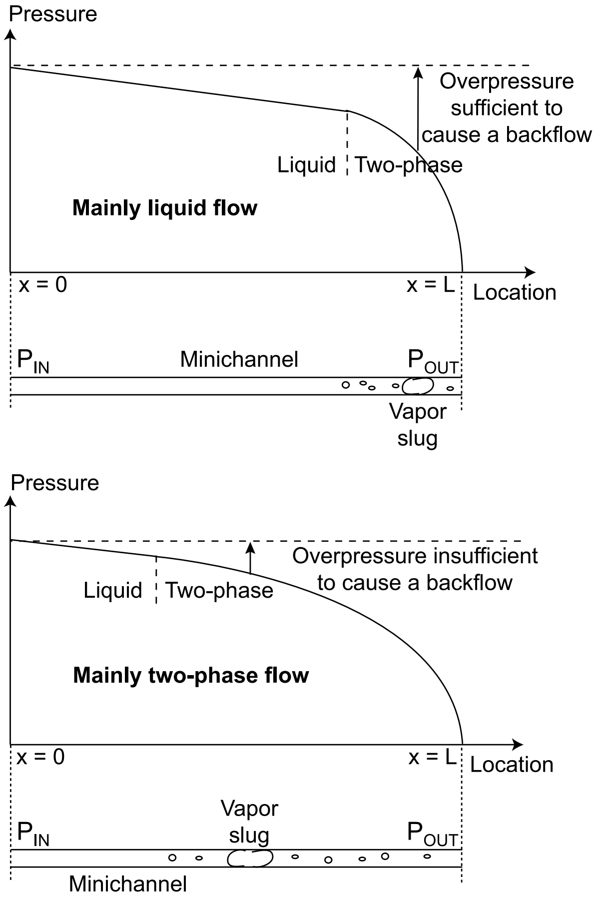
Analysis of Instabilities

Pressure Drop and Visualization of Flow Patterns

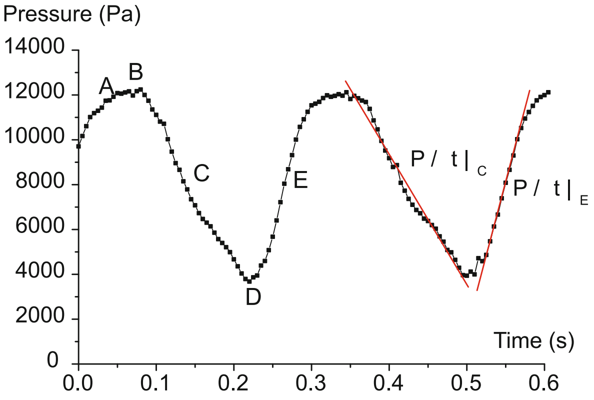
To analyze flow boiling instabilities in a minichannel or a microchannel, pressure measurements recorded at a high frequency (e. g., 200 Hz) are usually performed. The analysis of the microchannel pressure drop is then related to flow patterns to understand destabilization mechanisms.

Brutin et al. [7] recorded the pressure signal of the unsteady flow simultaneously with video recording to compare both frequencies: pressure drop and flow pattern oscillation frequencies. In Fig. 6, they analyze the two-phase flow behavior which is partially presented with pictures in Fig. 7. The different steps observed during one period are the following:

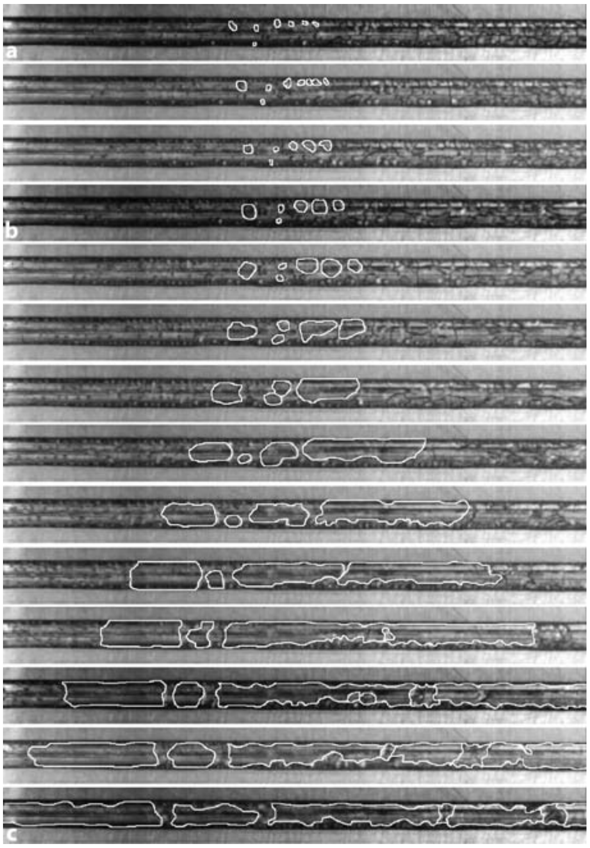
- Liquid flows in the channel (point A). Bubbles are created at the beginning of the two-phase flow zone. Their size and generation rates are such that bubbles coalesce into vapor slugs which evolve in the channel. Vapor slugs generate over-pressure which reduces the upstream boiling flow rate.



Flow Boiling Instability, Figure 5 Local pressure in a minichannel for two situations: a mainly liquid flow and a mainly two-phase flow



Flow Boiling Instability, Figure 6 Typical outlet pressure signal during unsteady boiling shown over 2 periods. ($D_H = 888.9\,\mu$m, $L = 200$ mm, $Re_L = 955$, $Q_W = 9.6\,W\,cm^{-2}$)



Flow Boiling Instability, Figure 7 Vapor slug formation during flow boiling: example of backflow (5 ms between 2 pictures) (some bubble outlines were evidenced in order to follow their evolution)

- Bubbles growing before the vapor slug slow down, stop (point B) and then quickly reach the entire channel cross-section. Vapor created by bubble expansion must be evacuated, but downstream in the channel vapor slugs block the flow.
- Expanding vapor pushes the inflow back to the entrance using the buffer tank as a mass flow storage (point C).
- Eventually the channel is full of vapor (point D). The surface temperature rises due to the fact that the heat flux is permanently supplied to the fluid and not removed by boiling.
- When the channel is empty and upstream pressure before the channel entrance is sufficient, the entire vapor slug which occupies the channel is expelled. The channel is refilled with liquid (point E).
- Due to the high surface temperature, bubbles are formed rapidly (point A) and the phenomenon is repeated.

If we look at the evolution of pressure in Fig. 6, we observe three distinct parts in one period (about 275 ms). The first consists of the decrease in pressure for approximately 150 ms from B to D. The average pressure decrease in C is 62 kPa/s, whereas in the second part the refilling of the liquid, with a duration of about 65 ms, corresponds to

the D to A part on the curve. The average pressure increase in E is about 136 kPa/s. The third part between A and B flowing in the channel and slowing down accounts for only 60 ms of one period.

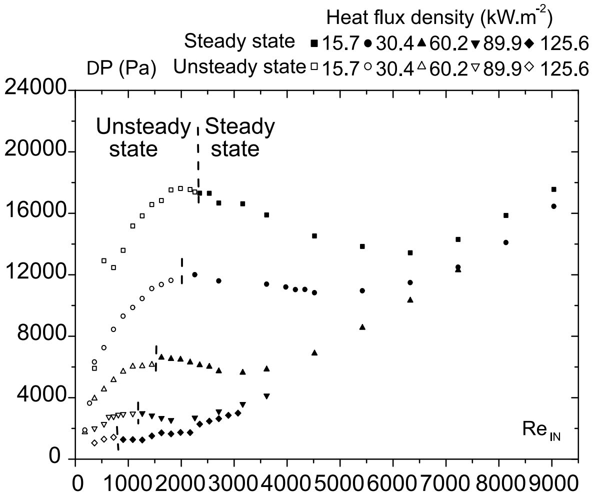
Qu et al. [2] observed in their experiment that hydrodynamic instabilities influence inlet and outlet pressures and can induce a degree an uncertainty in the measurement of pressure drop. They recorded temporal pressure signals and made the following observations: even with a small heat flux supplied to the parallel channels, the case of pressure drop oscillations presents pressure fluctuations with quite constant frequency, whereas in the case of instability in the parallel channels the fluctuations are small and random.

Hetsroni et al. [3] also found evidence of a coupling phenomenon for an array of 17 parallel microchannels. In Fig. 7 from [3], they found evidence of two-phase flow oscillations. Only one channel is followed as a function of time. The water-steam flow is from the left to the right. Steam appears in the 5th picture. The liquid–vapor interface then moves to the exit or to the entrance. This interface movement is representative of a non-constant mass flow provided to the microchannel. The inlet condition before the plenum is a constant inlet pressure; however, due to the plenum, the flow can come back and induce such coupling. The frequency of the interface oscillation can usually be related to the total pressure drop oscillation frequency.

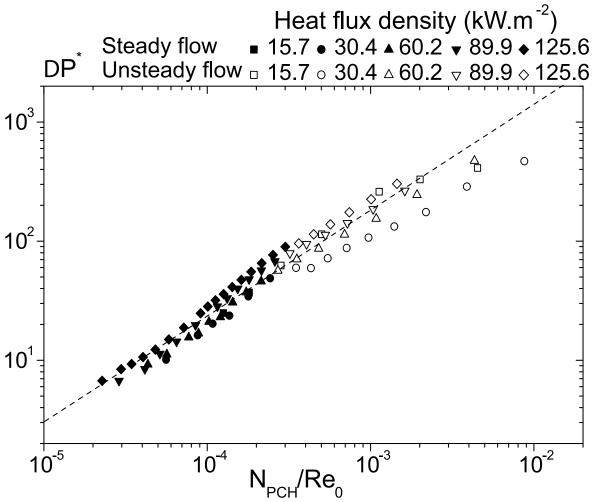
Scaling Laws Analysis

Scaling laws help to understand the flow patterns and heat transfer phenomenon without any constraint of geometry, fluid type or operation conditions. The terms used to determine these scaling laws are dimensionless and usually balance the physical processes involved. In the present case of flow boiling, the pressure drop is considered without dimension usually using the dynamic pressure.

Figure 8 from [8] presents the total minichannel pressure loss as a function of the inlet Reynolds number. The total pressure loss includes liquid, two-phase and vapor depending on the boiling stage in the minichannel. The curve behavior is a classical N-shape observed for all the heat fluxes studied. The total minichannel pressure loss is the sum of fluid pressure loss for each zone and arises when the friction term in the two-phase zone reaches a maximum then decreases when the flow is mainly vapor. With increasing heat fluxes, the pressure loss shifts to higher values and the N-shape is more and more pronounced. Using the experimental results of the visualization, it is possible to propose a global behavior of the fluid flow in the channel with the non-dimensioned pressure loss vari-



Flow Boiling Instability, Figure 8 Average pressure loss versus inlet Reynolds number when the buffer is not connected to the loop for 5 heat fluxes



Flow Boiling Instability, Figure 9 Pressure loss scaling law for all heat flux densities provided: non-dimensioned pressure loss function of the ratio between the phase change number and the Reynolds number for only exit vapor qualities strictly between 0 and 1

ation. If we remove all points which present liquid flow operating conditions and those for mainly vapor flow, we obtain in Fig. 9 [9] only the operating conditions which satisfy the exit vapor quality strictly between 0 and 1.

The case studied is characterized by a constant mass flow rate supplied to the channel entrance. All the results concerning pressure loss are on one line, which means the same variation law. Equation (2) gives the pressure loss scaling law numerically. It is also possible from Fig. 9 to extract the criterion for the transition from steady to

unsteady. This law provides an equivalent friction factor for the two-phase flow.

$$\Delta P^*_{\text{comp}} = 4.46 \times 10^4 \left(\frac{N_{\text{pch}}}{\text{Re}_0}\right)^{0.818} \tag{2}$$

Figure 9 evidences a possible generalization of the steady and unsteady results. The stability transition appears for a given abscissa and thus a given ordinate. These coordinates are summarized by the ratio K_2/K_1 previously detailed with Eq. (21). The experimental value of K_2/K_1 is $4.94 \times 10^{-6} \pm 30\%$ with a comparison with the theoretical value which is $3.92 \times 10^{-6} \pm 7.5\%$. We obtain a good agreement between experimental and theoretical thresholds. The gap of 26% for the confinement case should be compared with the total uncertainty of 37.5%. The uncertainty of the experimental and theoretical destabilization thresholds (Eqs. (3), (4)) is 4 times the liquid inlet velocity uncertainty, 4 times the hydraulic diameter uncertainty plus the total pressure drop and the heat flux uncertainties.

$$\Delta P^* = \frac{\Delta P}{\frac{1}{2}\varrho_0 U_0^2} \tag{3}$$

$$\frac{N_{\text{pch}}}{\text{Re}_0} = \frac{Q_W}{U_0^2}\frac{4L\nu_0}{\varrho_0 D_H^2} \tag{4}$$

The two-phase flow oscillation frequencies observed can also be analyzed using a non-dimensional approach. Their experimental values are obtained on the basis of the fast Fourier transformation of the pressure drop which evidences frequencies of high energy. The fundamental frequency is the one we deal with here. The oscillation mechanism is based on the two-phase transport along the minichannel; the pressure oscillations are mainly driven by a convective phenomenon. Thus the convective time (τ) defined in Eq. (5) is used:

$$\tau = \frac{L}{U_0} \tag{5}$$

The non-dimensional two-phase flow frequency ($F.\tau$) is plotted as a function of ($N_{\text{pch}}/\text{Re}_0$). A single curve is found for all the operating conditions. This behavior confirms that the oscillation frequency is mainly driven by the phase change phenomenon and inertia effects (Fig. 10). The dispersion is probably due to the uncertainty associated with the measurement of the frequency.

Scaling laws of flow boiling instabilities can also be applied to heat transfer. In Brutin et al. [9] the heat transfer coefficient calculated is based on the average surface and fluid temperature. A total heat flux is provided ($\overline{Q}_W$) whereas locally the heat flux is redistributed inside the aluminum rod. Thus the local surface and fluid temperatures cannot be used to calculate a local heat transfer coefficient but can only provide a global heat transfer coefficient. Using the average temperature difference between surface and fluid ($\overline{T}_S - \overline{T}_F$) and the total heat flux transferred to the fluid, we calculate a global heat transfer coefficient (Eq. (6)). Figure 12 of [8] presents only operating conditions which correspond to a two-phase zone in the minichannel. The objective is to analyze how the two-phase flow contributes to heat transfer.

For increasing heat fluxes, the N-shape is more and more pronounced. Dark points in Fig. 12 of [8] represent a steady flow whereas the white points are for an unsteady flow. A mean heat transfer coefficient is deduced. Introducing the Stanton number, we compare the heat flux transferred to the fluid with the heat transported with the fluid. If we only consider the operating conditions which satisfy a two-phase zone mainly in the minichannel (Fig. 8 of [9]), a heat transfer scaling law appears (Eq. (8)). Thus it is possible to predict a mean heat transfer coefficient when a two-phase zone is mainly inside the minichannel.

$$\overline{h} = \frac{\overline{Q}_W}{\overline{T}_S - \overline{T}_F} \tag{6}$$

$$\text{St} = \frac{\overline{h}}{\varrho_0 Cp_0 U_0} \tag{7}$$

$$\text{St} = 0.776 \left(\frac{N_{\text{pch}}}{\text{Re}_0}\right)^{0.589} \tag{8}$$

Destabilization Mechanism

To use or predict flow boiling instabilities, it is essential to understand the mechanisms which lead to the instabilities. These mechanisms can usually be found by analyzing the flow patterns. For flow boiling in a microchannel, the previous section evidenced that flow boiling instabilities appear and lead to periodical pressure oscillations. The flow even returns to the entrance (Fig. 7). To determine the destabilization mechanism which occurs in such a situation, we quantified the phenomena involved in the instability, such as vapor generation rate, total channel pressure drop, etc.

Brutin et al. [9] studied the transition from steady to unsteady flow boiling and developed a transition criterion. This study was performed experimentally in minichannels but the theory also applies to confined geometries such as microchannels. This criterion is based on observations of the unsteady two-phase flow: the two-phase flow stops at a location in the microchannel; then all the fluid after this location is expelled towards the exit whereas all the fluid

before this location is sent back to the entrance. This two-phase backflow has been evidenced previously [7]; however, the location of this split remained unexplained.

On the basis of Fig. 5 from [9], L_c was defined as the location in the channel where the flow stops and the slug expands and then purges all the fluid out of the minichannel. U_0 is the injection liquid velocity at the bottom of the minichannel and $\overline{U}$ the average two-phase flow evacuation velocity. Two terms were quantified: the over-pressure induced by the expansion of the vapor slug, and the injection pressure minus the minichannel outlet pressure.

The pressure necessary to evacuate all the fluid from the minichannel is the minichannel pressure loss because the outlet pressure is higher than atmospheric pressure. To estimate the friction pressure loss in the minichannel, acceleration and gravity terms were ignored. The physical properties of two-phase flow were considered to be the average between the inlet and the outlet. When unsteady states appear, the fluid was considered as entering in a saturated condition. Thus the expression was established of the over-pressure (ΔP_{slug}) required to evacuate the entire two-phase flow from the minichannel (Eq. (9)). The flow regime considered just after the flow stops is laminar as this minimizes the energy used for the evacuation; a turbulent regime would necessitate much more enthalpy and thus the over-pressure would be much higher. In the expression $\overline{\lambda} = \alpha/\overline{\text{Re}}$, $\alpha = 82.36$ was taken for their geometry aspect ratio. The minichannel pressure loss is $\Delta P_{\text{minichannel}}$. The over-pressure created by the vapor slug is scaled by the dynamic pressure $(1/2)\,\varrho_0 U_0^2$.

$$\Delta P_{\text{slug}} = \overline{\lambda}\frac{L}{D_{\text{H}}}\frac{\varrho_{\text{m}} U_{\text{m}}^2}{2} = \frac{\alpha L \overline{\nu} \varrho_{\text{m}} U_{\text{m}}}{2 D_{\text{H}}^2} \tag{9}$$

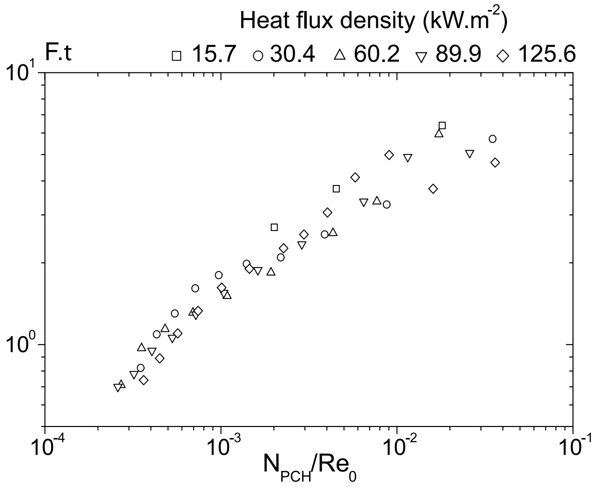
$$\frac{\Delta P_{\text{slug}}}{\frac{1}{2}\varrho_0 U_0^2} = \overline{\lambda}\frac{L}{D_{\text{H}}}\frac{\overline{\varrho} U_{\text{m}}^2}{\varrho_0 U_0^2} = \frac{\alpha L \overline{\nu} \varrho_{\text{m}} U_{\text{m}}}{\varrho_0 U_0^2 D_{\text{H}}^2} \tag{10}$$

If the over-pressure created by the vapor slug is higher than the minichannel pressure loss, the slug can grow and purge the minichannel. This condition can be written as Eq. (11) and in non-dimensioned form as Eq. (12).

$$\Delta P_{\text{slug}} > \Delta P_{\text{channel}} \tag{11}$$

$$\frac{\Delta P_{\text{slug}}}{\frac{1}{2}\varrho_0 U_0^2} > K_1 \tag{12}$$

Thus K_1 is the critical threshold to be reached. Viscosity, density and average velocity of the two-phase flow to be purged must be determined. With the average vapor quality it is possible to estimate the product between the density and average velocity of the two-phase flow. Thus if



Flow Boiling Instability, Figure 10 Non-dimensioned oscillation frequency as a function of $N_{\text{pch}}/\text{Re}_0$

we consider Eq. (13), the solution of the enthalpy equation gives Eq. (14). The heated perimeter for a rectangular microchannel $(d + 2e)$ will henceforth be referred to as δ for the purpose of mathematical simplification.

$$\varrho_0 U_0 L_{\text{V}} \frac{\text{d}\chi_{\text{V}}}{\text{d}z} = \frac{Q_{\text{W}}(d + 2e)}{A_{\text{H}}} \tag{13}$$

$$\chi_{\text{V}}(z) = \frac{Q_{\text{W}}\delta z}{A_{\text{H}} L_{\text{V}} \varrho_{\text{L}} U_{\text{L}}} \tag{14}$$

The average vapor quality $(\overline{\chi}_{\text{V}})$ is obtained by the continuous averaging of the vapor quality along the minichannel. It can also be defined as the ratio between the average vapor mass flow rate and the total liquid flow injected (Eq. (16)).

$$\overline{\chi}_{\text{V}} = \frac{1}{L}\int_{z=0}^{z=L} \chi_{\text{V}}(z)\,\text{d}z = \frac{Q_{\text{W}}\delta L}{2 A_{\text{H}} L_{\text{V}} \varrho_0 U_0} \tag{15}$$

$$\overline{\chi}_{\text{V}} = \frac{\overline{\dot{m}}_{\text{V}}}{\dot{m}_0} = \frac{\varrho_{\text{m}} U_{\text{m}}}{\varrho_0 U_0} \tag{16}$$

$$\varrho_{\text{m}} U_{\text{m}} = \frac{Q_{\text{W}}\delta L}{2 A_{\text{H}} L_{\text{V}}} \tag{17}$$

The average viscosity $\overline{\nu}$ is estimated from the Dukler correlation (Eq. (18)) for a homogeneous medium. Using the average vapor quality, it is deduced that the average two-phase flow viscosity is $\nu_0/2$.

$$\begin{aligned} \overline{\nu}(z) &= \nu_{\text{V}}\chi_{\text{V}}(z) + \nu_{\text{L}}\left[1 - \chi_{\text{V}}(z)\right] \\ &= \nu_{\text{L}} - \chi_{\text{V}}(z)\left[\nu_{\text{L}} - \nu_{\text{V}}\right] \end{aligned} \tag{18}$$

F

The criterion which must be satisfied in order to allow vapor slug expansion is given by Eq. (19). When it is expressed using the inlet control parameters (heat flux: Q_W; liquid inlet velocity: U_0), we obtain

$$\frac{\alpha L \nu_0 \varrho_m U_m}{2\varrho_0 U_0^2 D_H^2} > K_1 \tag{19}$$

$$\frac{Q_W}{U_0^2} > K_1 \frac{4\varrho_0 A_H L_V D_H^2}{\alpha \nu_0 \delta L^2} \tag{20}$$

The threshold of Eq. (20) will be referred as K_2 in further calculations. The relation between K_1 and K_2 is given by Eq. (21) which only depends on physical and geometric parameters. The uncertainty of the threshold is only due to the uncertainty of the hydraulic diameter of the minichannel.

$$\frac{K_2}{K_1} = \frac{\alpha \nu_0 \delta L^2}{4\varrho_0 A_H L_V D_H^2} \tag{21}$$

Using this theoretical threshold it is possible to link the critical pressure loss to a critical heat flux through Eq. (22). There exists a critical pressure loss for a given heat flux, fluid and geometry which destabilizes the two-phase flow.

$$\frac{\Delta P^c_{\text{channel}}}{Q^c_W} = \frac{\varrho_0}{2}\frac{K_2}{K_1} = \frac{\alpha \nu_0 \delta L^2}{8 A_H L_V D_H^2} \tag{22}$$

Key Research Findings

Research over the last decade has provided a huge amount of data on flow boiling instabilities in microchannels. As far as we know today, the instabilities which occur in microchannels appear in the same way as in classical channels (see Table 2). Scaling laws have been evidenced for the stability transition criteria, such as the oscillation frequency of the instabilities, as has been shown in the previous sections. This enables us to conclude that all flow boiling instabilities in microchannels have at least one origin, which is space confinement. However, other phenomena, such as coupling with the experimental loop or the injection device, can lead to other supplementary instabilities.

Future Directions for Research

The literature provides studies on flow boiling in single and parallel microchannels. Both configurations lead to flow instabilities which are clearly identified. The specificity of flow instabilities in microchannels is the appearance of intermittent dryout which can lead to vapor recoil. New experiments on a smaller scale need to be performed to investigate the phenomena which occur at the scale of a bubble. In such confinements where the bubble size is close to or bigger than the hydraulic diameter, the physics involved does not seems to be the classical physics used to model or study pool boiling or flow boiling in ducts. The physical description required to build the theory and the models needs to be close to the triple line.

Such instabilities also appear for different gravity levels, which is also a research subject investigated over the last decade. The ESA (European Space Agency) and CNES (French Space Agency) currently fund research programs on boiling on a microscale either in pool boiling at the scale of a bubble or for flow boiling. The objective is to enable the industrial development of compact heat exchangers working in microgravity. Experiments must be performed in microgravity, using for example parabolic flights (Novespace®) during which it is possible to create microgravity conditions (± 0.05 g) lasting about 20 s.

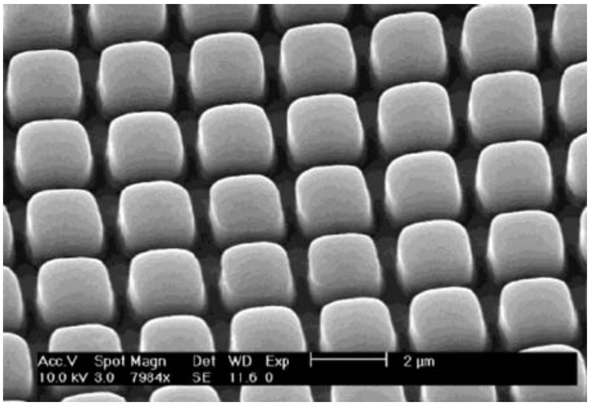
Definition

Electrokinetic or pressure-driven liquid flow in microchannels with three-dimensional (3D) surface roughness generated by manufacturing techniques or by adhesion of biological particles from the liquid.

Overview

Fundamental understanding of liquid flow through microchannels is important to the design and operation of Lab-on-a-Chip devices. The microchannel surfaces may exhibit certain degrees of roughness generated by the manufacturing techniques or by adhesion of biological particles from the liquids. The reported surface roughness elements range from 0.1 to 2 μm [1–3]. Microfabrication techniques such as photolithography can also make 3D elements inside microchannels (see Fig. 1). The surface roughness of microchannels not only increases the reaction-sensing surface area but also plays an important role in determining the flow characteristics. In early experimental investigations of flow and heat transfer in microtubes and trapezoidal microchannels, the increase in flow friction and decrease in heat transfer attributed to surface roughness effects were observed [1–3].



Flow in Channels with 3D Elements, Figure 1 An example of a silicon surface with microfabricated, symmetrically arranged prism elements

For low Reynolds number pressure-driven flow through microchannels, the pressure drop over the microchannels is greatly increased by the existence of the 3D surface roughness elements, and periodical fluid expansions and compressions between rough elements are generated. These were clearly predicted by the 3D numerical simulations developed by Hu et al. [4]. The roughness elements act on the flow in two ways: causing the expansion and compressions of the streamlines, and obstructing the flow directly, both giving energy losses of the fluids.
The roughness on channel walls also significantly influences the electrokinetic flows [5]. The electrical field is distorted by the presence of the nonconducting surface roughness elements, which makes the electroosmotic slip velocity of the liquid nonuniform [5]. The electroosmotic flow in a rough microchannel induces a periodic pressure field between rough elements that makes the central flow velocity smaller than that in the near-wall region, and hence reduces the overall flow rate. The induced pressure field causes an exchange of liquid between the rough element gaps and the central flow, causing an even-out effect [5]. The flow congestion and flow circulation can be obtained in microchannels with heterogeneously charged 3D elements (i. e., with different zeta potentials) and a tidal wave-like concentration field is found in heterogeneous channels with oppositely charged rough elements [6]. The electrokinetic flow behaviors in rough microchannels were verified by using the current monitoring technique and particle tracking technique [7].
As an application, the flow in rough microchannels was applied theoretically in the nucleic acids extraction process [8], which is the first critical step for many nucleic acid probe assays. Using a microchannel with 3D prismatic elements on the channel wall can dramatically increase the surface area-to-volume ratio and hence

enhance the nuclei acid adsorption on the wall. The opportunity for molecule adsorption is also increased due to the induced pressure resisting the central bulk electroosmotic flow. It is found that decreasing the electroosmotic flow velocity or the channel height enhances nuclei adsorption.

Definition

Flow cytometry is a popular technique for counting and sorting individual cells or particles. Also, it is used for measurement of various physicochemical characteristics and distribution of cell populations. A flow cytometer Lab-on-a-Chip is a microfluidic tool for flow cytometry that is made using microfabrication techniques. It incorporates many components and functionalities of a typical room-sized laboratory onto a small chip.

Overview

Reynolds' late 19th century principles of laminar flow and 20th century advances in flow microscopy, cell counting techniques and ink jet technology form the intellectual foundations of flow cytometry [1]. Moldvan (1934) was the first to suggest an instrument for identifying single cells using a microscope with a photodetector. Before Coons (1941) directly labeled antibodies with fluorescent dyes, there was no technique for visualizing cells and identifying their physical structure and orientation. Microscopes equipped with cameras or photodetectors enabled the precise quantitative analysis of fluorescence intensity patterns within the field of view [1]. Kamentsky and Melamed (1965) developed a microscope spectrometer that measured and recorded ultraviolet absorption and the scatter of blue light arising from the flow of cells. Then, in 1967, they modified the spectrometer to create a spectrophotometric cell sorter with electronic actuation, which separated cells of predetermined optical properties from a large population of cells in suspension. In particular, the monoclonal antibody technique, which was invented by Georges Köhler and Cesar Milstein in 1975, also led to a vast increase in the number of cellular constituents that could be specifically stained and used to classify cells.

Wallace Coulter invented a non-optical means of counting and measuring the size of particles suspended in a conducting fluid (1953). In this approach, cells displaced conducting solution while flowing through an orifice, resulting in increases of electrical resistance measured across the orifice. Crosland-Taylor (1953) was the first to introduce the principle of hydrodynamic focusing, in which particles injected into a faster stream of fluid flowing in the same direction could be spatially confined. Fulwyler (1965)

developed an electronic cell sorting device that combined Coulter methodology with ink jet technology. The device added a charge to the droplets containing cells differently according to the cell volume measured in a Coulter aperture, thereby allowing deflection of the droplets under an electrostatic field. Dilla and coworkers (1969) developed the first fluorescence-detection cytometer with the principle of hydrodynamic focusing. The cytometer, which included a photomultiplier and an argon ion laser, was configured with the axes of flow, illumination and detection all orthogonal to each other.

Improvements on the above pioneering works in flow cytometry and related fields have led to the development of modern flow cytometers for various applications. Currently, there are a number of commercial flow cytometers that can sort up 10,000 cells per second without affecting cell viability. Through different staining techniques and minor modifications of conventional flow cytometry, analytical capabilities have been extended from single molecules to large biological particles, including carbohydrates, lipids, cholesterol, proteins, ions, chromosomes, DNA/RNA, islet cells and embryonic stem cells. Although conventional flow cytometers provide rapid and reliable analytical cell sampling capabilities, complex optical components like focused laser beams, various optical filters/photodetectors, and complicated electronics make the conventional flow cytometer bulky and expensive. Moreover, its operation still relies on specialized personnel, complex preparation procedures and a relatively high volume of cells or particles to be analyzed.

Over the past decade, the drawbacks of conventional flow cytometers coupled with the increased need for miniaturization and sophisticated analysis have motivated the development of the micromachined flow cytometer. It has many potential benefits including disposability, smaller size, lower consumption of sample, reagents and power, enhanced performance and inexpensive instrumentation. Also, the integration of the microfluidic and detection systems on a single chip can enhance the reliability and functionality of the flow cytometer. For example, Miyake et al. (1991) was the first to report a multilayered flow chamber that could generate a hydrodynamically focused narrow stream of fluorescent dyes and particles within a water sheath. Similarly, Sobek et al. (1993) demonstrated a micromachined flow cytometer fabricated on quartz wafers and consisting of two symmetric parts bonded together to define the geometry of a sheath flow chamber and a detection channel. Later, Larsen et al. (1997) and Koch et al. (1999) presented designs for micromachined Coulter counters that could count individual particles; however, electrical testing of these designs was not performed. Alternatively, Aletendorf et al. (1996) demonstrated a bench top optical flow cytometer utilizing silicon V-groove flow channels, in which a laser diode and a photodiode detector were used for cell counting. Nowadays, the goal of novel micromachined flow cytometers is to enable more precise and rapid manipulation of cells or particles and to take advantage of different driving forces for controlling fluid flows. Also required is the integration of optics and electronics to perform detection and sorting of cells or particles of interest. Herein, we present the basic principles of flow cytometer operation and discuss and recent progress in micromachined flow cytometers. We recommend that the audience read [1, 2] for understanding these fields.

F

Basic Methodology

Basic Principles

A flow cytometer is an instrument for counting and sorting suspended cells or particles in a stream of fluid and analyzing their physicochemical characteristics. A flow cytometer has several key components: (a) a flow cell that carries the suspended single cells through the instrument and past the light source, (b) a light or excitation source, typically a laser that emits light at a specific wavelength, (c) a detector that is capable of measuring the light signals from the cells, (d) data-analysis electronics that characterize the multiparametric properties of the cells, and (e) a sorter that is able to separate each cell according to the predetermined optical properties. The basic operation principles of a flow cytometer are shown in Fig. 1. Before suspension in a sample reservoir, cells or particles can be combined with various fluorescent probes that stain cellular components to elucidate functions of interest. The suspended cells or particles are aspirated into a flow cell through a nozzle by air pressure applied on top of the sample or a syringe controlled by a precise motor. A flow cell delivers the sample stream to the center of the sheath flow and then accelerates the flow to squeeze the central sample flow into a narrow stream and to maintain a cell spacing within the surrounding fluid sheath. This phenomenon, called hydrodynamic focusing, is the keystone of a flow cytometer (Fig. 1a).

Every single cell or particle is then intercepted as it flows by a fixed light source like a laser beam and then the light is either scattered or absorbed. Scattered light is either reflected or refracted. In most flow cytometers, there are two types of scatter; forward-angle scatter and right-angle scatter. Forward-angle scatter is the amount of light scattered at small angle ($< 10°$) in the forward direction with respect to the direction of the laser beam, and is known to be related to the size of the particle. Right-angle scatter consists of photons scattered at 90° with respect to the incident laser beam, and depends primarily on the cell

structure and granularity. Absorbed light of the appropriate wavelength may be re-emitted as fluorescence if the cell contains a naturally fluorescent substance or fluorescent dyes are added to the sample. The fluorescent signal helps to identify cells of interest. The scattered or re-emitted light is collected by a number of detectors where the stream passes through the light beam: one photodetector in line with the light beam (a forward scatter detector) and other photodetectors perpendicular to it (side scatter and fluorescent detectors). A set of dichroic mirrors and filters split the optical signals in spectral wavelength ranges. The resulting electrical pulses are digitized and then the data is stored, analyzed and displayed through a computer system (Fig. 1b).

The amount of scattered or fluorescent light subsequently needs to be displayed for interpretation. These profiles are normally displayed as single dimension (histogram) or two dimensions (cytogram). A histogram displays a frequency distribution of the cell for any particular parameter, whereas a cytogram displays the data in two dimensions like a spatial map. Both histograms and cytograms can represent the population distribution of scattered and fluorescent signals received from a large number of cells or particles. Also, multiple fluorescent dyes can be used simultaneously in a flow cytometer. Therefore, this allows a multiparametric analysis at the single cell level and so it can be used to select and purify a specific subset of cells or particles within a population.

The most common method for sorting is the stream-in-air configuration in which a continuous stream of cells or particles emerging from a nozzle is converted into droplets containing single cells using mechanical vibration of the nozzle tip. If a stream of liquid is vibrated along its axis, the stream will break up into droplets. The characteristics of this droplet formation are governed by an equation: $v = f \cdot \lambda$, where v is the velocity of the stream, f is the frequency of the vibration applied, and λ is the distance between droplets [1]. After forming the droplets in a regular pattern, a charge is added the droplets. Then, the charged droplets are deflected by a strong electric field into different collecting chamber (Fig. 1c).

Coulter Counter

The Coulter counter is a resistive pulse technique of particle sizing invented in 1953. The measurement principle is as follows. A particle passes through a pore and displaces conducting fluid in that pore (Fig. 2). The resistance of a pore R_p increases by δR_p when a particle enters since the particle displaces conducting fluid. Assuming that the current density is uniform across the pore, δR_p can be estimated for a pore aligned along the z-axis by [3]

$$\delta R_p = \rho \int \frac{dz}{A(z)} - R_p \quad (1)$$

where $A(z)$ represents the cross sectional area occupied by fluid at a particular z-position of the pore containing a particle, and ρ is the resistivity of the fluid. The particle resistivity is assumed infinite in this analysis. For a spherical particle of diameter d in a pore of diameter D and length L, the relative change in resistance is expressed as [3]

$$\frac{\delta R_p}{R_p} = \frac{D}{L}\left[\frac{\arcsin(d/D)}{\sqrt{1-(d/D)^2}} - \frac{d}{D}\right] \quad (2)$$

where L is the pore length. For cases where cross section $A(z)$ varies quickly, i. e., when $d \ll D$, Debolis and Bean (1970) formulated an equation based on approximate solution to the Laplace equation:

$$\frac{\delta R_p}{R_p} = \frac{d^3}{LD^2}\left[\frac{D^2}{2L^2} + \frac{1}{\sqrt{1+(D/L)^2}}\right] F\left(\frac{d^3}{D^3}\right) \quad (3)$$

where $F(d^3/D^3)$ is a numerical factor that accounts for the bulging of the electric field lines into the pore wall. If R_p is the dominant component of measurement circuit, then relative changes in the current are equal in magnitude to those in the resistance.

Fabrication

We briefly describe the general methods to fabricate flow cytometers. Conventional flow cytometers contain flow chambers or cuvettes made from glass or quartz tubes, with an injector inserted into the middle of the tube. Recently, microfabricated flow cytometers have been developed using photolithography and micromachining techniques. The two kinds of micromachining techniques are surface micromachining, where thin layers of new materials are added to a substrate, and wet bulk micromachining, where a substrate is etched isotropically or anisotropically depending on etchants. Typical substrates are silicon, glass and quartz. In addition, soft microlithography can replicate microfluidic components by casting polymer against a master mold. The master mold is a positive relief structure that hollows out negative relief structures in the cured polymer cast against it. Poly(dimethylsioxane) (PDMS), which is an optically

Key Research Findings

Hydrodynamic Focusing

The microfluidic device design and the relative flow rate of sheath and sample play important roles in hydrodynamic focusing. Lee et al. (2001) proposed a theoretical model to predict the width of focused center flow inside a microfabricated flow cytometer [14]. Based on potential flow theory, they derived the equation for flow inside a planar microfabricated flow cytometer under the two dimensional situation shown in Fig. 3a. The flow is considered laminar, and the diffusion and mixing between focused stream and sheath flows is assumed negligible. With these assumptions, conservation of mass yields.

$$\dot{m}_{\text{in}} = \rho_1 \bar{v}_1 \cdot D_1 + \rho_2 \bar{v}_2 \cdot D_2 + \rho_3 \bar{v}_3 \cdot D_3 \tag{4}$$

$$\dot{m}_{\text{out}} = \rho_a \, \bar{v}_a \, \cdot D_a \tag{5}$$

$$\bar{v}_2 \cdot D_2 = \bar{v}_c \cdot d \tag{6}$$

where $\dot{m}_{\text{in}}$ and $\dot{m}_{\text{out}}$ are mass flow rates (per unit depth) of the inlet and outlet flows; D_1, D_2 and D_3 are the width of inlet channels 1, 2, and 3, respectively; $\bar{v}_1$,$\bar{v}_2$ and $\bar{v}_3$ are average velocities in sections 1, 2 and 3; $\bar{v}_a$ is the average velocity inside the outlet section; $\bar{v}_c$ and d are velocity and width of focused beam, respectively. If the sheath flow rate is much higher than the sample flow rate, the final output flow will be dominated by the sheath flow and then the velocity profile can be approximated as a parabolic flow of just the sheath fluid. It follows that

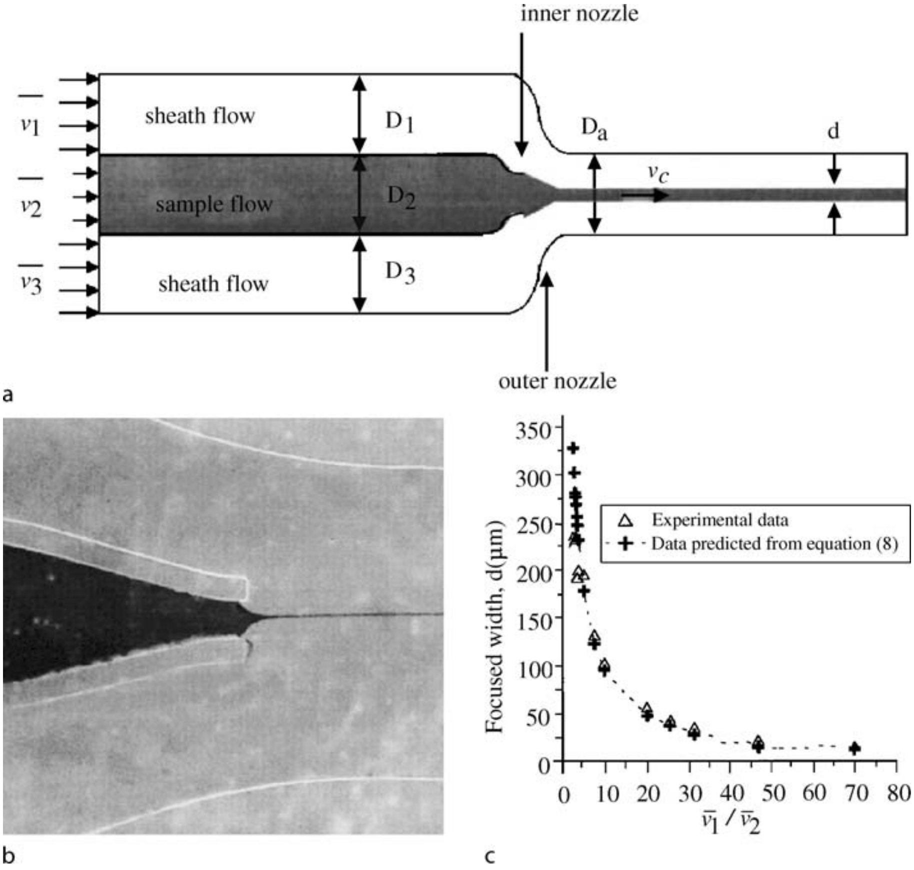
$$v_c = v_{\max} = 1.5\bar{v}_a \tag{7}$$

Therefore, the width of the focused center stream can be derived as

$$\begin{aligned} d &= \frac{\bar{v}_2}{v_c} \cdot D_2 \\ &= \frac{\rho_a D_a}{1.5\big(\rho_1(\bar{v}_1/\bar{v}_2)(D_1/D_2) + \rho_2 + \rho_3(\bar{v}_3/\bar{v}_2)(D_3/D_2)\big)} \end{aligned} \tag{8}$$

This expression indicates that the width of the focused stream is inversely proportional to the ratio of sheath flow rate to sample flow rate and proportional to volumetric flow rate of the sample flow. Lee et al. also performed experiments showing two-dimensional hydrodynamic focusing could achieve a focused stream with width less than 10 μm when the sample was injected at the middle of the outer nozzle and the ratio of sheath flow rate to sample flow rate was increased (Fig. 3b). Their experimental results agree well with theoretical predictions.

Chung et al. (2003) investigated the difference between two- and three-dimensional hydrodynamic focusing using numerical simulation based on Poiseuille flow, which is pressure driven flow between stationary parallel plates with no contribution from gravity, and experimental observations with scanning confocal microscopy. Two- and three-dimensionally focused streams were achieved by planar and two-level channel geometries using poly(dimethylsiloxane) (PDMS). They found that two dimensional focusing was not as successful as three



Flow Cytometer Lab-on-Chip Devices, Figure 3 Hydrodynamic focusing for mircofabricated flow cytometers: (**a**) schematic diagram of a 2-dimensional microfabricated flow cytometer for a theoretical approach, (**b**) photograph of focused sample stream inside a flow cytometer, and (**c**) variation of the width of the focused stream as a function of the relative flow rates of sample and sheath [14]

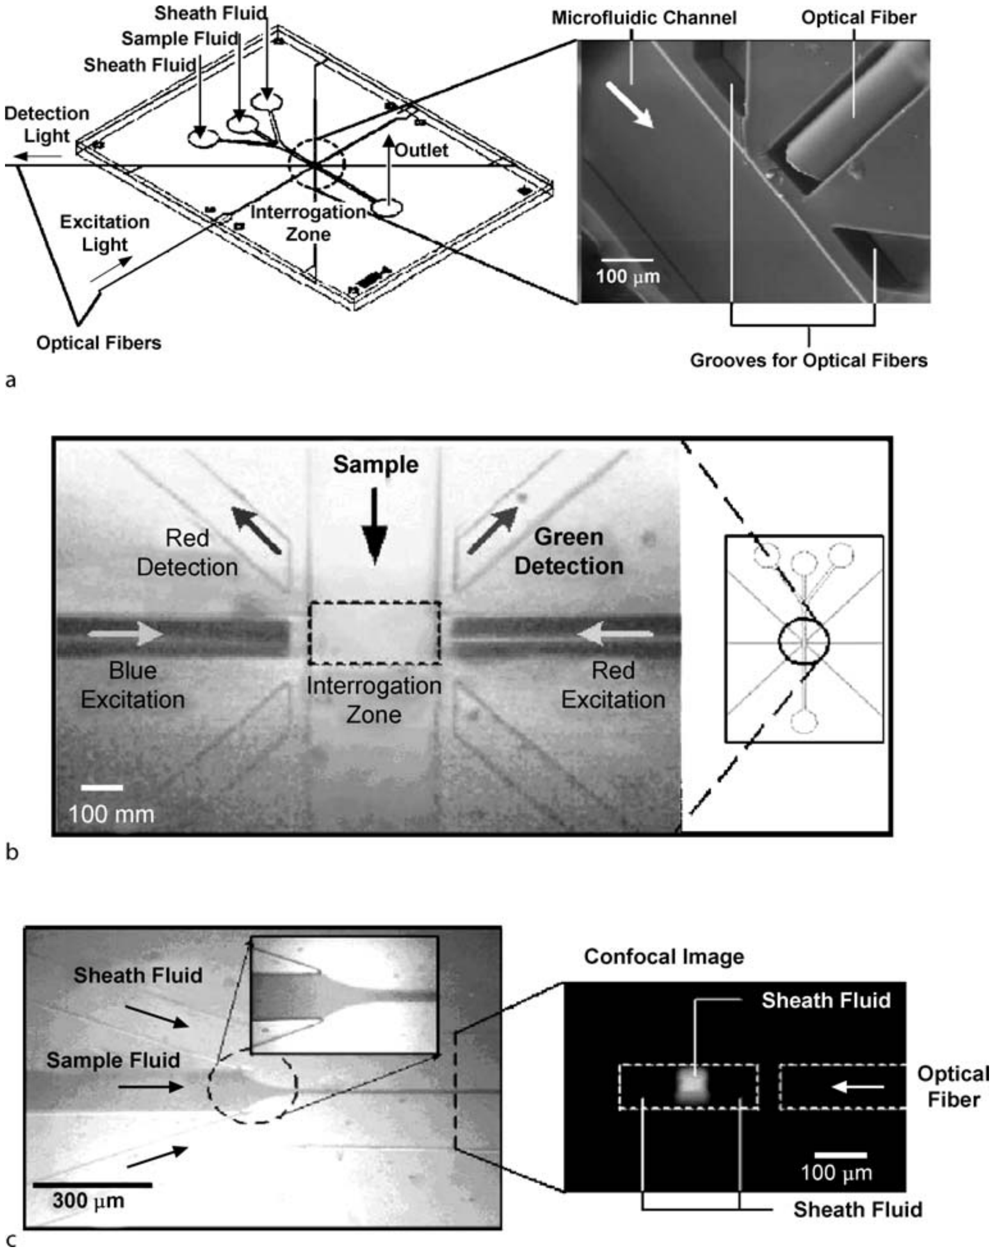
dimensional focusing. That is, three dimensional focusing better confined sample particles in the vertical direction and made detection signals more stable.

Although hydrodynamic focusing with sheath fluid serves as a standard technology in conventional and microfabricated flow cytometers, large amount of sheath fluid is requires to process a small amount of sample and continuous pumping of sheath fluid at high flow rates is needed to generate a narrow sample stream. Further reduction in the size and volume of the whole system is also limited. Alternative methods are electrokinetic focusing, which uses direct current (DC) at high voltages, and dielectrophoretic focusing, which uses alternating current (AC) to focus particles and liquids into a narrow stream. These topics are of significant research interest but are beyond the scope of this entry.

Optical Detection

Micromachined flow cytometers open new opportunities to integrate optical components and solid-state devices with the microfluidic platform. Tung et al. (2004) investigated the feasibility of silicon-based PIN photodiodes, which consisted of P–N junctions with an intrinsic region in the middle combined with self-aligned optical fibers for multi-color excitation and multi-angle fluorescence detection in PDMS-based flow cytometers [4]. Replacing photomultiplier tubes (PMTs) and avalanche photodiodes (APDs) with PIN photodiodes for fluorescence detection in flow cytometry presented significant technical challenges, since the fluorescent signals generated from biological cells only produce a few nA of current in the PIN photodiodes. Thus, Tung et al. applied a lock-in amplification technique to increase the signal-to-noise ratio (S/N). At a single interrogation point, multi-color laser excitation and multi-angle fluorescence detection were demonstrated to detect hydrodynamically focused fluorescent microspheres and biological particles (Fig. 4).

Lee et al. (2003) proposed a novel approach to integrate polymeric optical waveguides onto microfabricated flow cytometers. Instead of inserting optical fibers through



Flow Cytometer Lab-on-Chip Devices, Figure 4 Integrated optical components on a PDMS-based flow cytometer: (**a**) design of PDMS observation channel with embedded optical fibers (arrangement shown with 45° angle between excitation and detection optical fibers), (**b**) arrangement of optical fibers for two-color excitation/detection experiment, and (**c**) optical and confocal microscope photos demonstrating hydrodynamic focusing (the water containing fluorescein is excited using a blue ($\lambda = 440$ nm) laser) [4]

microfabricated grooves, they developed a new method to embed photoresist (SU-8)-based optical waveguides with a thin layer of spin-on-glass (SOG). The seamless configuration and large difference in refractive indices between SU-8 (1.80) and SOG (1.36) enhanced the efficiencies of light guiding and coupling. The working principle is that the detection light can propagate in the waveguide by total internal reflection. Light intensity, which changes when cells or particles pass through the interrogation point, is collected by the other waveguide buried on the other side of the microfluidic channel. The advantage of this method is that it permits counting and analysis of cells and particles without microscopes and delicate optical alignment.

The impedance signal is measured differently ($Z_{AC} - Z_{BC}$). As the distance between two measurement areas and time t_{tr} separating the signal spikes are known, the speed of the particle can be calculated, and (**b**) Signal inphase amplitude of 2000 erythrocytes and ghost cells recorded simultaneously for 2 frequencies [15]

Electrical Detection

In optics-based flow cytometry, molecular level detection individual cells or particles is enabled by tagging biomarkers with various fluorescent probes. These probes inherently alter the cells/particles: tagging requires an incubation step, antigenic exposure risks triggering cell differentiation, and non-surface probes require membrane permeabilization. Although some leukocytes can be separated without the use of probes by their forward scatter and side scatter signals, the efficiency is not as high as that of fluorescence-based optical detection. Thus, new label-free detection methods are emerging in the field of microfabricated flow cytometers. Saleh and Sohn (2001) were the first to present a microfabricated Coulter counter on quartz substrate utilizing a four-point measurement of the current through the pore (Fig. 5) [3]. The Coulter counter was able to detect latex colloidal particles as small as 87 nm in diameter and 500 nm-diameter colloids with a resolution of ±10 nm, although its sensitivity depends on the relative size of the pore and the particle to be measured. Also, Saleh and Sohn in 2003 corrected off-axis effects

due to particles traveling off the central axis of the pore. Off-axis particles take longer to transit the pore due to the parabolic distribution of fluid velocity within the pore, causing wider pulses and large changes in electrical resistance due to the nonuniform distribution of electric current density. They proposed that off-axis effects can be effectively removed in the data analysis of a given population by the nearly linear correlation between height ΔR and width τ in measured resistance pulses. Nieuwenhuis et al. (2004) presented the integrated Coulter counter that has a controllable liquid aperture, defined by a non-conductive sheath liquid surrounding the conductive sample stream, whereas microfabricated flow cytometers reported before had a fixed Coulter aperture [5]. The dynamic Coulter aperture to the particle size enables to achieve optimal sensitivity and to prevent clogging.

Impedance spectroscopy of living biological cells over a wide frequency range gives various information such as cell size, membrane capacitance, and cytoplasm conductivity as a function of frequency. At low frequencies, the cell membrane offers a significant barrier to current flow and so the cell size can be measured as in Coulter counting. At intermediate frequencies, the decrease in plasma membrane polarization reduces the capacitance of the cell. This effect is known as β-dispersion or dielectric relaxation. At high frequencies, the plasma membranes are minimally polarized and so, above the β-relaxation frequency, the signal contains information about the heterogeneous structure and dielectric properties of the cell interior. Renaud and co-workers (2001) demonstrated successfully that a microfabricated cell impedance analyzer could discriminate between cell types and particle sizes with the rate of over 100 samples per second [15]. Simultaneous impedance measurements at multiple frequencies enabled the differentiation of subpopulations in the mixture of normal erythrocytes and erythrocyte ghost cells, illustrating the capability of identifying different cell types (Fig. 6). Recently, they proposed a model to determine the influence of different cell properties including size, membrane, capacitance and cytoplasm conductivity on the impedance spectrum in their flow cytometers and showed the discrimination between unlabelled neutrophils (granular, 12–15 μm diameter, multi-lobed nucleus), lymphocytes (agranular, 5-10 μm, large nucleus), and monocytes (agranular, 12-18 μm diameter, U-shaped nucleus) [16].

Cell Sorting

The ability of high speed sorting based on the predetermined properties of cells or particles has been an important issue in the development of microfabricated flow cytometers. Quake and co-workers (1999) presented disposable fluorescence-activated cell sorting (FACS) of microbeads and bacterial cells in a microfluidic device based on electrokinetic switching of liquid streams [7]. When a fluorescently labeled cell was detected in the input channel, the sample stream flowing from an inlet to a waste port was quickly switched by reversing the electric field to deliver target particles selectively to a sample collector. This technique demonstrated sorting of fluorescent microbeads and E. coli at the rate of ~ 10 beads/s and 20 cells/s, respectively. Later, Fu et al. integrated pneumatically actuated components which enabled self-contained and automated cell trapping and sorting at a higher rate (26–44 cells/s)

Voldman et al. (2002) introduced an innovative dynamic array cytometer for single-cell assays and sorting based on the principle of dielectrophoresis, in which forces arise on particles in a nonuniform electric field due to induced polarization or charge dipoles (Fig. 546a) [8]. Their asymmetric extruded quadrupole geometry allowed noncontact trapping of multiple single cells, holding them against disrupting fluid flow and increasing the trapping efficiency. Also, the novel dielectrophoretic trap could be physically arrayed and electrically addressed. By controlling the potential of one electrode in each trap, selected subpopulations of cells could remain trapped or be released from the trap based on the fluorescence information.

Wang et al. (2005) described a high throughput cell sorter with all-optical control switch for live cells (Fig. 546b) [9]. The optical forces, which depend on the optical power and relative optical properties of the particle and its surrounding fluidic medium, were used to deviate the cell from the

flow stream to a sufficient degree to that it was directed toward the target output channel. They have shown that sorting runs of cell populations ranging from as few as 1,000 cells up to 280,000 cells can be completed in less than an hour.

Flow Cytometer Lab-on-a-Chip

A flow cytometer Lab-on-a-Chip should incorporate many components and functionalities of a typical room-sized laboratory onto a small chip. Although the perfect flow cytometer Lab-on-a-Chip has not yet emerged, we introduce novel examples for this issue. Recently, Wolff et al. (2003) designed and developed a new pressure-driven microfabricated FACS device with advanced functional components including a chamber for holding and culturing the sorted cells and monolithically integrated waveguides for cell analysis (Fig. 8a) [10]. They achieved a 100-fold enrichment of fluorescent beads at a throughput of 12,000 cells per second while sorting fluorescent latex beads from chicken red blood cells. In particular, a new structure for coaxial sample sheathing and hydrodynamic focusing was built on the principle of *the smoking chimney*, where the sample was sheathed and carried downstream from the inlet like a wisp of smoke from a chimney. Renaud and co-workers (2005) have developed a microfabricated impedance flow cytometer that incorporates deflective dielectrophoresis barriers and controlled pressure driven liquids flows (Fig. 8b) [6]. The integrated flow cytometer had the following capabilities;

- cells trapped in electric cages could be subjected to two or more different fluids for cell transfection
- cells could be brought into an adjacent liquid (reagent) stream and washed shortly afterwards
- cells could be characterized by the opacity, which is the ratio of the impedance magnitude at a high frequency to a low frequency.

Lee and co-workers (2006) presented a compact cell counting/sorting system with several essential components including a micromachined flow cytometer chip device, an optical detection system and a data analysis and control system to achieve the functions of cell sample injection, optical signal detection and cell collection. Its dimensions were 37 cm in length, 16 cm in width and 18 cm in height (Fig. 8c) [11].

Future Directions for Research

We can envision that the future ► flow cytometer Lab-on-a-Chip devices will miniaturize and integrate monolithically a variety of optical components like light sources, photodetectors, filters, waveguides and lenses that can detect multiple fluorescence colors simultaneously. Other potential approaches without optical components include integrated flow cytometers based on electrochemical impedance detection, electrokinetic focusing/switching/sorting, MEMS-based filtering/pumping/switching, and electromagnetic isolation. Also, future cytometers may combine optical components with non-optical components monolithically for high throughput multi-parametric analysis of cells or particles.

Flow Patterns

Definition

In single phase flow, flow pattern means whether the flow is laminar or turbulent, or whether flow separation or secondary flow exists. In multiphase flow, flow pattern refers to the internal geometry of the flow; i. e., the relative location of interfaces between the phases, such as stratified and dispersed.

Definition

In microfluidics, the volumetric flow rate is the volume of fluid flowing per unit time in the cross section of a microfluidic channel. The mass flow rate is significant in multiphase flow, where different fluid phases have different densities. A fluidic pressure sensor measures the pressure drop due to the flow of fluid. Velocimetry is a technique for measuring the velocity profile of fluids by means of particles which are viscously dragged by the bulk of the fluid. Under laminar flow with no slip at the wall boundaries, a parabolic velocity distribution exists, and a good

flow sensor integrates the parabolic velocity profile over the cross section of the flow.

Overview

In microfluidics, control and manipulation of fluid flow can be accomplished by pressure-driven, electrokinetic, magnetohydrodynamic, centrifugal, and capillary forces. When forces such as electrokinetic and magnetohydrodynamic forces act on the walls of a microchannel, slip in the fluid flow occurs at the walls. On the other hand, when forces such as pressure-driven forces act on the inlet or outlet, a laminar flow of fluid experiences no slip at the walls. Thus the middle of the channel flows at a higher velocity than near the walls. Figure 1 shows a microfluidic device used in a biosensing application. Figure 1a shows the flow of particles under a constant pressure gradient. Figure 1b shows the parabolic velocity profile of a flow front of high-density particles. Note that the particles in the middle of the channel travel with a higher velocity, thereby showing a lower density, and the particles near the walls travel with a lower velocity, thereby showing a higher density. Observing a statistical distribution of particles in a flow is equivalent to discretizing the entire fluid volume with velocity elements. This velocity profile can be integrated mathematically at any cross section of the fluid flow in order to compute the flow rate. The flow of a fluid with a velocity u and pressure p at a time t is given by the Navier–Stokes partial differential Eq. (1)

$$\frac{\partial \boldsymbol{u}}{\partial t} + (\boldsymbol{u} \bullet \text{grad})\, \boldsymbol{u} + \text{grad}(p) = \frac{1}{\text{Re}} \Delta \boldsymbol{u} \tag{1}$$

where Re is the Reynolds number, given by the ratio of inertial to viscous forces, and is very small for the laminar-flow regime of microfluidics. Figure 2 shows the flow of a fluid under constant pressure. The bulk fluid is dispensed by drawing the flow out at the bottom outlet and venting air at the top inlet. Figure 3 shows the flow characteristics when a constant negative pressure is applied at the outlet. These calculations were based on computational fluid dynamic (CFD) simulations using the volume-of-fluid (VOF) model for the immiscible fluids air and water. A hydrophobic material with a contact angle of 109 °C was assumed in the CFD simulation, and fluidic properties of air and water were also assumed. The fluidic impedance caused by the geometry of the channel was evaluated from the pressure–flow-rate characteristics. In the case of a hydrophobic wall, there is a threshold pressure that drives the flow against a hydrophobic force. A steady-state flow is obtained, and the flow is proportional to the pressure. Integration of the flow rate at every element of the cross section of a flow channel is performed in an ideal flow sensor.

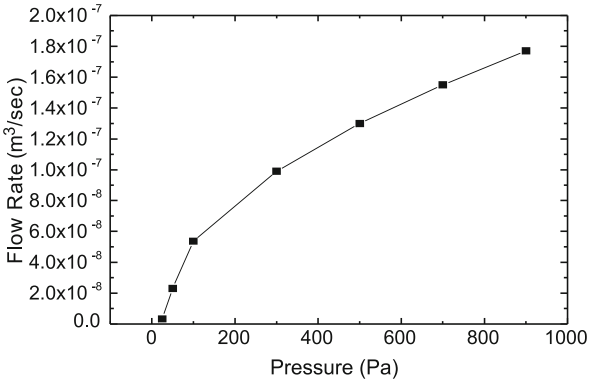
The measurement of flow rates and the performance of quantitative analysis on fluids in minute volumes is greatly advancing the development of multifunctional, high-throughput Lab-on-a-Chip devices. Traditionally, there have been many MEMS-based flow sensors for gaseous flows. In recent times, several advancements have taken place in measuring microflows of liquids. Some examples of sensing principles for the measurement of microflu-



Flow Rate Measurements, Methods, Figure 3 Flow characteristics for a hydrophobic geometry of the kind shown in Fig. 2, showing the applied negative pressure and the flow rate at the outlet

idic flow include heat transfer detection [1], molecular sensing [2], noninvasive optical techniques [3], atomic-emission detection [4], streaming-potential measurements, electrical-impedance measurements [5, 6], electrochemical redox cycling [7], amperometric sensing [8], ion-selective field-effect transistors, micromechanical sensing [9], and detection of periodic flapping motion [10]. Flow sensors are critical for controlled, precision flow to enable active micrototal analysis systems.

Basic Methodology

Many of the well-established macroflow sensing methods such as the use of shear stress sensors, thermal anemometers, magnetohydrodynamic sensors, particle imaging, and fluorescent imaging have been adapted and scaled down for microfluidics. However, miniaturization and integration issues have opened up new opportunities for microflow sensing. Broadly, flow sensors can be classified as either obstructive or nonobstructive to the flow. Obstructive flow sensors add fluidic resistance to the flow, and so nonobstructive flow sensors are generally preferred. These nonobstructive flow sensors can themselves be classified into invasive and noninvasive flow sensors. In invasive flow sensors heat, electric current, or foreign substances such as fluorescent dyes or particles are added to the flow in order to perform the flow rate measurement. For example, fluorescence-correlation-spectroscopic and optical-Doppler-coherence tomographic measurements fall into this category. In noninvasive flow sensors, the sensing element does not physically make contact with the flow. Mostly, the flow sensing depends on optical parameters of the fluid, such as the refractive index, that depend on the flow rate. Sonic and radio-frequency signals can also be used for such measurements. In reality, there are no ideal noninvasive flow-sensing techniques. However, flow sensors that minimally modulate the flow optically, thermally, or electrically have been adapted for micrototal analysis applications. There is still research under way into high-sensitivity and very low-flow-rate measurements.

Time-of-flight (TOF) measurement is popular in microflow measurements. The time of flow of a pulse of temperature or of molecular tracers from one point in a microchannel to another point is characterized to measure the flow rate. An emitter and a collector are integrated into TOF sensors. Various optimizations of these sensors have been carried out, using temperature pulses or electrochemical production of molecular tracers. These sensors calculate the flow rate at one point in the cross section of the channel and are calibrated with a known flow rate. Flow measurement using microparticles captures the velocity profile at many such locations in the channel cross section and allows one to calculate the flow rate. Figure 4 shows the principle of a flow sensor using a CFD simulation of convective diffusion of heat or molecular tracers generated at an emitter. The collector in the flow sensor records a measure of the flow. The relation between the flow sensor reading and the actual flow rate is nonlinear, and the flow sensor is calibrated for a window of operation of flow measurements.

Experimental Techniques for Flow Sensing

Heat-Transfer-Detection-Based Flow Sensors

These thermal-anemometer-based flow sensors can sense very low flows in microchannels. The measurement principle is based on the thermal time of flight. The length of the heating pulse and the time of flight used in the measurement are measured in milliseconds. An example of the structure of a flow sensor is shown in Fig. 5 [1]. The structure consists of a heater in the middle, with an upstream and a downstream temperature sensor integrated into the wall of the channel. When there is no flow in the channel, heat diffuses into the two temperature sensor regions and no differential temperature is detected. An increase in the flow rate in the channel favors convection of heated fluid in the direction of the flow, and the differential temperature detected by the sensors increases.

The process flow for the fabrication of the microfluidic system includes a single or double metallization layer, a polymer layer for the fluidic system, and a glass sealing cap. There have been some efforts during fabrication to minimize the thermal-dissipation loss. The temperature difference between the two points where the sensors are located is measured with a differential current amplifier, and the flow rate is calibrated. At low flow rates, the tem-

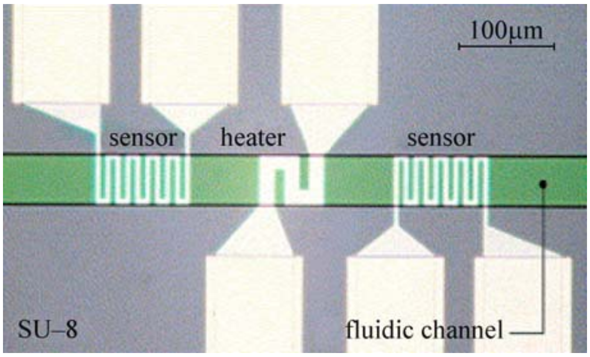
perature difference is a linear function of the flow rate as in Fig. 6. Measurements without heat insulation decrease the sensitivity of the flow sensor and increase the lower limit of flow rate detection. The distance between the heater and the sensors is optimized for the maximum differential temperature.



Flow Rate Measurements, Methods, Figure 5 Photomicrograph of a microfluidic mass flow sensor [1]

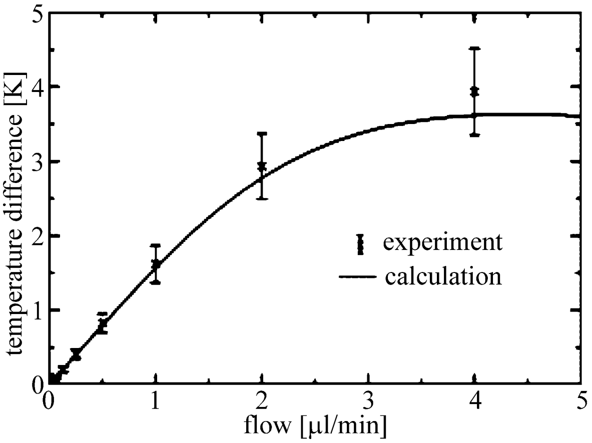
Micromechanical Flow Sensors

Micromechanical flow meters measure shear forces produced as a result of fluid flow. The deflection of a micromechanical plate due to the shear force can be measured optically using a system coupled to a laser deflection system. Figure 7 shows a schematic of such a plate, encapsulated in a channel. The major interaction between the fluid and the plate is through the stress field, which contains both normal (pressure) and shear stresses.

Assuming steady, unidirectional flow in the channel, the Navier–Stokes equation can be written as

$$\frac{\partial^2 u}{\partial y^2} + \frac{\partial^2 u}{\partial z^2} = \frac{1}{\mu}\frac{\mathrm{d}P}{\mathrm{d}x}$$

where u is the velocity of the fluid in the x-direction, μ is the dynamic viscosity of the fluid, and $\mathrm{d}P/\mathrm{d}x$ is the pres-



Flow Rate Measurements, Methods, Figure 6 Flow characteristics of a heat-transfer-based flow sensor. The lowest flow rate without heat insulation is on the order of 30 nL/min [1]

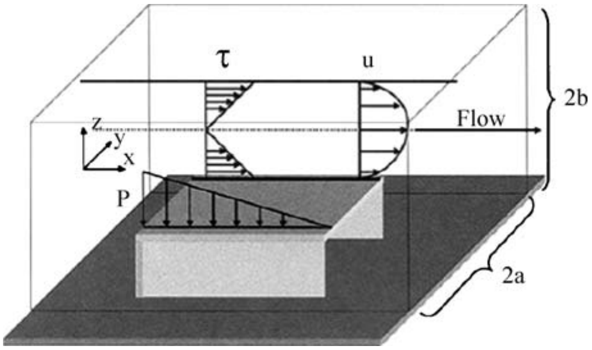
sure gradient along the direction of flow. The equation can be solved for the x-component of the fluid velocity to yield a relation between the volumetric flow rate and the pressure gradient, as below:

$$\frac{\mathrm{d}P}{\mathrm{d}x} = \frac{3\mu Q}{4ab^3}S$$

where Q is the volumetric flow rate, a and b are half of the height and half of the width of the channel, respectively, and S is a factor depending on the geometry of the channel. The shear stress acting on the top surface of the plate is given by

$$\tau = -z\frac{3\mu Q}{4ab^3}$$

Flow was established in the microfluidic channel shown in Fig. 7 by means of a syringe pump, and the angular deflection of the plate was monitored. The encapsulated plate provided local flow information along the length of the channel. Such plates operate independently of the absolute pressure, and sensors of this kind can provide local flow information along the length of a microfluidic system. The resolution of the angular-deflection measurement system was approximately 50 μrad, yielding a flow resolution of about 1 μL/min for the sensor. Figure 8 shows the response of the plate to a flow of ethanol [9]. The response of the flow meter was measured for flow rates ranging from 2.1 to 41.7 μL/min.



Flow Rate Measurements, Methods, Figure 7 Schematic of a plate encapsulated in a channel, showing the flow direction and the velocity profile for laminar flow above the device [9]

Molecular Sensing

This type of electrochemical flow sensor is similar to a thermal sensor; here, molecules such as oxygen are generated by applying an electric current. One such system is based on measuring dissolved oxygen in an aqueous solution using two closely spaced integrated oxygen sensors. Figure 9 shows the geometrical details of such a flow sensor [8].

Upon application of a negative potential to the working electrodes, oxygen is reduced and a current passes through:

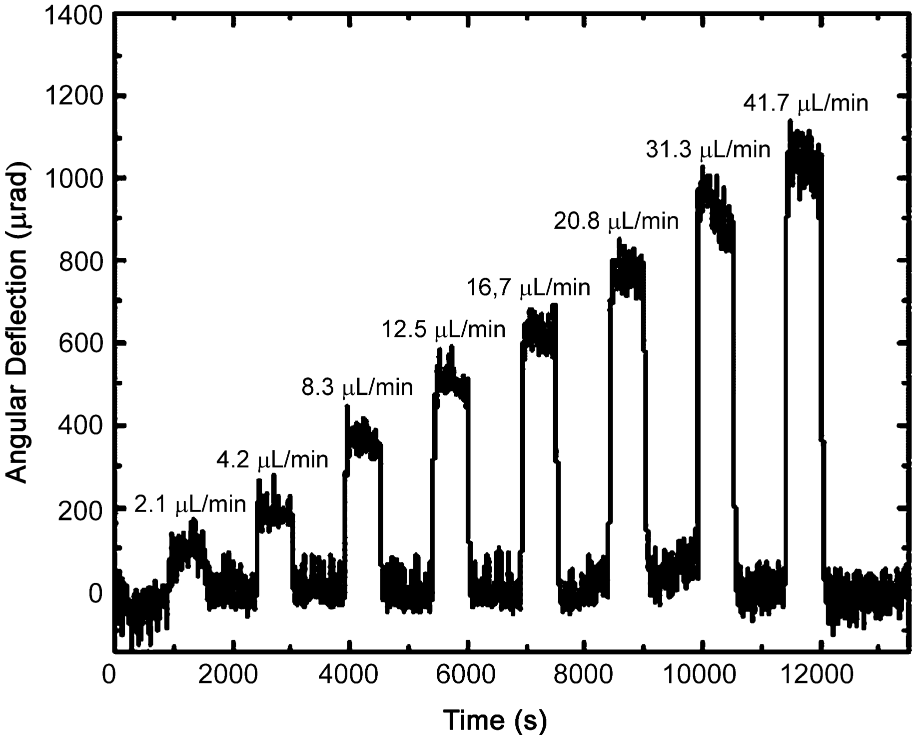
$$O_2 + 4H^+ + 4e^- \rightarrow 2H_2O$$

During measurement, the upstream amperometric oxygen sensor consumes part of the dissolved oxygen and the response of the downstream amperometric sensor is reduced, since the two sensors are closely spaced. The velocities in the y and z directions and diffusion along the x direction can be neglected. The kinetics of the electrode reaction are fast enough to deplete the oxygen immediately, and the oxygen concentration at the surface of the working electrode is zero. The current passing through the working electrode, i, is calculated according to Faraday's law:

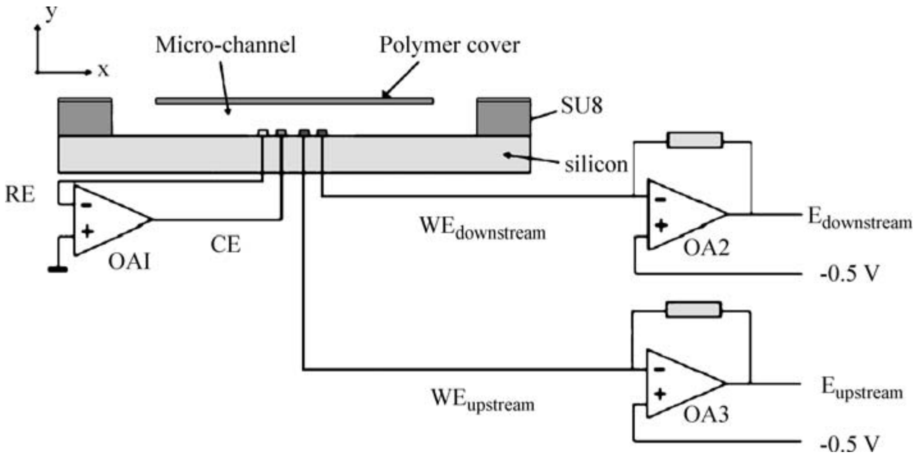
$$i = 4\mathrm{F}AD\frac{\mathrm{d}c}{\mathrm{d}y}$$

where F is the Faraday constant, c is the concentration of oxygen, D is the diffusion coefficient, and A is the area of the working electrode.

The difference between the responses of the two sensors is related to the convective transportation. By comparing the outputs of the two amperometric sensors, the flow rate can be obtained. Figure 10 shows the measured amperometric response of the upstream oxygen sensor at different flow rates. For curve a, a gas mixture of 10% oxygen and 90% nitrogen was bubbled into a Phosphate Buffered Saline (PBS) solution. For curve b, air was bubbled into



Flow Rate Measurements, Methods, Figure 8 Graph of the response of the plate to a flow of ethanol at eight different flow rates [9]



Flow Rate Measurements, Methods, Figure 9 Longitudinal cross section of a fabricated flow sensor and the related measurement setup. (The upstream and downstream oxygen sensors share a common counter and reference electrode) [8]. RE – reference electrode, CE – counter electrode, WE – working electrodes, OA – operational amplifier, SU8 – channel material

the solution. The figure shows that the current passing through the oxygen sensors is related to both the flow rate and the oxygen concentration in the solution. The ratio of the responses of the two sensors is related only to the flow rate and is not affected by the change of the dissolved oxygen concentration. This electrochemical flow sensor can detect flow rates in the region of several microliters per minute, and the advantage of this flow sensor is that no additional tracers have to be added or produced during the flow measurement.

Electrical-Impedance Sensing

Electrical-impedance-based flow sensing uses a pair of electrodes along the channel; this type of sensor is suitable for conducting solutions. An understanding of the

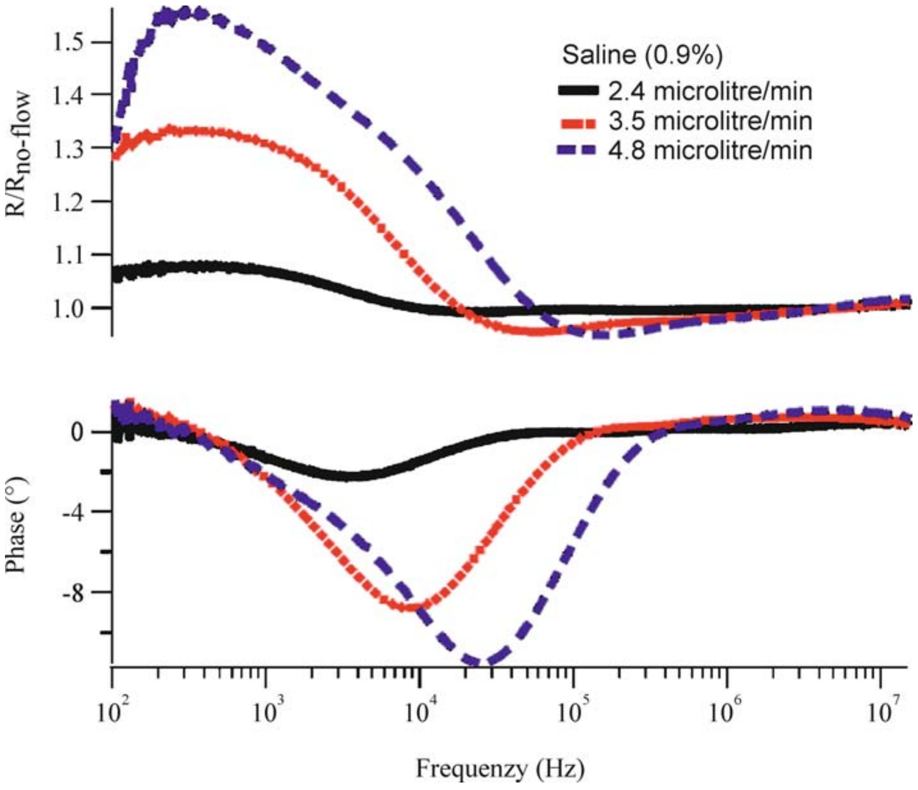
(The peaks in (**b**) correspond to the flow rate values labeled) [6]

electrical double layer is important for understanding the principle of operation of this flow sensor. When the flow rate is increased, the counterbalancing ions are replaced by the bulk solution, thereby lowering the average ionic concentration within the recording zone. This local concentration drop results in an increase in the real part of the impedance. Under hydrodynamic conditions, forced convection dominates the transport of ions to the electrodes within the flow channel. The electrical double layer formed across the channel, as shown in Fig. 11, is formed from two capacitances of the equivalent circuit, namely the diffusion layer capacitance (C_s) and the outer Helmholtz plane capacitance (C_e). The former is due to an excess or depletion of ions in the channel, and the latter is due to free electrons at the electrodes and is independent of the electrolyte concentration. The smaller of these capacitances dominates the admittance, since these capacitances are in series. The frequency of the applied ac voltage, the flow rate, and the conductivity of the fluid are the factors affecting the admittance of the fluidic system, and the flow-sensing principle is based on the optimization of these parameters.

For the electrochemical oxidation of a species A to A^{+} in a microchannel, the convective–diffusive equation for mass transport under steady-state conditions is given by



Flow Rate Measurements, Methods, Figure 14 Magnitude and phase data for the flow condition after the impedance spectra of the solution have been divided by the no-flow spectra [5]

Flow Rate Measurements, Methods, Table 1 Summary of the most popular flow sensors

Method	Flow rate limit	Sensitivity	Limitations
Heat transfer	0.01 μL/min	1.4 mV/(nL/min)	Heats the sampling fluid (~ 1 K/min/μL), complex fabrication
Mechanical	1.0 μL/min	50 μrad/(μL/min)	Moving parts, complex fabrication
Molecular sensing	2.5 μL/min	–	Aqueous fluids with dissolved oxygen
Optical	0.048 μL/min	–	No integration available
Flapping frequency	0.1 mm/s	–	Reported for gas flow, complex fabrication
Impedance sensing	0.05 μL/min	10^{-4} mA/(μL/min)	Limited to conducting fluids

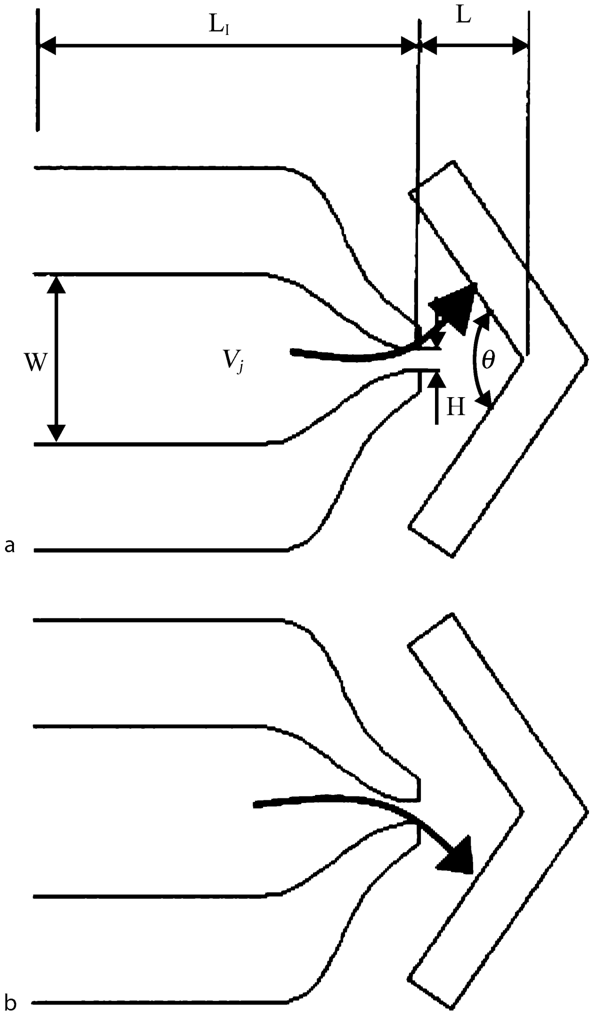
Eq. (2) below:

$$D_A \frac{\partial^2 [A]}{\partial y^2} - v_x \frac{\partial [A]}{\partial x} = 0 \qquad (2)$$

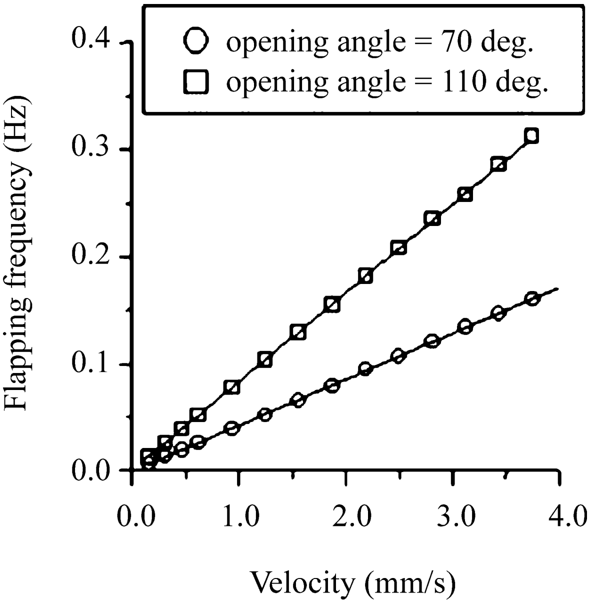
$$\frac{\partial A}{\partial t} = 0 \qquad (3)$$

$$i_L = 0.925 n \mathrm{F} [A]_{\mathrm{bulk}} D_A^{2/3} Q^{1/3} w \cdot \sqrt[3]{\frac{x_\mathrm{e}^2}{h^2 d}} \qquad (4)$$

Here $[A]$ is the concentration of the species A, D_A is the diffusion coefficient, and v_x is the velocity in the direction of flow. The first term represents lateral diffusion in the microchannel, and the second term represents transport along the length of the channel. Under steady-state flow conditions, the boundary condition is given by Eq. (3). The solution of this equation predicts the mass-transport-limited current as a function of the flow rate Q as given by Eq. (4), where n is the number of electrons transferred, F is the Faraday constant, x_e is the electrode length, h is the cell half-height, d is the width of the cell, and w is the electrode width. Note that the current due to the flow of electrolyte is directly proportional to the cube root of the volume flow rate of the fluid. An ac voltage signal is considered rather than a dc voltage, since the application of an ac voltage to the flow sensor does not promote any electrode reactions. Optimization of electrical parameters such as the voltage



Flow Rate Measurements, Methods, Figure 15 Schematic representation of the flapping motion of the jet column for a microflow sensor with a convergent nozzle and a V-shaped plate. Periodic flapping motion occurs when the impinging jet reaches the V-shaped plate. (**a**) Jet column flaps upwards, and (**b**) jet column flaps downwards [10]



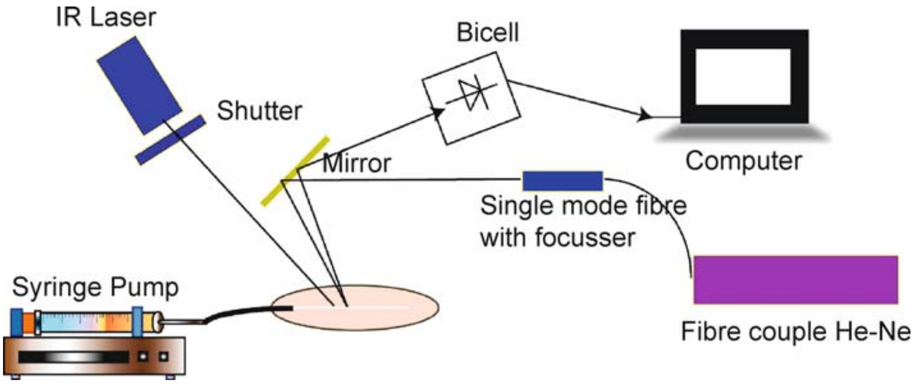
Flow Rate Measurements, Methods, Figure 16 The flow velocity is linearly proportional to the flapping frequency, and two sensors with different opening angles have similar behaviors [10]

and frequency of the ac signal is an essential condition for measuring low flow rates.

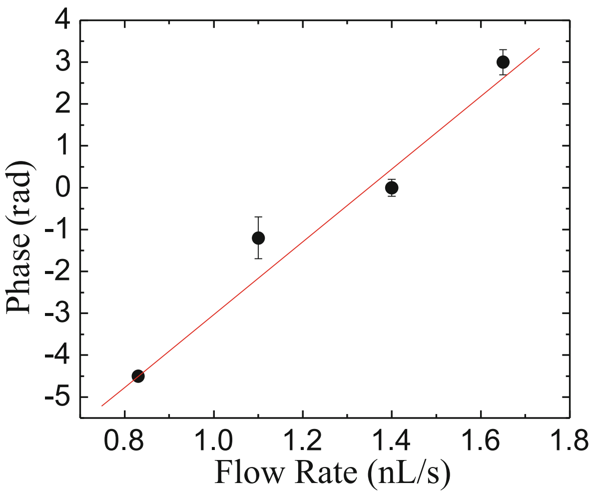
A flow sensor of this type was fabricated on a glass substrate with gold surface electrodes (Fig. 12a), and the microfluidic channel was made of PDMS. Gold of thickness 100 nm was deposited on an adhesion layer of titanium of thickness 20 nm using e-beam deposition. A spun layer of Shipley photoresist (1827) was used for patterning the metal (Fig. 12b). PDMS channels of width 500 μm were made from an SU8 mold. The glass and PDMS were bonded together after treatment with an oxygen plasma for 1 min. The fluidic channel was aligned with the parallel electrodes using a stereo microscope. The measuring instrumentation was similar to that used in strain gauge and thermocouple interfaces. The microfluidic flow was maintained at a constant flow rate using a Harvard Picoplus syringe pump. This flow sensor was capable of measuring very low values of flow rate, starting at 0.05 μL/min (< 1 nL/s). The response showed a cube root behavior even at very low flow rates, as shown in Fig. 13 [6]. The sensitivity after optimization was 5.2×10^{-4} mA/(μL/min). Fluorescent beads of diameter 2.5 μm were sent through the channel, and video microscopy of their flow profile was performed. The flow sensor results were compared with the velocity of the beads (shown by the asterisks in Fig. 13) and showed a similar response. Figure 14 shows the magnitude and phase data for the flow condition after the impedance spectra for the solution had been divided by the no-flow spectra [5].

Periodic-Flapping-Motion Detection

A flow sensor using this principle has been demonstrated [10] for gas flows; it works on the principle of detecting a periodic flapping motion of a planar jet impinging on a V-shaped plate downstream in the low-Reynolds-number regime. The Strouhal number St, which describes an oscillating flow by the ratio of the inertial forces due to unsteady flow to the inertial forces due to changes in velocity, was found to remain nearly constant if the open-



Flow Rate Measurements, Methods, Figure 17 Block diagram of the experimental setup for a backscatter interferometric flow-sensing system [3]



Flow Rate Measurements, Methods, Figure 18 Calibration curve of phase change vs. flow rate in a microfluidic channel [3]

ing angle of the V-shaped plate was appropriately chosen. The Strouhal number is defined as

$$\mathrm{St} = \frac{f_F L}{Vj}$$

where f_F, L, and V_j are the flapping frequency, the length of the impinging jet, and the jet exit velocity, respectively. Instead of sensing DC current or voltage signals induced by small volumes in the flow, this flow sensor detects the oscillation frequency of the periodic flapping jet, resulting in a higher sensitivity and a larger dynamic range than those of existing products. The sensor is composed of a planar convergent nozzle, a V-shaped plate downstream, and a pair of sensing resistors. A sample flow containing a dye allows the flapping motion of the impinging jet to be visualized under a microscope. The flapping motion has been confirmed experimentally even at a low flow velocity (0.15 mm/s). The flapping frequency is detected using built-in microsensing resistors driven by a constant-current circuit. Figure 15 shows a schematic of the flapping motion of the jet column for a microflow sensor with a convergent nozzle and a V-shaped plate. Even on the microscale, the flow velocity is linearly proportional to the frequency of the flapping motion, as shown in Fig. 16, and the velocity or volumetric flow rate of small amounts of flow can be measured by detecting the flapping frequency.

Optical-Sensing-Based Flow Sensors

Backscatter interferometry, optical coherent tomography, and particle-imaging velocimetry are some of the optical techniques for flow sensing. The backscatter interferometric flow-sensing system [3] may be considered to be in this category. This system is based on synchronous detection, and measurements of the phase difference with respect to fluid-heating events upstream produced by a focused IR source. The heating upstream is repeated for several cycles using a mechanical shutter inserted into the IR beam path. The frequencies of both the shutter and the detected signals are synchronous and time-varying. However, the detected signal downstream lags behind the shutter signal by the amount of time it takes for the fluid to warm up and propagate from the heating region to the detection region. The fluid flow velocity in the microchannel can be quantified by performing Fourier decomposition of the signals and calculating the phase change between the appropriate harmonics of those signals in the Fourier domain. A block diagram of the experiment is shown in Fig. 17. The interferometric backscatter detector is based on a fiber-coupled HeNe laser that illuminates a portion of an isotropically etched channel, and a position-sensitive transducer to measure fringe pattern shifts. An infrared laser with a mechan-

ical shutter is used to heat a section of the flowing volume, and the resulting refractive-index change is detected downstream as a time-dependent perturbation. The fluid velocity is quantified by changes in the phase difference with respect to the shutter signal, as in Fig. 18. This flow sensor has been established to be suitable for flow measurements in the range $3-6\,\mu L/h$ with a detection limits of $0.127\,nL/s$.

Key Research Findings

There have been reports on the theory of most types of flow sensor, and CFD simulations and experimental validations of them. Table 1 summarizes the most popular flow sensors, with the flow rate resolution or lower limit, and their limitations.

Future Directions for Research

There is a need for the development of flow sensors integrated into specific applications. Integrated micrototal analysis systems would require a feedback loop for reconfigurable and programmable assays, for controlling the dosage in the case of drug delivery, for reagent concentration control in bioassays, and for advanced on-chip micropumps that have flow regulation built in. Moreover, it is necessary to develop linear flow sensors which require no calibration and do not affect the fluid or the flow rate.

Definition

Surface acoustic wave (SAW) devices are widely used for frequency filtering in mobile communications [1]. Recently published works [2–10] have demonstrated the use of SAWs to manipulate liquid flow in microfluidic devices. A SAW is excited by the application of a radiofrequency (rf) signal to an interdigital transducer (IDT) on a piezoelectric substrate such as quartz or $LiNbO_3$. The wavelength of the SAW, having a typical value of a few micrometers, is determined by the geometry of the IDT. The amplitudes of the SAW are typically about a nanometer, depending on the applied rf power. As a SAW propagates on the surface of a piezoelectric solid, any viscous

materials such as liquids located at the solid surface will absorb most of its energy, which is indicated by an exponentially decaying amplitude. The interaction between the SAW and the liquid creates an acoustic radiation pressure (ARP) in the direction of propagation of the SAW in the liquid. This induces liquid currents or jets called acoustic streaming. This can lead to the flow of the liquid if the amplitudes of the SAWs are large enough [2].

Overview

The piezoelectric chip generating the SAW is coupled to microfluidic devices. The flow actuated by the SAWs is nonintrusive. There are no mechanical moving parts inside. It can comprise sealed containers without external plumbing. SAWs have been used to manipulate droplets [2–4] and to mix and pump liquids [5–10].
Wixforth et al. [3] have shown that droplets can be split, merged, mixed and actuated along predetermined trajectories using SAWs. Because of the nonlinear interaction between a SAW and a droplet, only droplets of certain size are agitated by a given SAW wavelength and power. This effect can be used to dispense droplets of a certain size out of others. When the SAW amplitude reaches a critical value, the pulse excitation even causes droplet ejection [4]. The ability of SAWs to stir and mix liquids is also used to eliminate non-uniformities in concentrations, as in a micro-mixer [5–8]. A higher applied rf power on the IDTs leads to a significant improvement in the mixing efficiency. However, the temperature also increases with the higher applied voltage [8]. Another feature of flow by SAWs is the rapid decay of the induced velocity field away from the IDTs. Guttenberg et al. [9] have shown that the velocity decreases with the inverse third power of the distance from the ultrasound generator.

Fluidic Diodes

Definition

Fluidic devices exhibiting different hydrodynamic properties for the two different fluid flow directions.
In the *forward* direction, fluid passes through a fluidic diode easily, encountering very small hydraulic resistance (dissipance). In the other, *reverse* direction the resistance is high. When supplied with an alternating fluid flow, this difference in properties results in the fluidic rectification effect. The simplest way how to obtain the diode properties is to use a moving component blocking the available flowpath in one of the two directions. More robust, easier to make, and capable operating at a higher frequency are no-moving-part diodes.

Fluidic Pumping

Definition

A method of generating non-return (or nearly non-return) fluid flow by processing the supplied alternating flow.
Fluidic devices need a supply of the fluid with which they operate. Sometimes there is an available external fluid source and in other cases the fluid may be provided from a pressurized vessel. Most often, however, the fluidic circuits are supplied with fluid flow from a fluidic pump. This consists of two essential parts: an alternator producing an alternating flow, usually by motion of a reciprocating plunger, piston, or diaphragm, and a rectifier which changes the alternating flow into a one-way or non-return flow.

Fluidic Rectification

Definition

The process of converting an alternating fluid flow into a one-way flow.
Usually fluidic devices need for their operation a source of one-way fluid flow. Much easier to generate, however, is an alternating flow produced by reciprocating motion of a displacing component. The simples way how to rectify an alternating flow is using a non-return valve with a moving component blocking the available flowpath. In the so called *valve-less* pumps the rectification effect is obtained by using inertial effects in fluid on one of the three basic sorts of devices: fluidic diodes, fluidic jet-type rectifiers, and traveling-wave rectifiers.

Definition

Fluid metering concerns the measurement of fluids, liquids in particular, in the form of flow rate and/or fluid volume. Apart from accuracy and precision, the uncertainty and traceability of measurements are important factors to be considered. For micro- and nanofluidic applications, the fluid may flow in channels with dimensions of a few millimeters or below, with flow rates ranging typically from microliters to nanoliters per minute, and the fluid may be dispensed in volumes on the order of microliters to picoliters.

Overview

Microfluidics is bringing about innovations in biotechnology, medicine, energy, and many other industries, and is one of the major branches of nanobiotechnology research [1]. However, the lack of reliable and accurate flow metering or even flow monitoring is one of

the key challenges to related applications that are delaying the commercial success of many innovations, because microfluidic products, especially those for medical use, must pass certification processes to prove their capability, reliability, safety, etc. Therefore, for accurate and reliable measurement, all metering techniques and devices should be traceable to basic SI units and/or international measurement standards. In the case of microscale fluid metering, the accuracy still needs to be improved, and the traceability chain and measurement standards need to be well established.

Fluids in capillaries or microchannels which are millimeters to micrometers in diameter or width can flow in a continuous form. Sometimes, however, in many applications, the fluid is dispersed into discrete droplets, for example in the case of a liquid that is injected onto a microarray chip. Therefore, in this article, metering of fluids is categorized into continuous flow rate measurement and droplet volume measurement.

Metering of Continuous Fluid Flow

In the case of flow in microscale pathways, some important parameters in macroscale fluid mechanics remain important, but the features of the flow are very different. The influences of viscosity and surface effects are much more significant compared with fluid flow in traditional pipelines or channels. That is, the ratio of the inertial force to the viscous force (Reynolds number) is in general smaller than unity, and the ratio of the inertial force to surface tension (Weber number) is also small, so that accurate microfluidic metering is somewhat more difficult than metering for macroscopic flows. For gas flows, the effect of the Knudsen number, defined as the ratio of the molecular mean free path to the channel size, is high and cannot be ignored for microscale channels, and hence the fluid metering discussed here will be for liquids only. The Reynolds number Re, the Weber number We, and the Knudsen number Kn are expressed as follows:

$$\begin{aligned} \mathrm{Re} &= \frac{\text{inertial force}}{\text{viscous force}} = \frac{\rho U L}{\mu}\,, \\ \mathrm{We} &= \frac{\text{inertial force}}{\text{surface force}} = \frac{\rho U^2 L}{\sigma}\,, \\ \mathrm{Kn} &= \frac{\text{molecular mean free path}}{\text{channel size}} = \frac{\lambda}{L}\,, \end{aligned} \tag{1}$$

where ρ and μ are the density and dynamic viscosity, respectively, of the fluid, U is the mean fluid velocity in a channel with a characteristic length L, σ is the surface tension, and λ is the molecular mean free path.

The flow rate in microfluidics, which is a key parameter in microbioassays, drug delivery, biomedical microfluidic systems, etc., ranges from some milliliters per minute to nanoliters per minute or even less.

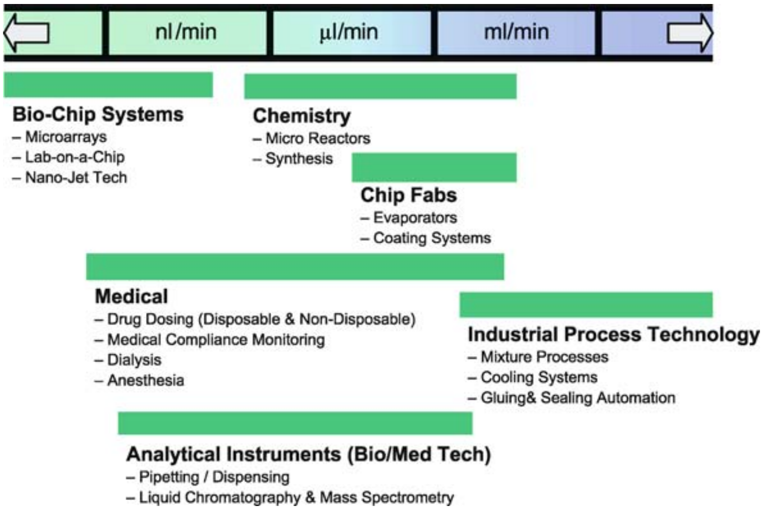
As shown in Fig. 1, the flow rate for medical uses ranges from about 1 nl/min to about 10 ml/min in the case of anesthesia, dialysis, and drug dosing. For analytical instruments for biomedical technology such as liquid chromatography and mass spectrometry, the flow rate is mainly in the range of nanoliters per minute to microliters per minute. For nanobiotechnology applications, such as microarrays for high-throughput diagnosis and labs-on-a-chip for biochemical analysis, the required flow rate reduces to less than 1 nl/min, a level typically referred to as *subnanoliter per minute*.

Many technologies have been developed to monitor or measure fluid flow in microdevices. The underlying mechanisms of these devices are based mainly on thermal or mechanical principles; examples of the variables to be measured are temperature, differential pressure, and drag force, which translate to thermal changes, deflection of cantilever beams, and shear strain, respectively. Most of these microflow sensors are manufactured by microelectromechanical systems (MEMS) processes without moving parts, and the flow rate measurements are mainly translated from velocity detection. For example, because flows in microchannels are in most cases laminar, the pressure drop Δp along a channel can be expressed as follows:

$$\Delta p = \mathrm{Re} \cdot f \frac{\mu L}{2 D_\mathrm{h}^2} U\,, \tag{2}$$

where f is the friction coefficient, L is the channel length, D_h is the hydraulic diameter, and U is the mean flow velocity. From Eq. (2), we can see that Δp is a linear function of U, and the flow rate, which is the product of the flow velocity and the channel cross section, can be determined by measuring the pressure difference.

Because direct measurement of flow rate by using microscale devices is difficult, most microflow sensors are designed to meter flow velocity. This is convenient and useful. For instance, a carbon nanotube (CNT) has been used as a flow sensor which generates a voltage when a polar liquid flows over it. The voltage produced shows a logarithmic dependence on the flow velocity, and the sensor exhibits a dynamic range of operation covering six orders of magnitude, from 100 nm/s to some cm/s [2]. This level of dynamic range is virtually impossible to achieve with traditional macroscale flow meters. Theoretically, multiplying the metered velocity by the cross-sectional area of the microchannel or capillary gives the flow rate. However, because of the uncertainty in the mea-



Fluid Metering, Figure 1 Flow rate ranges suitable for various industries

surement of areas in such small dimensions, the flow rate or fluid quantity is usually obtained by use of some built-in conversion after calibration.

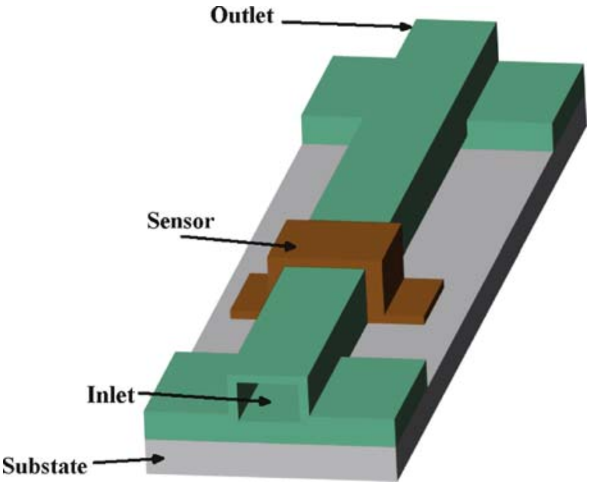
Metering of Discrete Droplet Volumes

The measurement of discrete droplet volumes is now playing a more and more important role in various applications such as pipettes, drug dispensing systems, inkjet printer heads, and microarray biochip spotters. The purpose of dispensing is to deliver a certain amount of a liquid sample, buffer solution, or frequently used library compound from a storage vial or mother plate to a cultivation container, test tube, assay plate, or microarray chip for subsequent handling. Applications in this field today are showing a trend toward a decrease in the volume of liquid to be handled, a trend that is promoted by the common interests of reducing the cost and increasing the speed and is made possible by the advancement of micro- and nanofluidic technologies.

The instrument most often used to dispense a measured volume of liquid is a pipette (also called a pipet or pipettor). It is commonly used in research in chemistry and molecular biology, as well as in medical tests, and the typical range of liquid volume that pipettes can handle is from 0.1 μl to 20 μl. For applications in which dispensing speed and cost-effectiveness are of particular concern, such as microarray biochips, automated dispensing is a prerequisite, and the liquid volume delivered goes down to nanoliters or even picoliters. The technologies used to deliver such tiny amounts of liquid are many, and can in general be categorized into contact dispensing, noncontact dispensing, and true contactless dispensing [3].

The dispensed liquid volume is one of the key parameters that need to be properly controlled in order for experiments and tests to be well conducted. In fact, experiments may fail simply because an erroneous liquid volume has been introduced, resulting mainly from an operator's poor technique or the use of uncalibrated instrument. For applications such as high-throughput screening, making sure that the liquid volume delivered is well controlled becomes even more important, since a small difference leads to a relatively large deviation, and the accuracy of the dispensed volume can substantially affect the analysis results. Therefore, measurement of the dispensed liquid volume is indispensable for satisfactory quality control of related products.

The method of measuring macroscale liquid volumes is simple and straightforward. The mass of the dispensed liquid is measured by a balance with appropriate precision, and then divided by its density. When the performance of a dispensing tool such as a piston-operated volumetric apparatus is evaluated, water is typically adopted as the working fluid, and the temperature is, in general, the only variable that needs to be monitored and controlled. The procedure suggested by the international standard ISO 8655-6 [4] is generally followed to ensure that the measurement uncertainty is within the acceptable range. However, for micro- and nanoscale droplet dispensing, the traditional weighing method encounters difficulties in yielding accurate and consistent measurement results. Therefore, the International Organization for Standardization (ISO) published a new standard, ISO 8655-7 [5], in 2005, detailing the use of nongravimetric methods, in particular photometric and titrimetric methods, for the assessment of equipment performance. Many other methods for



Fluid Metering, Figure 2 Example of a MEMS structure for metering the flow rate in a microchannel, based on the theory of constant-temperature anemometry

measuring or monitoring liquid volume have also been proposed, such as methods based on droplet images, fluorescent intensity, electric impedance, and interference fringes. These methods are somewhat specific and require further justification of their traceability when used in fluid metering; thus, they will not be discussed here.

Basic Methodology

Continuous Fluid Flow Measurement

Since thermal transfer accompanies the mass transfer of a fluid flow, microflow sensors based on thermal effects are the most common. An example of a MEMS thermal flow sensor is shown in Fig. 2.

When the sensor is heated and fluid flows through the sensor, heat will be taken away downstream. We can use this effect to measure the fluid flow. One application of the thermal effect is similar to the hot-wire anemometry used to measure wind velocity. Let us imagine that the sensor is made of tungsten wire, which will produce heat when electric power is supplied. If we try to keep the wire at a constant temperature, a higher current is needed for a faster fluid velocity. When thermal balance is reached, the heat generated by the electric power equals that dissipated owing to fluid flow. Therefore,

$$\begin{aligned} I^2 R_\mathrm{w} &= h \cdot A \cdot (T_\mathrm{w} - T_0) \\ &= \mathrm{Nu} \cdot (k_f/d) \cdot A \cdot (T_\mathrm{w} - T_0)\,, \end{aligned} \tag{3}$$

where I is the electric current, R_w is the resistance at the working temperature T_w, h is the heat transfer coefficient, A and d are the cross-sectional area and diameter, respectively, of the wire, Nu is the dimensionless heat transfer rate (Nusselt number), k_f is the coefficient of heat conduction, and T_0 is the fluid temperature. The dimensionless heat transfer rate can usually be expressed as

$$\mathrm{Nu} = A' + B'\,\mathrm{Re}^n\,, \tag{4}$$

where A', B', and n are empirical constants, usually determined by calibration. For a given working fluid and wire, the Nusselt number can then be expressed in terms of the mean fluid velocity U as follows:

$$\mathrm{Nu} = a + bU^n\,, \tag{5}$$

where a and b are constants to be determined. The resistance R_w at the working temperature T_w can be obtained from the following equation:

$$R_\mathrm{w} = R_0 \cdot \left[1 + \alpha\,(T_\mathrm{w} - T_0)\right]. \tag{6}$$

Thus, we have

$$\frac{(R_\mathrm{w} - R_0)}{R_0} = \alpha\,(T_\mathrm{w} - T_0)\,, \tag{7}$$

where R_0 is the resistance at a fluid temperature T_0, and α is the temperature coefficient of resistance. Equation (3) can be rewritten as the following equations:

$$I^2 R_\mathrm{w} = A \cdot (k_f/d) \cdot (T_\mathrm{w} - T_0) \cdot (a + bU^n)\,, \tag{8}$$

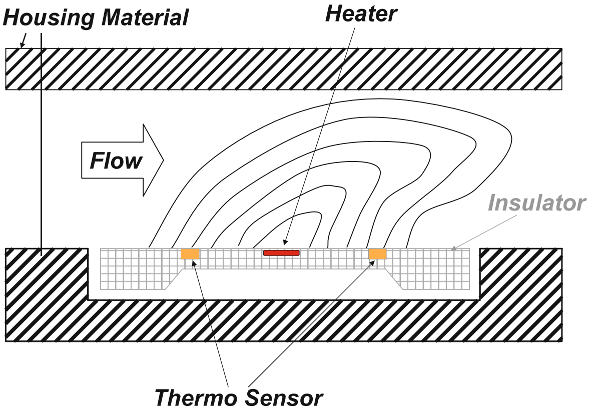
$$I^2 R_\mathrm{w}^2 = A \cdot R_\mathrm{w} \cdot (k_f/d) \cdot \frac{(R_\mathrm{w} - R_0)}{\alpha R_0} \cdot (a + bU^n)\,. \tag{9}$$

If the fluctuation in fluid temperature remains insignificant and the resistance R_w is made constant by keeping T_w constant with a feedback circuit, the relationship between the voltage drop in the wire V_w and the fluid velocity can be formulated as

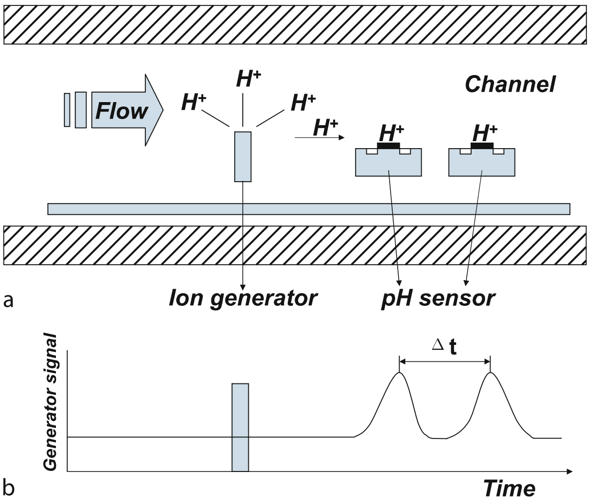
$$V_\mathrm{w}^2 = I^2 R_\mathrm{w}^2 \propto \left(a + bU^n\right). \tag{10}$$

The coefficients can be determined by a calibration process, and the fluid velocity can then be obtained by measuring the voltage drop. When the fluid velocity has been obtained, the volumetric flow rate can be calculated by multiplying the velocity by the cross-sectional area.

A sensing line embedded in the wall of a microchannel is more complicated than a single tungsten wire, but the analysis is the same. In order to successfully integrate a suitable metering element, various sensing structures need to be designed and tested. Linearity, reliability, and sensitivity to velocity variation are key features to be concerned



Fluid Metering, Figure 3 Illustration of the operational principle of a microflow sensor that uses a heating element to heat the fluid, and two thermosensors to measure the temperatures upstream and downstream of the element. The temperature difference is used to determine the flow rate



Fluid Metering, Figure 4 Illustration of the operational principle of a microflow sensor that uses an ion generator and two pH sensors to measure the flow rate. The ions follow the fluid flow, and the difference of the arrival times at the two sensors determines the flow velocity

with. Generally, a design with high temperature coefficient of resistance in Eq. (6) is preferred, since this should increase the sensitivity of the sensor.

Another approach to measuring fluid flow, which also applies thermal principles, is illustrated in Fig. 3.

A resistor providing a continuous heating power of a few milliwatts is placed in the flow channel. At both the left and right sides of the resistor, two thermosensors are embedded symmetrically to measure the temperature. If the fluid in the channel is still, the temperature field, represented by the isotherms, is symmetric and the two sensors will measure the same temperature. When the fluid flows at some velocity, the isotherms will be distorted and hence the thermosensors will measure different temperatures, which are then used to determine the fluid velocity. The temperature field affected by the fluid flow can be simulated numerically by using the Navier–Stokes equations with a boundary condition of constant flow velocity.

The concept of *time of flight* has also been adopted, similarly to its use in ultrasonic flowmeters for macroscale flows. A heat pulse is generated upstream by a laser or electric coil, and the heated fluid is detected downstream. The time difference is used to determine the velocity and then the volumetric flow rate. However, diffusion of heat in the fluid results in a broadened temperature distribution when the fluid reaches the sensors, and hence results in difficulty in determining the transit time accurately. An ion generator can be used to replace the heater for the purpose of determination of the time of flight [6].

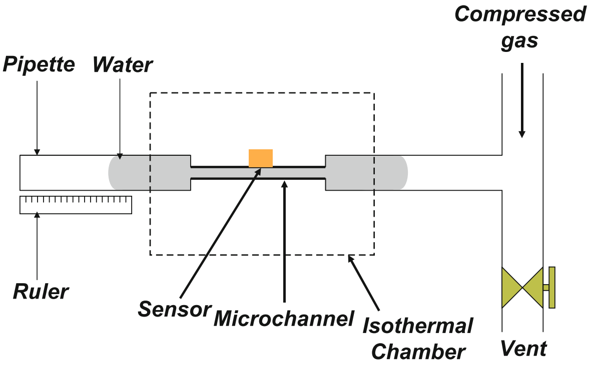
As shown in Fig. 4, H^+ or OH^- ions are generated on demand by an upstream ion generator, and two pH-sensitive sensors located downstream are used to detect the time of flight of ions flowing from the upstream sensor to the downstream sensor.

Verification of Flow Rate Measurement

As mentioned earlier, most metering devices in fact measure the flow velocity. When a measurement is made with a microflow sensor, if the flow in the microchannel can be resolved simultaneously by using high-resolution velocimetry, such as by means of a microresolution particle image velocimetry (μ PIV) system that has been calibrated by use of a calibrated interferometer and timer, traceability can be achieved by comparing the results. For devices that indicate a flow rate or fluid quantity on a panel, however, direct tracing back to reference standards is faster and more reliable. For example, a flow sensor or flow controller such as a syringe pump can be calibrated by use of a standard flow rate system that has been certified and is traceable to basic physical standards such as standards of time, length, mass, and luminous intensity.

Some researchers have tried to set up calibration facilities to verify the metering performance of their microflow sensors. A simple way is to connect the sensor to a pipette with a scale [7]. As shown in Fig. 5, the liquid is pushed by compressed air, and the scale is read over a time interval to obtain a reference flow rate. The meter error E can be easily estimated by direct comparison:

$$E = Q_\mathrm{m} - Q_\mathrm{s} = Q_\mathrm{m} - \left(\frac{\Delta l \cdot \pi d_\mathrm{i}^2}{4 \Delta t} \right) , \qquad (11)$$



Fluid Metering, Figure 5 Schematic diagram of an experimental setup for the calibration of a microflow sensor. The liquid, driven by compressed air, flows through the sensor under test into a pipette with a scale. The liquid volume collected in the pipette within a certain time interval is used to determine the flow rate

where Q_m is the meter reading of the microflow sensor, and Q_s is the reference standard obtained from the distance of travel Δl of the liquid–air interface during a time interval Δt and the inner diameter d_i of the pipette.

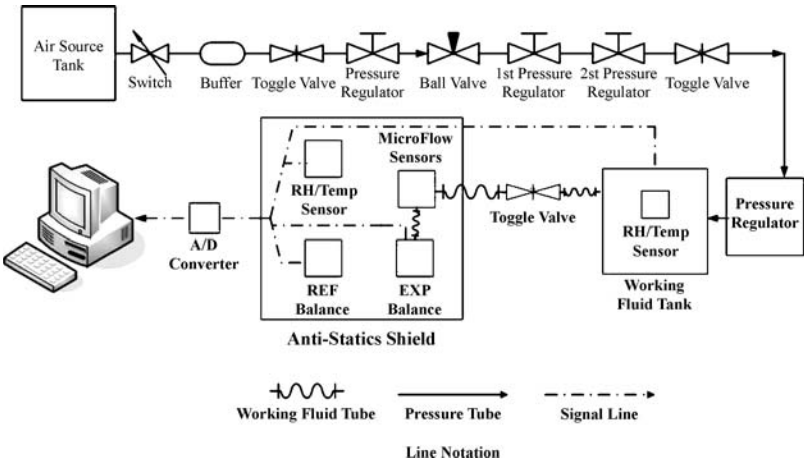
In another approach, which is a little more complicated [8], a glass capillary is placed on a cooled metal plate to stabilize the temperature of the fluid and then an infrared laser pulse heats up a mass of liquid. Because the refractive index is a function of temperature, instruments that are sensitive to the change of refractive index are installed downstream to detect the heated liquid. However, thermal diffusion makes it complicated to accurately determine the arrival time of the heated mass of liquid.

For a standard of flow rate metering, traceability is the top priority; the measurement uncertainty should be sufficiently small, and a system that features simple operation, low measurement uncertainty, and high repeatability is desirable. Therefore, approaches based on weighing are, above all others, favorable candidates for such a purpose. As shown in Fig. 6, a gravimetric primary metering standard has been set up to achieve these requirements [9]. Liquid water is driven by a pneumatic pressure control mechanism to obtain flow rates down to less than a microliter per minute. The measurement capability depends on the weighing of the collection beaker, the stability of the pressure difference, the time interval, and the variation of the ambient temperature. Buoyancy variation and liquid evaporation are critical concerns for measurements associated with such a small quantity of liquid.

In this setup, a liquid in a reservoir tank is pushed into 1/8 inch connection pipes or microchannels by a preset air pressure. The air pressure must be well controlled, for example by using a two-stage valve system followed by a pressure modulator. The liquid flows through the microflow sensor to be verified and then into a collection tank installed on a high-precision balance. To eliminate buoyancy effects due to changes in the air density during calibration, a twin-balance arrangement has been adopted. This means that a similar collection tank is installed on another balance, and the difference between readings before and after the calibration period is used for buoyancy compensation. Both the balances are well covered with a glass shield to avoid any influence from the ambient air flow. In addition, the liquid in the collection tank is covered with low-volatility oil to eliminate evaporation. The oil should be full to the edge of the collection tank, which is placed inside a larger beaker. The oil will overflow into the larger beaker so as to maintain a constant outlet pressure and reduce possible weight variations.

After the fluid meter has been connected in series between the reservoir and the collection beaker, calibration can begin when the fluid flow reaches steady state. The recorded weights before and after a preset time interval are used to calculate the mass flow rate. The mass flow rate is expressed accurately as follows:

$$
\begin{aligned}
q_m &= \frac{m_1 - m_0}{t} \\
&= \frac{V_{cv} \times \rho_{l,1} + W_1 + (V_{tank} + \Delta V_{tank}) \times \rho_{a,1}}{t} \\
&\quad - \frac{(V_{cv} \times \rho_{l,0} + W_0 + V_{tank} \times \rho_{a,0})}{t} \\
&= \frac{V_{cv} \times (\rho_{l,1} - \rho_{l,0}) + (W_1 - W_0)}{t} \\
&\quad + \frac{V_{tank} \times (\rho_{a,1} - \rho_{a,0}) + \Delta V_{tank} \times \rho_{a,1}}{t} \\
&= \frac{V_{cv} \times (\rho_{l,1} - \rho_{l,0}) + (W_1 - W_0)}{t} \\
&\quad + \frac{(W_1 - W_0)/\rho_{l,1} \times \rho_{a,1} + V_{tank} \times (\rho_{a,1} - \rho_{a,0})}{t} \\
&= \frac{V_{cv} \times (\rho_{l,1} - \rho_{l,0}) + (W_1 - W_0)}{t} \\
&\quad + \frac{(W_1 - W_0)/\rho_{l,1} \times \rho_{a,1} + V_{tank,\,ref} \times (\rho_{a,1} - \rho_{a,0})}{t} \\
&= \frac{V_{cv} \times (\rho_{l,1} - \rho_{l,0}) + (W_1 - W_0)(1 + \rho_{a,1}/\rho_{l,1})}{t} \\
&\quad + \frac{(W_{ref,1} - W_{ref,0})}{t} \\
&= f(V_{cv}, \rho_{l,1}, \rho_{l,0}, W_1, W_0, \rho_{a,1}, W_{ref,1}, W_{ref,0}, t)\,, \qquad (12)
\end{aligned}
$$



Fluid Metering, Figure 6 Diagram of a twin-balance weighing system serving as a primary standard for microflow sensor calibration

where q_m is the mass flow rate in g/min, m is the liquid mass in the collection beaker in g, W is the reading from the balance in g, V_{cv} is the control volume between the outlet of the fluid meter and the collection beaker in cm^3, ρ_l and ρ_a are the density of the liquid and air, respectively, in g/cm^3, and t is the collection time in minutes. The subscripts 0 and 1 represent the initial and final conditions, respectively, and ref denotes the reference balance. A total of nine variables are considered in the equation. The volume flow rate q_v can be obtained by dividing the mass flow rate by the liquid density:

$$q_v = \frac{q_m}{\rho_{l,1}} = g(V_{cv}, \rho_{l,1}, \rho_{l,0}, W_1, W_0, \rho_{a,1}, W_{ref,1}, W_{ref,0}, t) . \quad (13)$$

The density of liquid water is a function of its temperature T_l, and can be determined from the following formula:

$$\rho_l = 0.99985308 + 6.32693 \times 10^{-5} \times T_l - 8.523829 \times 10^{-6} \times T_l^2 + 6.943248 \times 10^{-8} \times T_l^3 - 3.821216 \times 10^{-10} \times T_l^4 . \quad (14)$$

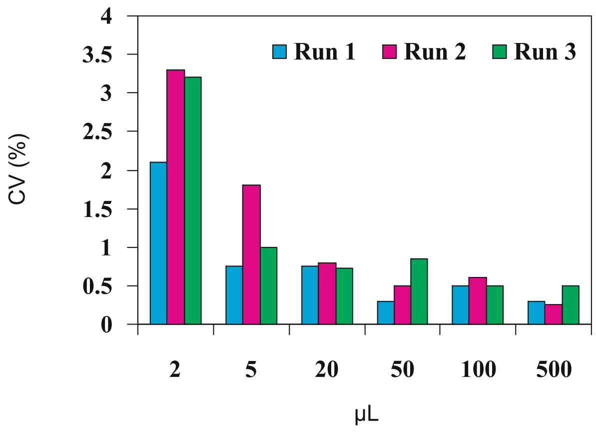
A check standard, used to confirm the reliability of the calibration, is always necessary. For example, a circular capillary can be used, and the Hagen–Poiseuille formula can be applied to obtain the theoretical flow rate,

$$q_V = \frac{\pi}{8} \frac{r_0^4 \cdot \Delta p}{\nu \cdot \Delta l} , \quad (15)$$

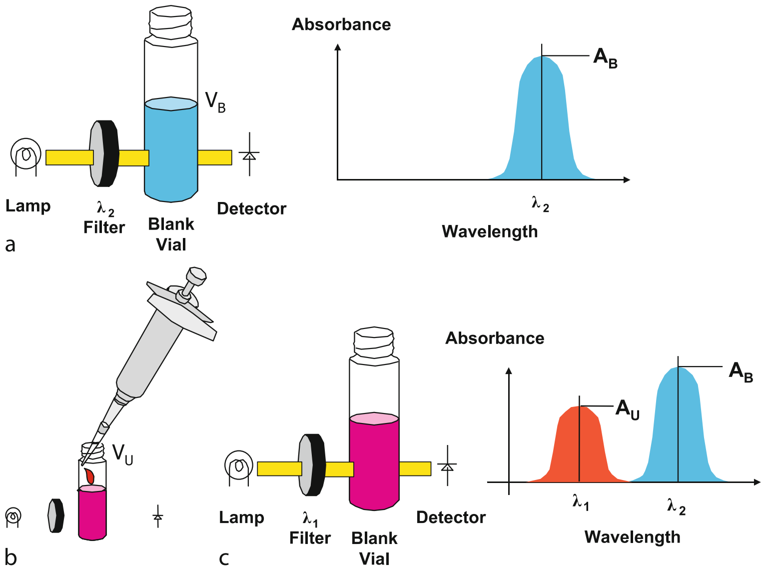
where r_0 is the inner radius of the capillary tube, Δp is the pressure difference between two detection points a distance Δl apart, and ν is the dynamic viscosity. Periodically connecting this capillary to the calibration standard and measuring the flow rate simultaneously for comparison is important.

Volume Measurement of Discrete Droplets

The gravimetric method is suitable for measuring the volume of liquid dispensed by pipettes, and it is commonly adopted to assess the performance of such instruments. Trained personnel are required to carry out such tests. The balances used for this purpose may have a precision of four to seven decimal places, depending on the volume to be measured and the desired accuracy. It should be well



Fluid Metering, Figure 7 Performance verification results for measurements of dispensed liquid volumes conducted by the gravimetric method



Fluid Metering, Figure 8 Measurement procedure using the dual-dye, dual-wavelength photometric method for the determination of dispensed liquid volume

established that the experimental setup is free from environmental disturbances such as vibration and air flow. Two points need to be addressed when the gravimetric method is used. The first one is the determination of the Z-factor, which is the transformation factor between the volume V and mass m of liquid. The volume dispensed is determined by the following equation:

$$V = m \cdot Z\,. \tag{16}$$

The Z-factor has units of microliters per milligram (μl/mg), and its value, dependent on barometric pressure and temperature, is tabulated in the literature [4]. For example, at one atmosphere, the value of the Z-factor for temperatures between 15 and 30 °C ranges from 1.0020 to 1.0054. The second point is the error due to evaporation, which inevitably takes place during the measuring process. Especially for small volumes below 50 μl, the evaporation rate should be calculated, and the design of the weighing vessel and the test cycle time are important. The mean volume $\bar{V}$ in the case of multiple dispensing can be calculated from the following equation:

$$\bar{V} = (\bar{w} + \bar{e} \cdot t) \cdot Z\,, \tag{17}$$

where $\bar{w}$ is the average weight, $\bar{e}$ is the average evaporation rate, and t is the test cycle time.

For the measurement of very small volumes of liquid, the gravimetric method becomes difficult to implement with accuracy.

As demonstrated in Fig. 7, which shows the results for a pipette checked using the gravimetric method, the coefficient of variation (CV, defined as the ratio of the standard deviation to the mean) for a run consisting of 10 measurements of a given volume increases considerably when the dispensed liquid volumes are less than 5 μl. Evaporation, buoyancy, vibration, and the effects of static electricity are the primary causes of these results. A possible alternative method to determine microscale droplet volumes is one based on measurement of the concentration of a liquid solution. Two practices, also recommended by the ISO standard [5], are commonly used, namely the photometric and titrimetric methods.

The theory of operation of the photometric method for determining dispensed liquid volumes is based on the Beer–Lambert law, which can be written as follows:

$$A(\lambda) = \log_{10}\left(\frac{I(0)}{I(l)}\right) = -\log_{10}(T(\lambda)) = \varepsilon(\lambda) l C\,, \tag{18}$$

where A is the absorbance, which is a function of the wavelength λ of the incident light; $I(0)$ and $I(l)$ are the intensities of the incident and transmitted light, respectively; l is the length of material that the light travels through; T is the transmittance; ε is the molar absorptivity; and C is the molar concentration of the material. Eq. (18) implies that for a given substance and a fixed wavelength of light, the absorbance of the sample has a linear relationship to its molar concentration and the path length. Although a setup with a single-dye, single-wavelength design is feasi-

ble for determining the volume of liquid delivered, a dual-dye, dual-wavelength ratiometric photometry technique is generally used since it enables the measurement to be independent of the path length.

The measurement procedure using the dual-dye, dual-wavelength photometric method is shown in Fig. 8. A test vial is loaded with a blank solution of known volume (V_B) and concentration (C_B), with a peak absorbance (A_B) at a wavelength λ_2. A drop of the sample solution, which has a peak absorbance at another wavelength λ_1 and nearly zero absorbance at λ_2, with a known concentration (C_S) and an unknown volume (V_U), is dispensed into the test vial, and it is mixed fully with the blank solution. The absorbance (A_U) of the mixture at the wavelength λ_1 is then measured. With a knowledge of the extinction coefficients of the blank and sample solutions ε_B and ε_S, respectively, the unknown droplet volume can be calculated using the following formula derived from the Beer–Lambert law:

$$V_U = V_B \left[\frac{\frac{A_U}{A_B}}{\frac{\varepsilon_S C_S}{\varepsilon_B C_B} - \frac{A_U}{A_B}} \right] . \tag{19}$$

The sources that need to be taken into consideration in the evaluation of the measurement uncertainty of the photometric method include instrument-related uncertainties, for example imprecision and drift in absorbance readings; reagent-related uncertainties, for example uncertainties in the volume and temperature of the reagents, incomplete mixing, pH dependence, and evaporation; and system-related uncertainties, for example system nonlinearity.

The principle of the titrimetric method is based on the chemical equivalence of two solutions. In general, any titration system can be used. A test solution with a known concentration C_D and an unknown volume V_U is dispensed into a titration vessel containing a receiver liquid, followed by a titration process with a titration solution of known concentration C_T. An auxiliary solution may be required to adjust the pH value before the titration starts. The equivalence point E_Q (in milliliters) is determined by potentiometric detection, for example with a silver electrode. The unknown volume can be calculated using the following formula:

$$V_U = E_Q \times \frac{C_T}{C_D} . \tag{20}$$

The titrimetric method described here is, according to ISO 8655-7 [5], suitable for measuring dispensed liquid volumes greater than 500 µl. This is not satisfactory, since our goal here is to measure liquid volumes of a few microliters or under. However, a technique based on the principle of titration of two liquids and measurement of the pH value of the resulting solution has been demonstrated to be feasible for the characterization of liquid volumes in the nanoliter range [10]. The long test cycle time and some issues in the evaluation of the uncertainty of this technique are, however, yet to be resolved.

Verification of measurements conducted by the photometric or titrimetric technique can be done easily by comparing the results with results from the gravimetric method if the volume dispensed is sufficiently large. However, for the measurement of small liquid volumes where the gravimetric method is no longer applicable, verification can be difficult. In that case, cross-validation between various measuring techniques and/or comparison with a calibrated dispenser is essential.

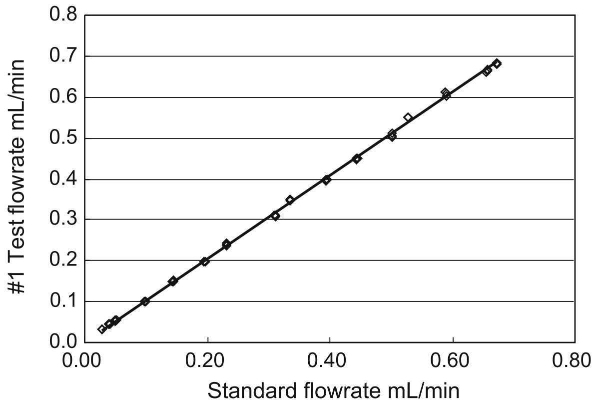
Key Research Findings

According to ISO GUM, which is a guide to the expression of uncertainty in measurements, the measurement uncertainty of the primary flow rate calibration system described above can be estimated as follows:

$$\begin{aligned} \left[\frac{u_c(q_\mathrm{m})}{q_\mathrm{m}}\right]^2 &= \left[\frac{\partial f}{\partial V_\mathrm{cv}}\frac{u(V_\mathrm{cv})}{q_\mathrm{m}}\right]^2 + \left[\frac{\partial f}{\partial \rho_{\mathrm{l},1}}\frac{u(\rho_{\mathrm{l},1})}{q_\mathrm{m}}\right]^2 \\ &+ \left[\frac{\partial f}{\partial \rho_{\mathrm{l},0}}\frac{u(\rho_{\mathrm{l},0})}{q_\mathrm{m}}\right]^2 + \left[\frac{\partial f}{\partial W_1}\frac{u(W_1)}{q_\mathrm{m}}\right]^2 \\ &+ \left[\frac{\partial f}{\partial W_0}\frac{u(W_0)}{q_\mathrm{m}}\right]^2 + \left[\frac{\partial f}{\partial \rho_{\mathrm{a},1}}\frac{u(\rho_{\mathrm{a},1})}{q_\mathrm{m}}\right]^2 \\ &+ \left[\frac{\partial f}{\partial W_{\mathrm{ref},1}}\frac{u(W_{\mathrm{ref},1})}{q_\mathrm{m}}\right]^2 + \left[\frac{\partial f}{\partial W_{\mathrm{ref},0}}\frac{u(W_{\mathrm{ref},0})}{q_\mathrm{m}}\right]^2 \\ &+ \left[\frac{\partial f}{\partial t}\frac{u(t)}{q_\mathrm{m}}\right]^2 . \end{aligned} \tag{21}$$

Similarly,

$$\begin{aligned} \left[\frac{u_c(q_\mathrm{v})}{q_\mathrm{v}}\right]^2 &= \left[\frac{\partial g}{\partial V_\mathrm{cv}}\frac{u(V_\mathrm{cv})}{q_\mathrm{v}}\right]^2 + \left[\frac{\partial g}{\partial \rho_{\mathrm{l},1}}\frac{u(\rho_{\mathrm{l},1})}{q_\mathrm{v}}\right]^2 \\ &+ \left[\frac{\partial g}{\partial \rho_{\mathrm{l},0}}\frac{u(\rho_{\mathrm{l},0})}{q_\mathrm{v}}\right]^2 + \left[\frac{\partial g}{\partial W_1}\frac{u(W_1)}{q_\mathrm{v}}\right]^2 \\ &+ \left[\frac{\partial g}{\partial W_0}\frac{u(W_0)}{q_\mathrm{v}}\right]^2 + \left[\frac{\partial g}{\partial \rho_{\mathrm{a},1}}\frac{u(\rho_{\mathrm{a},1})}{q_\mathrm{v}}\right]^2 \end{aligned} \tag{22}$$



Fluid Metering, Figure 9 Example of calibration of a microfluid meter using the gravimetric method

$$+\left[\frac{\partial g}{\partial W_{\mathrm{ref},1}}\frac{u(W_{\mathrm{ref},1})}{q_{\mathrm{v}}}\right]^2+\left[\frac{\partial g}{\partial W_{\mathrm{ref},0}}\frac{u(W_{\mathrm{ref},0})}{q_{\mathrm{v}}}\right]^2$$
$$+\left[\frac{\partial g}{\partial t}\frac{u(t)}{q_{\mathrm{v}}}\right]^2 ,$$

where u denotes the standard uncertainty of the variable within the accompanying parentheses, and the partial differential of each variable is the sensitivity coefficient. Each variable could contribute its measurement uncertainty to the final combined standard uncertainty u_{c}, in the form of a Type A or Type B uncertainty, defined in ISO GUM. If we consider a gravimetric system, that system could be a measurement standard for flow rates of 0.1 mg/min to 10 g/min (0.1 μl/min to 10 ml/min) at temperatures of 15 to 26 °C and pressures of 1 kPa to 60 kPa, and the relative expanded uncertainty of the system is smaller than 1.1%.

An example of a calibration is shown in Fig. 9, where flow rates obtained from a meter under test, denoted by squares along with a linear fit, have been plotted against those of a calibration system. Because the instruments used to measure the nine variables can have their own calibration chains, the traceability of the microflow meter has therefore been established.

If flow rates down to 1 nl/min are required, the gravimetric method is no longer practical owing to the limits of balances, and evaporation or leakage during the long time required for calibration.

Therefore, a chip-based, time-of-flight-type microflow rate calibrator, as shown in Fig. 10, has been proposed [9]. When an interface formed by two fluids that have different dielectric constants and are insoluble in each other, for example a water/air or water/oil interface, passes through an electrode node, the potential changes owing to the change in equivalent capacitance. In contrast to other approaches of this kind, which generally suffer from the effects of diffusion, the determination of the time of flight in this calibrator can be more precise, since the interface follows the flow faithfully and does not change over time while moving in the microchannel. The volume between any two electrode nodes could be obtained from a calibrated flow rate determined by a primary system and the time interval between two detection signals. This calibrator can thus be traced back to the primary standard and be used to calibrate lower flow rates.

In principle, the capability to determine small dispensed liquid volumes using concentration measurement increases as the amount of diluent or receiver liquid in the test container is reduced, as long as taking measurements remains possible with the instruments used. This feature is a consequence of the scalability of these methods. However, the use of a large volume is essential in order to obtain measurements with low uncertainty, and it is virtually inevitable, to a certain degree, that the uncertainty becomes higher as the liquid volume handled becomes lower. This is a trade-off and requires elaborate consideration when these methods are to be used.

Future Directions for Research

Accurate micro- and nanoscale fluid metering is important since it serves as a basis for evaluating the performance of microfluidic devices, and thus is critical to the quality control of those devices and systems using them. Establishment of a traceability chain and evaluation of the measurement uncertainty for flow rate and droplet volume metering instruments are important, especially for levels of liquid quantity that cannot feasibly be dealt with by gravimetric methods. Moreover, reliable methods to mea-

F

sure extremely small liquid volumes, for example 10 nl or below, are yet to be developed.

Fluorescence

Definition

Fluorescence is the property whereby some atoms and molecules absorb light at a particular wavelength and subsequently emit light of longer wavelength after a brief interval, termed the fluorescence life-time. Photons from an external source are absorbed by the fluorophore and this produces excited singlet state electrons. However, the time taken for these electrons to return to the lower energy level is known as the excited state lifetime. The emission of light occurs as fluorescence from an excited electron singlet state, where all the electrons in the molecule are spin-paired. The return to ground states occurs, with the emission of photons. Emission rates are fast being in the region of $10^8\ s^{-1}$ and fluorescence life-times are relatively short. Many fluorophores have sub-nanosecond life-times and, therefore, the fluorescence emitted by these dyes is short-lived.

Definition

Fluorescence is the phenomenon where a molecule absorbs energy from incoming light and instantaneously emits another light, in which the emitted light has a longer wavelength than the absorbed light. Fluorescence measurements are methods to quantitatively visualize and characterize a physical, biological, or chemical process, based on the characteristics of fluorescence that occurs during the process.

Overview

Fluorescence is a type of luminescence, which is light that is not generated by high temperature. In fluorescence, a molecule (usually called as a fluorochrome, a fluorophore, or a fluorescent dye) absorbs energy from incoming light and instantaneously emits another light, where the emitted light has a longer wavelength than the absorbed light [1]. The molecule stops emitting light immediately when there is no more incoming light. The fluorescence signals can be measured to quantitatively visualize and characterize a physical, biological, or chemical process. Fluorescence measurements are very useful because they are sensitive and specific to the studied process. Moreover, the fluorescently visualized process can be imaged in detail and analyzed further using various image processing and analysis techniques. This advantage, along with the high spatial measurement capabilities allowed by optical microscopy, is highly crucial for investigations in very small scale such as in microfluidics and nanofluidics. Several methods to measure fluorescence signals, in particular related to quantitative visualization and characterization of phenomena in microfluidic and nanofluidic channels, will be reviewed in this entry.

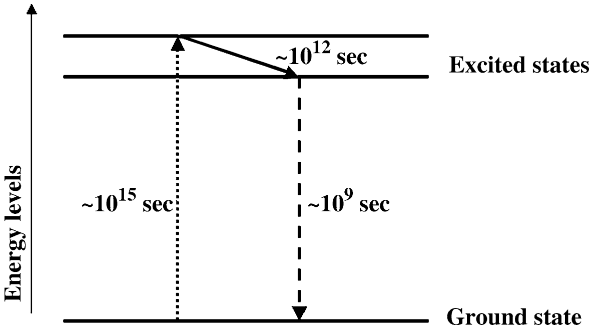
The fluorescence phenomenon occurs in three steps: excitation of the fluorochrome by the energy absorbed from incoming light (it occurs in 10^{-15} s); vibrational relaxation of the fluorochrome, where the energy of the fluorochrome is lowered from the original excited state to the lowest excited state (it occurs in 10^{-12} s); and emission of light with longer wavelength from the fluorochrome (it occurs in 10^{-9} s) [1]. The various energy levels involved in the fluorescence phenomenon are illustrated in the so-called Jablonski diagram, as shown in Fig. 1.

Both the energy absorbed from the incoming light and the energy contained in the emitted light occur in discrete amounts, which are termed quanta, and can be expressed by the equation:

$$E = \mathrm{h}f = \mathrm{h}\frac{\mathrm{c}}{\lambda}\,, \tag{1}$$

where E is the energy, h is Planck's constant ($6.626068 \times 10^{-34}\,\mathrm{m^2 kg\,s^{-1}}$), f is the light frequency, c is the speed of light in vacuum, and λ is the light wavelength. In general, fluorescence measurements are performed using lights with wavelengths ranging from ultraviolet to visible, which is between 250 and 750 nm. The difference of wavelengths between the excitation and emission light is caused by the second step in the fluorescence phenomenon, which is the vibrational relaxation of the fluorochrome. In this step, some of the absorbed energy is transformed into changes in structural arrangement of the fluorochome molecule. The shift of wavelength from the excitation light to the emission light is termed as the Stokes shift. Once a fluorochrome molecule reaches its original state, it can be excited again, and the fluorescence signal can be generated repeatedly using a continuous excitation light.

Fluorochrome molecules are usually characterized using their quantum yield and ►fluorescence lifetime. Quantum efficiency is a measure of the efficiency of the fluorochrome's fluorescence emission compared to all possible energy relaxation pathways. This dimensionless parameter is expressed as the ratio between the number of photons (that is the smallest discrete amount of light) emitted and



Fluorescence Measurements, Figure 1 The Jablonski energy diagram of the fluorescence phenomenon. The dotted line illustrates the excitation of the fluorochrome molecule, the solid line represents the vibrational relaxation of the excited fluorochrome molecule, and the dashed line shows the emission of light with longer wavelength

the number of photons absorbed. Hence, in general, fluorochromes with higher quantum efficiency are preferred. The fluorescence lifetime (τ) is the time that a fluorochrome molecule remains in the excited state before generating the emission light. The decaying of the fluorescence intensity coming from a fluorochrome molecule after a pulse excitation light is given by an exponential function:

$$I(t) = I_0 \mathrm{e}^{(-t/\tau)}\,, \tag{2}$$

where $I(t)$ is the fluorescence intensity at time t and I_0 is the initial fluorescence intensity immediately after the pulse excitation. Therefore the fluorescence lifetime can also be defined as the time in which the fluorescence intensity from the fluorochrome molecule decays to $1/\mathrm{e}$ of the initial intensity.

The fluorescence signal given by the emission light can be significantly reduced by two different phenomena: quenching and photobleaching. In quenching, the excited fluorochrome molecule loses its energy non-radiatively, for example through collisions with other molecules. Meanwhile photobleaching is the irreversible destruction of the fluorochrome molecules using very intense excitation light. For imaging purposes, both quenching and photobleaching should generally be avoided. However, for quantitative visualization of transport phenomena in microfluidics and nanofluidics, these phenomena can be useful, as we will discuss later.

Fluorescence signals are also influenced by characteristics of the environments surrounding the fluorochrome molecule. One of the most common environmental factors is the concentration of other molecules, which causes quenching as described above. Another factor is the pH of the aqueous medium containing the fluorochromes. In most imaging applications, the sensitivity of fluorochromes to different pH levels is unwanted. In biological and chemical measurements, however, the pH of the medium can provide extra information of the investigated process. To measure the pH level, two different types of fluorochromes are typically used; each is being sensitive to different pH levels. In this so-called ratio-metric measurement method, the emission light's intensity ratio between the two fluorochromes indicates the actual pH level of the medium.

Below we will describe the optical microscopy setups for performing fluorescence measurements. Afterwards we will discuss the application of the fluorescence measurements to quantitatively visualize and characterize transport of fluid and individual biological molecules in microfluidic and nanofluidic studies.

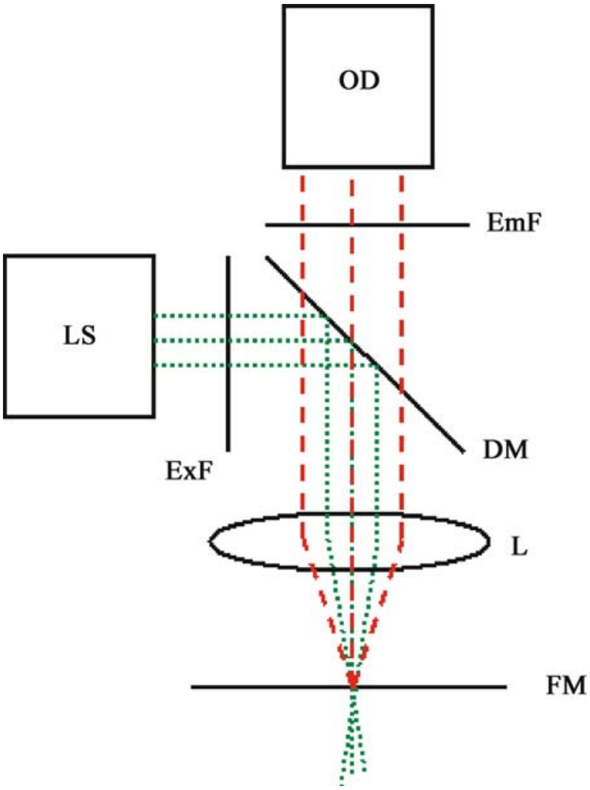
Basic Methodology

Fluorescence Microscopy Setup

In general, the fluorescence measurements can be done without using an optical microscope. Fluorescence signals given by bulk materials can readily be measured using standard macro-scale optical methods. For measurements in very small scales, such as the investigations performed in microfluidics and nanofluidics, however, an optical microscope is necessary. Here we start by describing the most common fluorescence microscopy setup. Figure 2 illustrates the basic anatomy of a fluorescence microscopy setup. The light that is used in the setup usually comes from a mercury (Hg) arc-discharge lamp, located at the back of the microscope. The emission light generated from the fluorescence measurements is then imaged to an optical detector, typically a digital CCD (charge-coupled devices) camera, for further processing and analysis.

Among the most important elements of the setup are the set of optical filters, which separate the excitation light from the emission light [1]. It comprises mainly the excitation filter, the emission filter, and a dichroic mirror (also known as a di-chromatic beam-splitter, which splits two lights with different wavelengths to two different paths). The excitation filter serves to ensure that only the light with a certain range of wavelengths illuminates, and eventually excites, the fluorochrome molecules. The filter absorbs all the light with wavelengths outside the desired range. After passing the excitation filter, the light is directed by the dichroic mirror onto the fluorochrome molecules. With the help of the lens near the molecules, the excitation light is focused toward the molecules. After excitation, the fluorochrome molecules eventually generate the emission light, which is then again collected by the same lens near the molecules. The collected emission light than pass through the dichroic mirror; a dichroic mirror is designed so that it reflects light with the same range of wavelengths as the excitation light, while it transmits light with the same wavelengths as the emission light. To ensure that only the emission light reaches the detector, the emission filter is used. This filter absorbs noises that have the same range of wavelengths as the excitation light, such as excitation light scattered by objects near the fluorochrome molecules.

A fluorescence microscope setup that uses such optical filter set, as depicted in Fig. 2, is known as an Epi-Fluorescence Microscope [1]. The word Epi-Fluorescence means that both the excitation light path and the emission light path use the same lens near the fluorochrome molecules. When excitation light illuminates the fluorochrome molecules, the lens serves as a condenser lens, which focuses the light into the object plane. Mean-



Fluorescence Measurements, Figure 2 The basic anatomy of a common fluorescence microscopy setup. LS = light source, OD = optical detector, ExF = excitation filter, EmF = emission filter, DM = dichroic mirror, L = lens, and FM = position of fluorochrome molecules

while, when the fluorochrome molecules generate emission light, the lens serves as an objective lens, which gathers light from the object plane into optical detectors. Therefore by using the Epi-Fluorescence Microscope setup, we can keep the fluorochrome molecules in the object plane always in focus, simultaneously for the excitation light path and the emission light path.

The fluorochrome molecules, which are exactly in the focal plane of the lens, can be imaged clearly in the optical detector. Other molecules, however, will be imaged poorly because they are out of focus. The transition between being in focus and out of focus occurs gradually, such that there is a range of space in which the molecules can still be imaged clearly even though they are not exactly in focus. This range of space, termed depth of focus [1], can be expressed as:

$$Z = n\lambda/(\mathrm{NA})^2 \,, \tag{3}$$

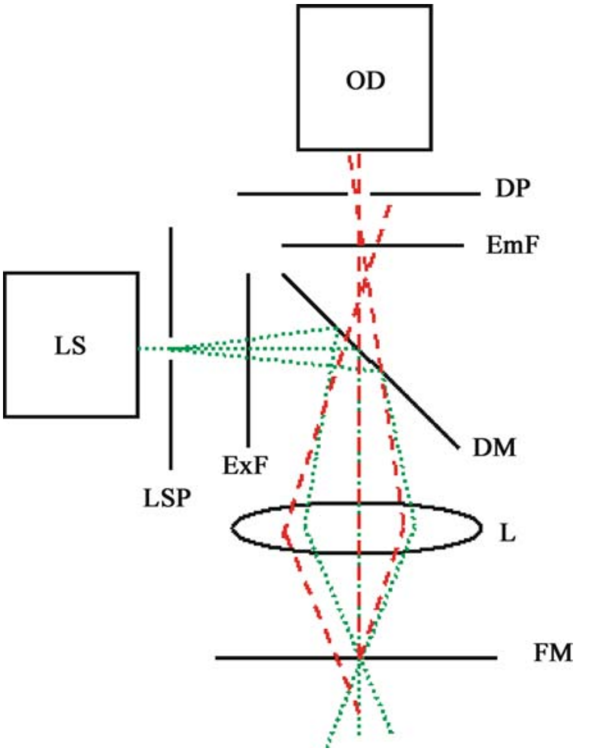
where Z is the depth of focus for a lens, n is the refractive index of the medium containing the fluorochrome molecules, λ is the wavelength of the emission light, and NA is the numerical aperture of the lens, which in turn is defined as $\mathrm{NA} = n(\sin\theta)$ with θ as the maximum angle that can be captured by the lens.

The notion of depth of focus is important in microfluidic and nanofluidic studies, because it influences the spatial resolution of the measurement. Let us consider a microfabricated channel with a channel depth of d, in which fluorochrome molecules are being contained and measured. If $Z > d$, then all the fluorochrome molecules are always in focus, and they all are imaged clearly in the optical detector. Consequently, in microfluidic channels, where the fluorochrome molecules are typically much smaller than the channel depth d, the position of the fluorochrome molecules along the channel depth cannot be resolved anymore. Hence, multiple molecules that are positioned near each other cannot be distinguished from each other, and three-dimensional measurements (for instance, to characterize the transport of fluid inside such channels) cannot be performed. In nanofluidic channels, however, where the fluorochrome sizes are more similar to the channel depth d, the measurements can be described as a quasi-2D problem, and it is not required anymore to resolve along the channel depth.

Meanwhile, if $Z < d$, then only fluorochrome molecules within the depth of field are imaged clearly n the optical detector. By scanning the position of the microfabricated channels relative to the lens, the positions of fluorochrome molecules along the channel depth can be resolved, and a 3D measurement can be performed.

If all the emission light, both from the fluorochrome molecules in focus and the fluorochrome molecules out of focus, is collected by the microscope setup, than the setup is termed as having a wide-field configuration. Emission light from molecules that are out of focus is typically not wanted in fluorescence measurements, because it serves as a background signal that reduces the measurement quality. To eliminate this background, another type of configuration, termed the confocal configuration [1, 2], is used. Figure 3 provides the schematic concept of a confocal configuration.

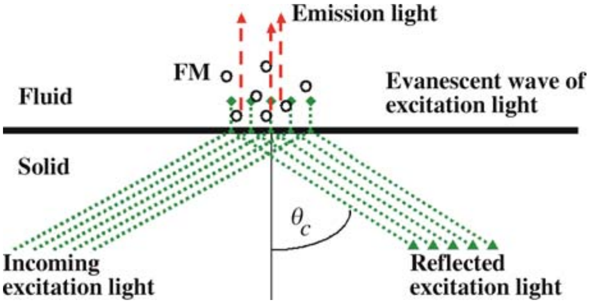
In a confocal configuration, a pair of pinholes is positioned near the optical filter set: one pinhole (called a light-source pinhole) is located prior to the excitation filter, while another pinhole (called a detector pinhole) is located after the emission filter. Their positions are arranged such that the lens images the light-source pinhole into a single point in the object plane, and this point in the object plane is imaged, again by the same lens, exactly into the detector pinhole. Using this configuration, the light-source pinhole ensures that a smaller volume in the object plane is illuminated by the excitation light; thus spatial resolution in exci-



Fluorescence Measurements, Figure 3 The schematic concept of a confocal fluorescence microscope configuration. LS = light source, OD = optical detector, ExF = excitation filter, EmF = emission filter, DM = dichroic mirror, L = lens, FM = position of fluorochrome molecules, LSP = Light-source pinhole, and DP = detector pinhole. Note that the emission light coming from out-of-focus fluorochrome molecules is blocked away by the detector pinhole

tation is improved compared to the wide-field configuration. Moreover, the detector pinhole ensures that emission light generated by fluorochrome molecules that are out-of-focus is eliminated; hence background fluorescence signals are removed from the measurements. There is a trade-off, however, between the advantages described above and the longer time required in measurements with a confocal configuration [1, 2]. Because a smaller excitation volume is obtained in a confocal configuration, the excitation volume needs to be scanned through the whole object; in case of measurements in microfluidic and nanofluidic channels, this means scanning along the depth, length, and width of the channels. Multiple pinholes can then be used to reduce the scanning time, where the pinholes perform fluorescence measurements on several excitation volumes simultaneously.

Compared to macro-scale fluidic channels, the surface-to-volume ratio in microfluidic and nanofluidic channels is significantly larger, and consequently the physical effects caused by channel surfaces become more promi-



Fluorescence Measurements, Figure 4 The schematic concept of TIRF. FM = fluorochrome molecules. Note that only fluorochrome molecules that reside very close to the solid–fluid interface is illuminated by the excitation light and generates the emission light; the other fluorochrome molecules are not involved in the measurement

nent. Therefore it also becomes increasingly important to understand microfluidics and nanofluidics phenomena at these surfaces. A particular fluorescence microscope setup that is suitable for this kind of measurements is the so-called TIRF (total internal reflection fluorescence) setup. Figure 4 illustrates the concept of TIRF.

In a TIRF microscopy setup, the fluorochrome molecules reside near a solid–fluid interface. The excitation light is illuminating the fluorochrome molecules from a steep angle, coming from the solid side toward the fluid medium. When this angle is larger than a certain critical angle θ_c, then almost all of the excitation light is reflected back from the solid–fluid interface toward the solid side. This critical angle is expressed as:

$$\theta_c = \sin^{-1}(n_f/n_s)\,, \quad (4)$$

with n_f as the refractive index at the fluid medium and n_s the refractive index at the solid side. Hence only a very small amount of the excitation light goes through the solid–fluid interface. This small amount of excitation light, termed as evanescent wave, decays rapidly as it travels away from the solid–fluid interface toward the fluid medium. In effect, the excitation light only illuminates a very thin region in the fluid medium, with depth of only tens of nanometers, near the solid–fluid interface. Consequently, only fluorochrome molecules very near to the solid–fluid interface are excited and fluorescence measurements can be performed in detail on the surface.

Flow Visualization

To be able to design devices based on microfluidics and nanofluidics, it is crucial to quantitatively visualize the flow of fluids in the microfluidic and nanofluidic channels. There have been many flow visualization methods being

developed for macro-scale fluid flow (for example: hot-wire anemometry), but most of them are not suitable for micro- and nano-scale measurements because they are too intrusive for micro- and nano-scale fluid flows [3]. Fluorescence measurements are very suitable for quantitatively visualizing flow in micro- and nano-scales, because it is non-intrusive and it allows for measurements with a high spatial resolution.

Fluorescence-based flow visualization methods can be categorized into two types: particle-based methods and scalar-based methods [3]. In particle-based methods, the fluid motion is deducted from the observed motion of fluorescence particles embedded in the fluid. The fluorescence particles are typically formed as microspheres, where fluorochrome molecules coat each sphere (see for example: the FluoSpheres from Invirogen, CA, USA). To infer the fluid flow, the motion of the fluorescence particles must be processed and analyzed. When a CCD camera is used in the setup, the image sequence capturing the particles motion can be processed and analyzed digitally in a computer. Several analysis methods are available: the most popular is the so-called Micro-PIV (micro-scale particle image velocimetry). This method analyzes patterns of particles ensembles, and infer the fluid motion by performing correlation analysis between the recorded patterns. Micro-PIV is derived from its macro-scale counterpart, PIV. Another particle-based method that can be used is PTV (particle tracking velocimetry), in which individual particles are tracked and the pathlines of the individual particles are analyzed to infer the fluid flow.

In scalar-based methods, the velocity of a conserved scalar is being observed and analyzed to infer the fluid flow. The fluorescence signals themselves can be used as the scalar by preparing a fluid solution containing the fluorochrome molecules. Due to the typically short fluorescence lifetime of fluorochrome molecules, however, it is difficult to visualize the fluid motion using only fluorescence; as soon as the excitation light is terminated, no emission light is generated anymore. Therefore a modification to this method is needed.

The first type of modification is performed by inducing photobleaching on the fluorochrome molecules. Prior to the measurement, the whole fluidic channel is illuminated and all the fluorochrome molecules generate emission light. Exactly at the beginning of the measurement, another excitation light, with much higher intensity illuminates a certain region of the fluidic channel for a very short time. To shape this certain region, for example in a straight line across the channel width, a line-shaped aperture positioned before the excitation filter. This extra excitation induces photobleaching, but only to fluorochrome molecules that is located within the straight light. Hence the motion of the photobleached region can be analyzed to infer the fluid flow. The main disadvantage of this method is that it needs an extra light-source for inducing the photobleaching.

The second type of modification is done by using the so-called caged-fluorescence dyes. The caged-fluorescence dyes are fluorochrome molecules that have been modified chemically so that they become non-fluorescent. When a certain light (normally ultra-violet light) is exposed to the caged-fluorescent dyes, however, the chemical modification is reversed and the original fluorochrome molecules become fluorescent again. Prior to the measurement, the caged-fluorescence dyes fill the fluidic channels. Exactly when the measurement starts, the ultra-violet light illuminates a certain region of the fluidic channel (for example: in a shape of a line, as in the photobleaching method described above). Therefore only caged-fluorescence dyes located within that certain region is transformed back into the original fluorochrome molecules, and the molecules motion can be studied to deduce the fluid flow. As in the photobleaching method, this method also requires an extra light-source to perform measurements.

Single-Molecule Detection

As we go from microfluidics to nanofluidics, and the sizes of tracer-particles are more and more reduced to the limit of a single-molecule of fluorochromes, the distinction between the scalar-based and particle-based methods becomes obsolete [3, 4]. In turn, the small dimensions of the microfluidic and nanofluidic channels also allow for increased sensitivity in the fluorescence detections: the background signal (caused by sample impurities and scattered photons) scales linearly with the size of the detection volume, while the fluorescence signal of each fluorochrome single-molecules is independent of the detection volume.

One of the most important applications of the single-molecule fluorescence detection in microfluidics and nanofluidics is the investigation on individual DNA (deoxyribonucleic acid) molecules [4]. DNA molecules are usually tagged using the so-called intercalating cyanine dyes. These fluorochrome molecules, popularly known as TOTO and YOYO, are virtually non-fluorescent in solution, but form highly fluorescent complexes with DNA molecules, with $>$ 1000-fold fluorescence enhancement [5]. The fluorescence signal of the DNA-dye complexes has been shown as insensitive to DNA base composition, and the fluorescence intensity is linearly proportional to the DNA length, which allows for fluorescence-based sizing of the DNA molecules. When tagged using these dyes, the motion of DNA molecules inside microflu-

idic and nanofluidic channels can be imaged and studied in detail.

Key Research Findings

Fluorescence measurements are very useful in general because of its sensitivity and specificity to the investigated physical, biological, or chemical process. Moreover, the fluorescently visualized process can be imaged in detail and analyzed further using various image processing and analysis techniques. This advantage, along with the high spatial measurement capabilities allowed by optical microscopy, is highly crucial for investigations in very small scale such as in microfluidics and nanofluidics.

Fluorochrome molecules are usually characterized using their quantum yield and fluorescence lifetime. Quantum efficiency is a measure of the efficiency of the fluorochrome molecules, which is expressed as the ratio between the number of photons emitted and the number of photons absorbed. In general, fluorochrome molecules with higher quantum efficiency are preferred. Meanwhile, the fluorescence lifetime is defined as the time in which the fluorescence intensity from a fluorochrome molecule decays to 1/e of the initial intensity, after a pulse excitation is introduced. This parameter is related to the speed and the temporal resolution that can be achieved during fluorescence measurements.

For fluorescence measurements in very small scales, such as the investigations performed in microfluidics and nanofluidics, an optical microscope is necessary. Among the most important elements of the setup are the set of optical filters, which separate the excitation light from the emission light. When both the excitation light path and the emission light path use the same lens near the fluorochrome molecules, the setup is termed as an Epi-Fluorescence Microscopy setup.

Depth of focus is defined as a range of space in which the fluorochrome molecules can still be imaged clearly even though they are not exactly in focus. This parameter is important in microfluidics and nanofluidics, as it influences the spatial resolution of the measurement. Emission light from fluorochrome molecules that are out of focus is typically not wanted in fluorescence measurements, because it serves as a background signal that reduces the measurement quality. To eliminate this background, the confocal configuration can be used. Meanwhile, to perform detailed fluorescence measurements on surfaces, the so-called TIRF (total internal reflection fluorescence) microscopy setup is usually used.

The main application of fluorescence measurements in microfluidics and nanofluidics is for quantitatively visualizing fluid flow. Two particle-based methods are commonly used: PIV, which uses the pattern of particles motion to induce the fluid motion, and PTV, which tracks individual particles to achieve the same objective. Alternatively, scalar-based methods can also be used, where the fluorescence signal itself serves as the observed scalar. Due to the typically short fluorescence lifetime of fluorochrome molecules, however, it is difficult to visualize the fluid motion using only fluorescence. Hence modifications are required, for example by inducing photobleaching and by using caged-fluorescence dyes.

As we go from microfluidics to nanofluidics, the distinction between the scalar-based and particle-based methods becomes obsolete, and in turn, the small dimensions of the microfluidic and nanofluidic channels also allow for increased sensitivity in the fluorescence detections. This, along with the invention of intercalating cyanine dyes, spurs another major applications of fluorescence measurements in microfluidics and nanofluidics: the investigation on individual DNA molecules.

Future Directions for Research

Fluorescence measurements are very important in studies on microfluidics and nanofludiics, with main applications on flow visualization and single-molecule detection. To achieve measurements with higher spatial resolution, which becomes more significant with the rapid development of nanofluidics, research efforts should be focused on developing more advanced fluorescence microscopy setups. The particularly useful setups will be the ones that can break the classic optical diffraction limit.

Fluorescence Resonance Energy Transfer (FRET)

Definition

FRET is defined as the energy transfer mechanism between two fluorescent molecules. When a donor molecule is excited at its specific fluorescent excitation wavelength its energy can be nonradiatively transferred to an acceptor molecule. This occurs through a series of dipole-dipole coupling reactions and is dependent on the distance between the molecules, the orientation of the molecules and the spectral properties of both. FRET techniques are widely used in fluorescence-based detection of biomolecules, fluorescence microscopy and molecular biology applications.

Definition

► Fluorescent probes are relatively small molecules that are used to label biomolecules such as proteins, antibodies and nucleic acids. They contain functional groups and specific physical and chemical characteristics that confer suitability for their use as detection moieties. To date, thousands of fluorescent probes are known each with varying spectral properties. Fluorophores may be intrinsic or extrinsic in nature. Intrinsic fluorophores are naturally occurring whereas extrinsic fluorophores are added to generate a fluorescence signal to facilitate measurement of a specific target molecule. Fluorescent labels have provided excellent sensitivity for a range of assay systems that can be applied to the determination of almost any analyte.

Overview

The use of fluorescence to facilitate measurements in biological systems has increased dramatically and includes applications in spectroscopy, flow cytometry, clinical chemistry, in situ hybridisation, immunoassays, immunocytochemistry, immunohistochemistry and microarrays. ► Luminescence is the emission of light from any substance occurring when an electron returns from an electronically excited state to ground state. There are two main categories of luminescence, fluorescence and phosphorescence and these are dependent on the nature of the excited state. ► Fluorescence is the property whereby some atoms and molecules absorb light at a particular wavelength and subsequently emit light of longer wavelength after a brief interval, termed the fluorescence lifetime [1]. Photons from an external source are absorbed by the fluorophore and this produces excited singlet state electrons. However, the time taken for these electrons to return to the lower energy level is known as the excited state lifetime. The emission of light occurs as fluorescence from an excited electron singlet state, where all the elec-

trons in the molecule are spin-paired. The return to ground states occurs, with the emission of photons. Emission rates are fast being in the region of $10^8\ s^{-1}$ and fluorescence life-times are relatively short. Many fluorophores have sub-nanosecond life-times and, therefore, the fluorescence emitted by these dyes is short-lived. ►Phosphorescence is the emission of light from triplet-excited states, whereby one set of electron spins is unpaired. This means that electrons in the excited orbital have the same spin as the ground state electrons. Therefore, transition to ground state is not possible and emission rates are slow (in the region of $10^3 - 10^1\ s^{-1}$). Phosphorescent life-times have durations in the millisecond range. Following exposure to light, phosphorescent substances glow for several minutes as the excited phosphors return to the ground state very slowly.

Fluorescence-based detection has a number of major advantages over other light-based investigative methods. Changes in concentration can be monitored very rapidly and samples are not affected or destroyed in the process. Fluorescence typically occurs from aromatic molecules e. g. naturally occurring fluorescent substances such as quinine, fluorescein, rhodamine B, acridine orange and 7-hydroxycoumarin. In contrast to aromatic organic molecules, atoms are generally non-fluorescent in the condensed phase. The lanthanides, however, a group of elements including terbium and europium do not follow this rule. Fluorescence occurs in these molecules as a result of electron transitions between orbitals. Lanthanides exhibit long decay-times due to the shielding effect of electron transitions between the orbitals and also low emission rates because of their low extinction co-efficients.

A fluorescence emission spectrum is a plot of fluorescence intensity versus wavelength (nm) or wavenumber (cm^{-1}). Emission spectra vary widely from fluor to fluor and are dependent on chemical structure and environmental conditions e. g. pH, buffer components, solvent polarity and dissolved oxygen. A number of processes are involved in fluorescence emission which can have an effect on the fluorescence characteristics of a fluorophore. These include collisions with quenchers, rotational and translational diffusion and complex formation with solvent/solute. Fluorescent molecules absorb photons of energy at one wavelength and subsequently emit energy at another wavelength. During the absorption process (excitation), the quantum energy levels of some flours increases with photon uptake. This absorption band is not isolated at a discrete (single) photon energy level but spread over a range of wavelengths, giving rise to a peak of maximal absorbance. The extinction coefficient (E) is the absorbance peak maximum and is specific for each fluorophore. The ratio of total photon emission over the entire range of fluorescence to the total photon absorption (range $0-1$) is known as the quantum yield (Q). The higher the quantum yield the brighter the luminescence (photon emission) will be. Another characteristic that is an important consideration for fluorophores is the size of its Stoke's shift. Stoke's Law states that the emission wavelength of a given fluorophore should be longer and of lower energy than the excitation wavelength, so that the emission spectrum should be separated sufficiently from its excitation spectrum.

The intensity of emitted fluorescence can be decreased by a number of processes and this is known as quenching. Collisional quenching occurs when the excited state fluorophore is de-activated upon contact with some other molecule in solution. Fluorophores can form non-fluorescent complexes with quenchers and static quenching can occur in the ground state since no diffusion or molecular collisions are occurring. Quenching can also happen by other non-molecular mechanisms such as attenuation of the incident light by the fluorophore itself or another absorbing species in the sample [2]. Another problem encountered with fluorescent labels is over labelling. As the level of probe attachment to biological molecule is increased, decreases in emission intensities can occur. This is because fluorophores self-quench at high label levels, due to the energy transfers from excited state molecules to ground state dimers.

In ►immunoassays, antibodies and antigens can be labeled directly with a fluorescent molecule. Fluorescence-based detection is a safe, rapid, non-invasive technique suitable for a wide range of biological applications. Fluorescence-based detection of antibody-antigen binding interactions was traditionally performed with organic fluorescent tags such as FITC, cyanine 3 & 5 and rhodamine [2]. Most organic fluorophores have narrow excitation spectra and broad emission bands. Therefore multiplexing of assays is difficult as spectral overlap can take place. Quenching, photobleaching and autofluorescence can also often occur, affecting the generated signal, giving rise to skewed or invalid results. Another problem associated with the use of organic fluorescent probes is that conjugation strategies must be tailored to both the target molecule for labeling and the fluorescent dye. Therefore, the efficiency of labeling is often compromised, whereby over or under labeling can occur. There are many techniques for the direct and indirect labeling of biomolecules with fluorescent tags for biological applications. The selection of an appropriate fluorescent tag is dependent on a number of parameters such as sample type, mode of action, immobilisation strategy, excitation and emission characteristics of the fluorophore and the type of analyte being detected.

The evolution of novel fluorophores that exhibit greater stability and brightness, has led to improved sensitivity and reproducibility in biological monitoring. The advent of inorganic fluorophores such as quantum dots, nanocrystals and functionalised nanoparticles has revolutionised fluorescence-based detection methods. Novel fluorescent probes have higher quantum yields and high resistance to photodegradation and the main advantages of such probes are their narrow predictable emissions, extreme photostability and brightness. Functionalisation of the polymer shell of such molecules is generally quite simple and allows direct coupling of the probe to biomolecules. For example, silica nanoparticles are easy to modify, either through NHS activation, silanisation or carboxyl modification facilitating conjugation to biomolecules. Recombinant proteins and antibody fragments can also be specifically engineered with fluorescent tags but these tags can often change the binding properties of the molecule due to changes in structure and conformation.

Basic Methodology

Detection of labels for use in biological applications can be performed by either spectrophotometric or radioactive methods. Labels can alternatively be indirectly detected through another labelled substance. The use of spectrophotometric probes includes both chromogenic (coloured) labels and fluorescent labels. Chromogenic labels are mainly used for the non-covalent staining of structural features within cells as the coloured pigments in the dye bind to specific areas in the cell. However, there are a number of problems associated with these tags. The sensitivity of visible wavelength dyes is generally not sufficiently sensitive for detection of low concentrations of antigen and, even if a biomolecule is covalently modified with the chromogen, a relatively large amount of dye is required. Biomolecules can also be labelled with radioactive probes. Radioactive probes are detected with highly specialised equipment and there are certain safety considerations that must be addressed when working with such materials.

However, with fluorescent labels sensitivity can be increased dramatically. Fluorescence-based detection is a simple safe and effective way of labeling molecules for biological applications. Fluorescent tags have a number of attributes including large quantum emission yield upon excitation and easy conjugation to biomolecules via reactive groups that make them highly suitable for biological detection. The availability of multiple tags directed to specific reactive groups on biomolecules allows multiplexing of assays, whereby different probes can be used to detect for multiple antigens on a biomolecule in tissue or cells.

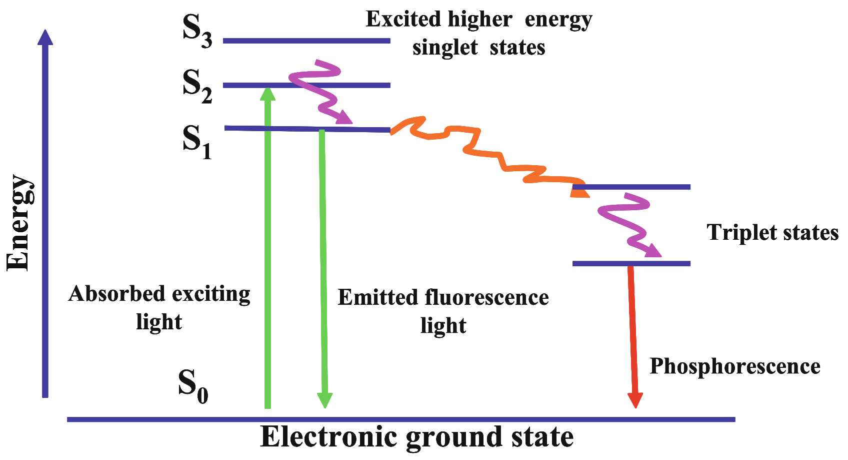
Fluorescent Labels

The physical and chemical properties exhibited by an ideal fluorescent label are shown in Table 1. These include high quantum yield and a large Stoke's shift to ensure good separation of excitation and emission wavelengths. A large Stoke's shift will increase the fluorescent signal generated as interference from Rayleigh scattered excitation light is decreased. The aromatic ring system contained in most fluorophores generates the luminescence and, as the ring gets larger, the emission shifts to red and the quantum yield increases. Aromatic ring constituents affect the fluorescent behaviour of each dye. Ring activators i. e. electron donating groups increase the quantum yield of a fluorophore whereas electron withdrawing groups decrease it. The presence of heavy atoms can also diminish the quantum yield by enhancing the probability of the excited singlet state going into triplet transition. Energy decay from a triplet excited state causes phosphorescence instead of fluorescence. The phosphorescent band is located at longer wavelengths and hence at lower energies, relative to the fluorescence spectrum. The energy transition to the triplet state is an opposite reaction to that of fluorescence and so a decrease in potential luminescence is caused. Polycyclic structures in the aromatic ring system are important to maintain fluorescent properties. Co-planar structures, i. e. rings in the same dimensional plane, show the greatest fluorescence. Malachite green and rhodamine have very similar structures yet the oxygen bridges on upper phenyl rings of rhodamine confer a planar shape, thus enhancing its luminescent qualities [2].

Intrinsic fluorophores are naturally occurring whereby the intrinsic fluorescence originates within the aromatic amino acids such as tryptophan, tyrosine and phenylalanine. The indole groups of tryptophan residues are the dominant source of UV absorbance/emission in proteins. Fluorescence emission from phenylalanine is observed

Fluorescent Labeling, Table 1 List of ideal properties of fluorescent probes

Properties	Ideal fluorescent probe
Light emitted	Narrow band of emission
Stability	Emits brightly Photostable
Stokes shift	Large shift Good distance between excitation and emission wavelengths
Quantum yield	High quantum yield, approaching 1
Fluorescence lifetime	Long lifetime
Light source	Broad excitation range Inexpensive



Fluorescent Labeling, Figure 1 Jablonski diagram (adapted from Lackowicz, 1983). When a photon provided by an external light source is absorbed by a fluorophore, it is excited from a vibrational level in the electronic ground state (S_0) to a higher electronically excited state. The electronic state of an organic molecule can be either a singlet state whereby all electrons in the molecule are spin-paired or a triplet state where one set of electrons is unpaired. The excited singlet states (S_{1-3}) are reached after initial absorption. A molecule in this energy level will quickly fall to the lowest vibrational level of this state by energy loss through collision. Fluorescence occurs as photon of light is emitted; returning the fluorophore to ground state. The Jablonski diagram shows the possible routes by which an excited molecule can return to ground state via unstable triplet states. A quick return to ground state results in fluorescence, whereas a delayed return is known as phosphorescence

only when the sample protein lacks both tyrosine and tryptophan residues and this is a very rare occurrence. Emission of tryptophan is very sensitive to local environmental changes and can be used as a reporter group for protein conformational changes. Spectral shifts are observed on binding of ligands and on protein-protein association. The emission maximum of proteins reflects the average exposure of tryptophan residues to the aqueous phase. Tryptophan fluorescence is subject to quenching by iodide, acrylamide and disulfide groups and also by nearby electron-deficient groups and protonated histidine residues. Extrinsic fluorophores are added to samples to provide fluorescence and change the spectral properties. In addition, the molecule of interest is often non-fluorescent or the intrinsic fluorescence is too weak. Proteins with weak intrinsic fluorescence can be labelled with fluorophores that have longer excitation and emission wavelengths than their constituent aromatic amino acids. There are huge numbers of such fluorophores available. Reagents are available that can be used for both the covalent and non-covalent labeling of proteins. In the case of covalently bound probes a variety or reactive groups are available for effective coupling with amine, sulfyhdryl and histidine side chains in proteins. Ideally, for labeling of biomolecules, each fluorophore should have several analog forms each with a different reactive group suitable for coupling to a different specific functional group on the target molecule. Popular organic labels include derivatives of fluorescein, rhodamine, coumarins and Texas red, as shown in Table 2.

Common Fluorophores

Fluorescein and rhodamine are common fluorophores used for the fluorescent labeling of proteins in biological applications. This is due to a number of advantageous properties such as long absorption maxima, insensitivity to solvent polarity, high molar extinction co-efficient and the availability of a wide variety of reactive derivatives. Fluorescein derivatives are characterised by a multi-ring aromatic structure, due to the planar nature of an upper, fused, three-ring system, (Fig. 2). Derivatives of the basic structure of fluorescein involve substitution of carbons number 5 or 6 of the lower ring, for modification and labeling of biomolecules. The effective excitation wavelength range is between 488 – 495 nm, while the emission spectrum lies between 518 – 525 nm, depending on the derivative. The quantum yield of fluorescein derivatives can be up to 0.75. However, quick photobleaching can be observed when the dye is dissolved in buffers, exposed to light or pH variations or subjected to long-term storage. Amine reactive fluorescein derivatives such as fluorescein isothiocyanate (FITC) react under slightly alkaline conditions with primary amines in biomolecules to form stable highly fluorescent derivatives. FITC is synthesised by modification of the lower ring at carbon positions 5 or 6. Isothiocyanates react with nucleophiles such as amines, sulfydryls and the phenolate ion of tyrosine side chains. They form a stable product on reaction with biomolecules at primary amines. FITC is almost entirely selective for modifying N-terminal amines in proteins. The reaction involves the attack of

Fluorescent Labeling, Table 2 List of common organic fluorophores

Fluorophore	Mr (Da)	λ_{ex}(nm)	λ_{em}(nm)	Fluorescent lifetime (ns)	Quantum Yield (Q)	Reacts with

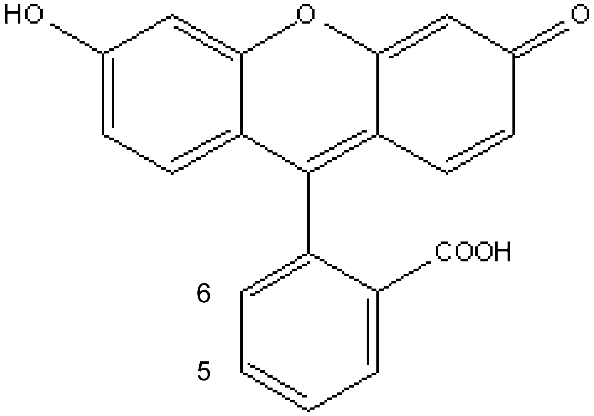
a nucleophile on the central electrophilic carbon of the isothiocyanate group. The resulting electron shift creates a thiourea linkage between FITC and the biomolecule. FITC is water soluble above pH 6.0 and isothiocyanate reagents are reasonably stable in aqueous solution for short periods, but degrade over time.

The main applications of FITC are as follows:

- labelling of antibodies to detect antigens in cells, tissues, immunoassays, blots, chips, and microarrays;
- detecting proteins after electophoretic separations;
- microsequencing analysis of proteins/peptides;
- identification of molecules separated by capillary zone electrophoresis;
- labels in flow cytometry.

NHS-Fluorescein is an amine reactive carboxy-succinimidyl ester group at carbon position 5 or 6 of the lower ring and is more stable than FITC. The NHS-ester reaction proceeds rapidly at slightly alkaline pH values, resulting in stable amide-linked derivative. It has similar properties to FITC with the extinction coefficient dependent on environmental conditions such as pH or buffer. NHS-fluorescein is insoluble in aqueous solution; therefore all stock solutions should be made up in an organic solvent. The optimal pH for NHS ester functionality is 7 – 9. NHS-fluorescein is also available with a long chain spacer. This may be useful for reducing steric hindrances around the fluorescent molecule encountered during labeling, thus minimising quenching effects.



Fluorescent Labeling, Figure 2 Structure of Fluorescein

Sulfhydryl-reactive derivatives of FITC contain sulfyhdryl groups on the lower ring structure. These groups direct the labeling to more limited sites on target molecules. Coupling through sulfhydryl residues instead of amines can avoid active centres in proteins, preserving functional activity. Sulfhydryl reactive sites are naturally available through free cystine side chains generated by the reduction of disulfides or the use of thiolation reagents. Iodoacetamido-fluorescein is an intense fluorophore derived by modification of a sulfhydryl reactive iodacetyl group at carbon 5 or 6. Iodacetyl groups react with sulfhydryls under slightly alkaline conditions to yield stable thioether linkages. They do not react with unreduced disulfides in cystine residues. It is important to protect these reagents from light since the light catalyzed breakdown of iodaecetyl groups causes quenching. The molar extinction co-efficient is dependent on environmental factors such as pH. These reagents are soluble in organic solvent and aqueous solution above pH 6.0. Fluorescein-S-malemide has a sulfhydryl reactive malemide group on the lower ring structure. It forms stable thioether bonds that are pH controlled and has fluorescent properties close to fluorescein. If no −SH groups are available disulfides can be reduced with thiolation reagents. Fluorescein-S-malemide is soluble in aqueous solution above pH 6.0 at low concentrations.

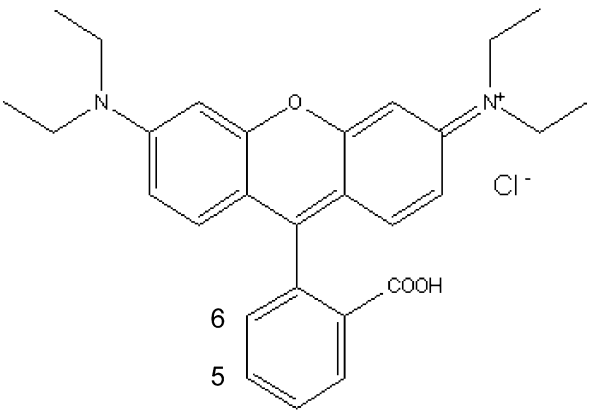
Fluorescent derivatives of fluorescein with hydrazide groups on carbons 5 or 6 can be used to label aldehyde or ketone-containing molecules. Hydrazides react with aldehyde and ketone functional groups to form hydrazone linkages. Many biomolecules have no aldehyde or ketones groups in their native state, except for those with sugar residues such as carbohydrates, glycoproteins and RNA. These molecules can be oxidised with sodium periodate to produce reactive formyl groups. Modification reagents that generate aldehydes upon coupling to a molecule can also produce hydrazide reactive sites. DNA and RNA can be modified with hydrazide reactive probes by reacting cytosine residues with bisulfite to form sulfone intermediates Fluorescein-5-thiosemicarbazide is a hydrazide derivative of fluorescein and is involved in a spontaneous reaction with aldehyde/ketone-containing molecules to form covalent hydrazone linkages. It can also label cytosine residues in DNA/RNA by way of bisulfite activation. This derivative is soluble in organic solvents and aqueous solutions above pH 7.0. However, it is prone to photobleaching and so protection from light is essential. It is useful for the site-directed labeling of antibodies through carbohydrate side chains. 5-((((2-carbohydazino)-methyl)-thio)-acetyl)-aminofluorescein is another derivative of fluorescein that has a longer spacer arm on carbon 5. It is very similar to fluorescein-5-thiosemicarbazide and reacts with aldehydes/ketones in the same way. It can label cytosine residues and is soluble in organic solvents and aqueous solutions above pH 7.0.

Rhodamine derivatives obtain their fluorescent character from a planar multi-ring aromatic structure. They are very similar to fluorescein but with a nitrogen atom replacing oxygen on the outer ring as shown in Fig. 3. Activated rhodamine probes have reactive groups made through substitution on carbon 5 or 6 of the lower ring. Alterations to the basic rhodamine structure modulate its fluorescence characteristics, giving rise to an intense and stable fluorescence. There are a number of derivatives of the basic rhodamine structure.

These include the following:

Tetra methyl rhodamine derivative 2 methyl groups on each nitrogen on the outer ring

Rhodamine B 2 ethyl groups on each nitrogen on the outer ring plus a carboxylate at position 3



Fluorescent Labeling, Figure 3 Structure of Rhodamine

Rhodamine G6 2 methyl groups on each nitrogen on the outer ring plus an ethyl ester on a carboxylate at position 3

Sulforhodamine B 2 ethyl groups on each nitrogen on the outer ring plus a sulfonate at position 3 and 5 (Lissamine rhodamine B)

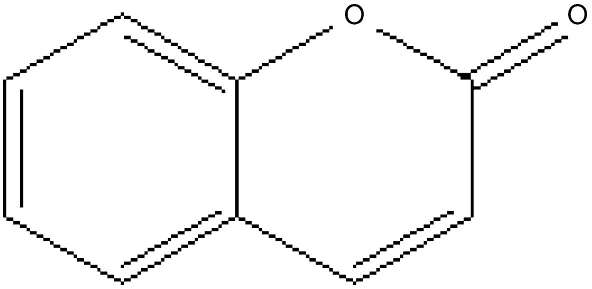
Sulforhodamine 101 (Texas red) intense luminescent properties in the far red region of spectrum

The basic characteristics of rhodamine probes are as follows. The effective excitation wavelength is in the visible light spectrum (500 – 590 nm) and associated emission wavelengths occur from high 500s to early 600s i. e. the orange to red portion of the visible spectrum. The quantum yield of rhodamine derivatives is generally lower than fluorescein, typically being 0.25. However, rhodamine probes exhibit slower bleaching in that the intensity fades slowly when dissolved in buffers or exposed to light. The red emission of rhodamine probes is in stark contrast to fluorescein so this makes it ideal for double staining when used in conjunction with FITC. A number of amine reactive derivatives are commonly used and these include tetramethylrhodamine (TMR)-isothiocyanate, NHS rhodamine, lissamine rhodamine sulfonyl chloride and Texas red sulfonyl chloride. Coupling through sulfhydryls instead of amines can help to avoid interference with active centres in biomolecules, thus minimising the effect on the biological activity. Reaction sites are available via free cystine side chains and the use of thiolation reagents. An example of a sulfhydryl reactive probe is TMR-iodoacetamide.

Finally, another group of derivatives are the aldehyde/ketone reactive probes. This group is based on the activation of a sulfonyl-hydrazine group of carbon number 5. They are based on Lissamine and Texas red structures and used to label aldehyde/ketone-containing molecules (with sugars). The most common aldehyde/ketone reactive probes are Lissamine rhodamine B hydrazine and Texas red hydrazine.

Coumarin Derivatives

Coumarins are naturally occurring substances found in Tonka beans, lavender oil and sweet clover and many are inherently fluorescent. The basic structure of a coumarin molecule is shown in Fig. 4. Some coumarin derivatives are also highly fluorescent e. g. 7-amino-4-methyl-coumarin-3-acetic acid (AMCA) has a carboxylate group that is easily functionalised for conjugation [4]. It gives rise to an intense fluorescence in the blue region of visible spectrum. Coumarins are also good donors for excited state energy transfer to fluorescein. Their emission spectra are in a region that does not overlap with other major probes and are therefore suitable for double staining applications. The main advantages of coumarin probes are a large Stoke's shift, a good quantum yield of ∼ 0.49 and activity over a wide pH range (3 – 10). Coumarin derivatives are easily coupled to biomolecules via a carbodiimide reaction with EDC. The most common probes are NHS-AMCA and sulfo-NHS-AMCA, which have similar properties. Coumarin labels are highly useful for double labeling techniques since their emission wavelengths are sufficiently distant from the more common organic fluorophores. Therefore, coumarins are highly appropriate for use in multiplexed immunostaining applications.



Fluorescent Labeling, Figure 4 Structure of Coumarin

BODIPY Derivatives

4,4-difluoro-4-bora-3a-4a-diaza-s-indacene (BODIPY) has a fused multi-ring structure. Modifications at 1, 3, 5, 7 and 8 carbon positions cause spectral shifts in excitation and emission wavelengths and functional sites for coupling. BODIPY derivatives have a high quantum yield (∼ 0.8) and are relatively insensitive to pH changes. One disadvantage of BODIPY probes is the relatively small Stoke's shift (20 nm maximum), which can cause problems since excitation at sub-optimal wavelengths is required to prevent interference and light scattering from the excitation source. BODIPY is suitable for use with molecules with only one free amine group, since the label is easily quenched by excess presence of dye.

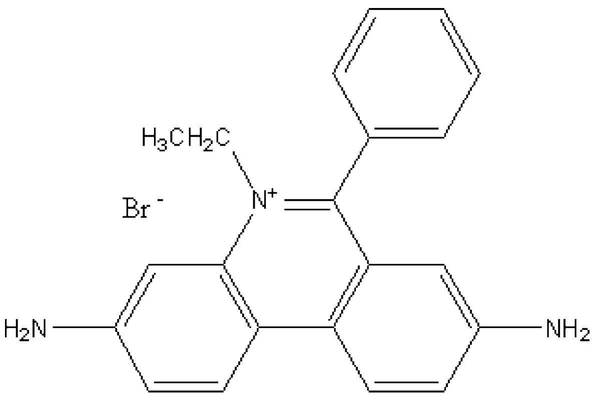
DNA Labels

There are numerous probes available that spontaneously bind to DNA, displaying enhanced emission. Ethidium bromide weakly fluoresces in water but this intensity is greatly increased upon binding to DNA (Fig. 5). The mode of binding is due to the intercalation of the planar aromatic ring between base pairs of double helical DNA. Acridine orange also binds to DNA by intercalation and 4'6-diamidino-2-phenylindole (DAPI) binds into the minor groove of DNA. Fluorescence is most enhanced

when adjacent to *adenine-thymine-rich* regions of DNA. These labels are used to image DNA on agarose gels using a UV transilluminator for molecular biological applications.

Non-Covalent Fluorescent Probes

Some dyes are weakly fluorescent or non-fluorescent until the occurrence of a particular event, i. e. enzymatic cleavage. An example of this is 7-umbelliferyl phosphate, a coumarin derivative, and a non-fluorescence phosphate ester that becomes highly fluorescent upon hydrolysis. It can be used to measure the activity of alkaline phosphatase in ELISA and enzyme-amplified DNA assays. Some dyes become fluorescent upon reacting with amines. Fluorescamine is one such dye and can be used for protein labeling but more common applications of this dye are the determination of protein concentration and as a tracking dye in protein sequencing. Anionic dyes can be used to bind to residues of proteins, which carry positive charges. Upon binding the fluorescent intensity can be either enhanced or quenched. In the case of enhancement, changes in microenvironment can cause changes in hydrophobicity of a given biomolecule. Probes that are non-fluorescent in water may be highly fluorescent in apolar media. Non-covalent probes can also be used in a quenching capacity, for example at pH 3.1; Eoisin Y exhibits strong green fluorescence, whereas on binding to protein, the fluorescence is quenched. Another example is the non-covalent binding of the near-infrared anionic dye IR-125 to casein. This was investigated with the use of steady-state and picosecond laser fluorescence measurements. In an aqueous borate buffer minimal fluorescence emission from the dyes was observed. When casein was added to the solution, enhancements in the fluorescence emission were found. The reason for this is that the dye distributes between the hydrophobic core of the protein and the interstitial aqueous solution. The dye molecules residing in the interior of the protein exhibit enhancements in their fluorescence due to a more favorable microenvironment.

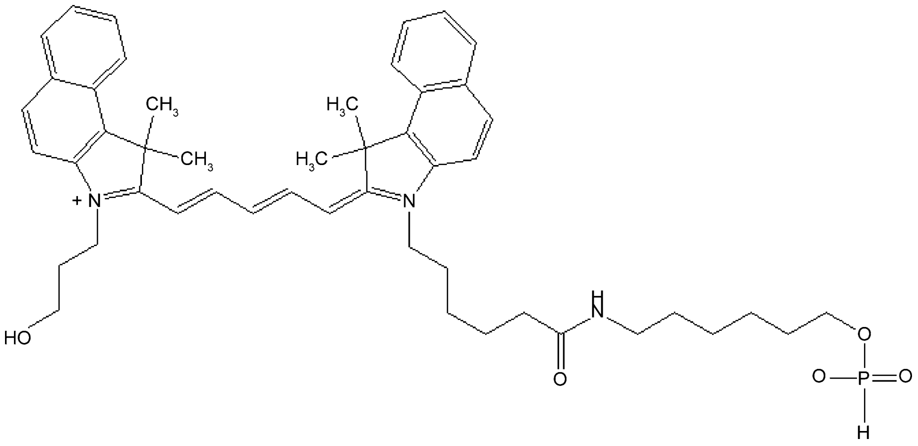


Fluorescent Labeling, Figure 5 Structure of Ethidium Bromide

Near-Infrared (NIR) Fluorescent Probes

NIR detection of biomolecules has a number of advantages including low fluorescence background, since very few naturally occurring molecules can undergo electronic transitions in this low energy region of the spectrum. Scatter is also reduced at higher wavelengths at this end of the spectrum and sample photodecomposition is reduced. Excitation is usually by a cheap, stable laser diode, which increases sensitivity. NIR probes have high quantum yields, large Stoke's shifts, photochemical stability and a high tolerance to quenching. Good examples of NIR probes are the group of cyanine dyes. These molecules have emission maximums between 600 – 800 nm. The quantum yields of these probes in aqueous solutions are very low. However, on binding to analytes changes in absorption and emission wavelengths are increased as the fluorescent life-time increases. Cyanine dyes can label proteins by covalent and non-covalent binding. The non-covalent attachment of cyanine is useful for the detection of large proteins, as the positive charge of dyes can be used for non-covalent labeling. Fig. 6 shows the basic structure of a cyanine dye.

Cyanine derivatives with alkyl SO_3^- groups and active groups such as isothiocyanate, iodoacetamide and N-succinimidyl can be used for covalent attachment to biomolecules. Di-carbocyanine dyes (adding a −CH = CH-entity to the polymethine chain of cyanine) cause a large red shift (up to 100 nm) in absorption maximum. Di-carbocyanine dyes with NHS-esters are suitable for the covalent labeling of molecules with primary/secondary amines, under slightly alkaline conditions. Cyanine dye fluorophores are bright fluorescent dyes that contain a −CH group linking two nitrogen-containing heterocyclic rings as shown in Fig. 6. They can be functionalised with NHS ester, maleimide, isothiocyanate and hydrazine chemistries for biomolecule attachment. They exhibit high molar extinction coefficients and favourable quantum yields. The small size of these dyes reduces steric hindrance, and therefore, loss of activity. Cyanine dyes can be used for standard fluorescence, fluorescence resonance energy transfer (FRET), time-resolved fluorescence (TRF) and fluorescence polarisation applications. The favourable properties of cyanine dyes include good aqueous stability, tolerance to organic solvents, pH insensitivity (range



Fluorescent Labeling, Figure 6 Structure of Cyanine 5

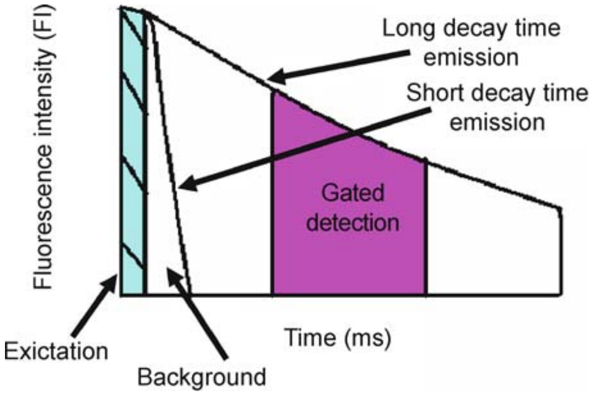
pH 3 – 10), low non-specific binding and high photostability. They are suitable for labeling via a range of amine, thiol and aldehyde groups. The sensitivity of fluorescence detection is often limited by autofluorescence of biological samples. This is decreased as the excitation wavelength becomes longer and, therefore, detectability over background is increased. Longer wavelength probes can be excited with simple excitation sources such as LEDs. Cyanine dyes have absorption and emission wavelengths above 650 nm. They also have a small Stoke's shift with the absorption maximum shifted from the emission maximum. The charged side chains of cyanine dyes are used for improved water solubility and to prevent self-association, the main cause of self-quenching.

Lanthanides

Long life-time probes are those with fluorescent lifetimes greater than those of traditional organic probes (1 – 10 ns). Lanthanides are transition metals with fluorescent life-time decay times between 0.5 – 3 ms [5]. Transition metal ligand complexes are made up of metal and organic ligands. They contain mixed singlet-triplet states and have intermediate lifetimes of 400 ns to μs. Their absorption co-efficients are very low and emissive rates very slow, giving rise to long life-times. They are not directly excited but use chelated organic liquids as conduits. Lanthanides can substitute chemically for calcium in calcium-dependent proteins. They can be used with proteins that do not have intrinsic binding sites. They are particularly useful in immunoassay applications. Biological samples can exhibit autofluorescence, which can be limiting, since autofluorescence from the sample decays on a nanosecond timescale, as does the fluorescence of most probes. However, due to the long decay time of lanthanides, they continue to emit following the disappearance of autofluorescence. ►Time-gated detection can be used with lanthanides whereby steady state intensity measurements are taken over a period of time following pulsed excitation. This principle of time-gated detection of long life-time probes is illustrated in Fig. 7.

In Vivo Labeling

The green fluorescent protein (GFP) from the jellyfish, *Aequorea Victoria,* is a versatile reporter for monitoring gene expression and protein localization in a variety of cells and organisms [11]. GFP emits bright green light on excitation. The chromophore in GFP is intrinsic to the primary structure of the protein, and fluorescence from GFP does not require additional gene products, substrates or other factors. GFP fluorescence is stable, species-independent and can be monitored non-invasively using the techniques of fluorescence microscopy, fluorescence-activated cell sorting (FACS), flow cytometry and fluorescence resonance energy transfer (FRET). Since the first use of the green fluorescent protein (GFP) in living organisms, over ten years ago, live cell fluorescence microscopy has become an indispensable tool for cell biologists. In recent years many fluorescent reporters suitable for in vivo experiments have been developed, including a wide range of fluorescent proteins in various colours. The technique of in vivo labeling of genes and proteins for microarray purposes is a useful tool in the development of the field of gene and protein expression analysis. In vivo labeling methods give accurate pictures of what is happening in the natural dynamic environment and these techniques are becoming a vital tool for fluorescence-based detection, especially for microarray applications.



Fluorescent Labeling, Figure 7 Principle of time-gated fluorescence detection. Time-gated fluorescence detection is used to monitor the fluorescence of a sample as a function of time after excitation by a flash or pulse of light. This figure shows a schematic of the system used with the lanthanides whereby steady-state intensity measurements of emitted fluorescence are taken over a period of time following pulsed excitation. Time resolution is optically gated, whereby short laser pulse acts as a gate for the detection of emitted fluorescence and only fluorescence that arrives at the detector at the same time as the gate pulse is collected. In time-gated detection systems, the detector is turned on after excitation and the fluorescence intensity generated is integrated. This method is useful for long lifetime probes

Fluorescent Labeling of Biomolecules

A standard protocol for the fluorescent labeling of biomolecules is difficult to derive as optimisation of labeling condition such as buffer; pH and concentration is highly specific for each dye. Gel filtration can be used to remove azide, which interferes with the labeling process or for buffer exchange and is often found as a preservative in biological preparations. Typically, phosphate buffered saline comprising of 0.13 mM NaH_2PO_4, 0.528 mM Na_2HPO_4 and 0.51 mM NaCl, pH 7.4 or 0.5 M carbonate buffer, pH 9.6, are used for labeling reactions. The amount of fluorescent labeling reagent used for each reaction is dependent on the amount of protein to be labeled. By using the appropriate molar ratio of labeling reagent to protein, the extent of conjugation can be controlled. For protein concentrations in the range of 2 – 5 mg/ml, a 10 M excess is used, for concentrations < 2 mg/ml, a 15 M excess is used and for protein concentrations < 1 mg/ml, 20 M excess of dye is used. The fluorescent label is generally dissolved in an organic solvent, as most fluorescent dyes are insoluble in aqueous solution, at concentration of 10 mg/ml. Taking into account the molar ratio of dye and biomolecule, the correct volume of label can be determined and added to the protein stock. The tubes are incubated end on end and left to react overnight at 4 °C, in the dark to avoid any photobleaching. The following day the fluorescent conjugate is purified to remove unreacted dye, either by gel purification, spin column centrifugation or dialysis. The conjugate concentration and dye/protein ratio are then determined spectrophotometrically. The level of label incorporation can be measured by determining the absorbance at or near the characteristic extinction maximum of the label. It is also important to determine the dye/protein ratio for all derivatives prepared with tags. The equations below are used to calculate this information.

$$\frac{A_{280} - (A_{\max} \times CF) \times DF}{E_{\text{protein}}} \tag{1}$$

$$\frac{A_{\max}}{E_{\text{dye}} \times Prot.Conc} \times DF \tag{2}$$

$A_{\max}$ = Absorbance of the conjugate at the excitation maximum wavelength for the dye; A_{280} = Absorbance of the conjugate at 280 nm; CF = Correction factor, i. e., A_{280} dye/$A_{\max}$ dye; DF = Dilution factor; E_{protein} = protein molar extinction co-efficient; E_{dye} = dye protein molar extinction co-efficient.

Biotinylation

Another efficient method of labeling biomolecules for fluorescence applications is biotinylation. Biotin is a B vitamin, which binds with high affinity to avidin and streptavidin. It is the strongest non-covalent binding reaction with an affinity constant (K_a) of 10^{15} M^{-1}. It can be easily conjugated to proteins since many derivatives are available. Analogues of biotin are also available with an extended spacer arm that reduces steric hindrances thus improving binding capability. Biotin forms a stable amide bond with primary amines at pH 7 – 9. The optimal biomolecule concentration for successful biotinylation is approximately 1 – 2 mg/ml. However, for less concentrated solutions of biomolecule this can be adjusted once the molar excess of both dye and biomolecule is taken into account. Unreacted biotin is removed from the biomolecule post-conjugation by ultrafiltration, microcentrifugation or dialysis. Silica-encapsulated quantum dots or nanoparticles can be coupled directly to streptavidin through a carbodiimide-mediated coupling reaction. This theoretically yields a high number of streptavidin molecules, typically up to 20, binding to the inorganic label. Biotinylated biomolecules can then be coupled directly to streptavidin-labelled fluorescent tags.

Novel Fluorophores

The main advantages of novel inorganic fluorescent probes such as nanoparticles and quantum dots are their narrow

predictable emission, extreme photostability, multiple tunable colours, brightness, broad excitation, large Stoke's shift and high quantum yields [6]. Functionalisation of the polymer shell of such molecules is generally quite simple and allows direct coupling of the probe to biomolecules. Silica nanoparticles are easy to modify, either through NHS activation, silanisation or carboxyl modification. Quantum dots are nanocrystalline semi-conductors that exhibit unique light emitting properties that can be customised by changing the size or composition of the dots. Quantum dots are typically 2 – 8 nm in size and covered with a layer of organic material that allows functionalisation of the surface for biomolecule attachment. The colour is determined by the size of the particles and the composition of the material used, which in turn dictate the optical properties. One of the main advantages of nanocrystalline fluorophores is that they absorb light over a broad spectral range. By absorbing all wavelengths shorter than their emission wavelength (blue wavelengths), only a single light source is required for the excitation of multiple coloured dots. This simplifies instrumentation, lowering costs and enabling multiplexing of assays. The narrow emission spectra of nanocrystals give rise to sharper colours and high spectral resolution, which improves assay sensitivity since nanocrystals emit more light than their constituent dye. Quantum dots are not liable to photobleaching, exhibit excellent photostability and, relative to conventional fluorophores, are up to 100 times more stable [6]. It is this photostability that allows repeated interrogation of the materials over longer periods. Quantum dots have high excitation cross sections, whereby they absorb much of the light with which they are irradiated, and high quantum yields in that they re-emit more than 50% of the light they absorb [7]. This gives rise to strong fluorescence signals, thus increasing detection sensitivity. The potential uses of quantum dots in biological applications include drug delivery, diagnostics, drug discovery, genetic analysis and observation of biomolecular interactions. Multiple proteins or biomolecules can be identified by multiplexing different coloured quantum dots in microarray applications.

Organic fluorescent labels such as FITC, Cy5 and rhodamine can exhibit high optical background in immunoassay applications, which reduces sensitivity [3]. The use of long-decay fluorescent probes and time-resolved detection allows for a significant decrease in background and, therefore, an increase in sensitivity. The lanthanide chelates, such as europium and terbium have traditionally been used as probes for the time-resolved fluorescent detection of analytes. Functionalised deriviatives of these dyes are available commercially for both homogenous and heterogeneous assays. However, an enhancement step is often necessary such as dissociative enhancement (DELFIA) or addition of enzyme labels to improve performance, resulting in an enzyme-amplified lanthanide luminescence system. Another group of structures, the metalloporphyrins are particularly suitable for biological applications, due to their relatively long decay times and provide a realistic alternative to fluorescent lanthanide chelate labels. Phosphorescent metalloporphyrins, such as the water-soluble platinum and palladium complexes of coproporphyrin, have a number of advantages as labels for immunoassay development. These include high quantum yields of up to 40%, simple laser excitation at 532 nm, broad red emission (600 – 750 nm) and long phosphorescent life-times (10 – 1000 μs). The platinum and palladium porphyrins can have either isothiocynate reactive groups or malemide reactive groups, allowing conjugation to be tailored exactly to suit the substance being labeled. There are two main conjugation strategies for porphyrin attachment to proteins. The first involves the activation of the porphyrin by carbodiimide, followed by nucleophilic attack of the primary amino groups of the biomolecule to produce bioconjugates via the amide bond. The second method employs carbodiimide to preactivate the porphyrin in the presence of an active ester, which results in a porphyrin derivative with active functional groups that can react with the amino groups of a biomolecule. Novel derivatives of platinum and palladium coproporphyrin were used to make phosphorescent conjugates of antibodies, avidin, biotin and neutravidin. These labels and conjugates were evaluated in solid phase immunoassays using commercial phosphorescence-based detectors. Successful use of these probes was reported for a number of plate-based assay formats [8].

Ruthenium complexes are designed specifically to have long fluorescence life-times close to 500 nanoseconds. These labels are laser-excitable metal ligand complexes and can be used to label amines on biomolecules under mild conditions. The main advantages of these dyes as protein-labels include high photostability, good water solubility, a lack of dye-dye interactions and large Stoke's shifts. In addition, the fluorescence signal of such long-lived fluorophores can be gated to eliminate the emission from short-lifetime fluorophores, and autofluorescence from cells and biomolecules, to further improve sensitivity. Castellano et al. [9] described the development and characterisation of highly luminescent ruthenium complexes for covalent linkage to human serum albumin (HSA) and human immunoglobulin (hIgG). The conjugation reactions were performed at 4 °C in the dark using a thiol-reactive ruthenium complex, dissolved in an organic solvent. Unreacted dye was removed by gel filtration and dialysis and the conjugates were characterised spectro-

F

scopically. Ruthenium metal-ligand complexes were also used in ►fluorescence resonance energy transfer (FRET) immunoassays. The antigen, ruthenium-labeled HSA was reacted with an anti-HSA antibody, labeled with a non-fluorescent absorber, reactive blue 4. The conjugation of ruthenium dye to HSA employed a simple covalent linkage using a 10 M excess of dye. The association of Ru-labeled HSA to the anti-HSA antibody was detected by a change in the spectral parameters of Ru-HSA. The intensity and decay time of Ru-labeled antigen decreased upon binding to the acceptor-labelled antibody. Antibodies labelled with NHS-functionalised ruthenium complexes have also been used for the electrochemiluminescence detection of interferon alfa-2b in human serum. Labelled antibodies were prepared by incubating the antibody with the Ru-NHS ester at a molar excess of 10 for one hour at room temperature with agitation. Unreacted dye was removed by dialysis.

Fluorescent nanoparticles exhibit considerable advantages in detection over organic fluorescent dye molecules and quantum dots. The superiority of nanoparticles is apparent in their stability, brightness and ease of functionalisation for bioconjugation. Ow et. al. [10] described a class of highly fluorescent core-shell nanoparticles, up to 20 times brighter and photostable than their constituent fluorophore. The fabrication of such molecules employs a microemulsion technology. This method encapsulates fluorescent dye molecules into a silica matrix, giving rise to dye-doped nanoparticles with high intensity of fluorescent signal. The excellent photostability of doped nanoparticles is due to exclusion of oxygen by the silica encapsulation. Surface modification post-fabrication allows efficient conjugation to biomolecules. Silica is easy to modify, either through NHS activation, silanisation or carboxyl modification [11]. SEM, TEM and fluorescence spectroscopy were used to characterise the doped nanoparticles to determine size uniformity, quantum yield, fluorescent life-time and fluorescent intensity. Each nanoparticle encapsulates thousands of fluorescent dye molecules in the protective silica matrix, providing a highly amplified and reproducible signal for fluorescence-based bioanalysis. Traditional immunoassays employ the use of one or more fluorescent dye molecules linked to an antibody to trace the antibody-antigen binding interaction. Nanoparticles have been successfully conjugated to antibodies, proteins, streptavidin and avidin. The efficiency of the conjugation process can be monitored and the conjugation rate predicted, with respect to the initial ratio of biomolecule to nanoparticle (NP) by applying mathematical formulae which take into account the size of the nanoparticles, their capacity for binding (mg protein present per mm^2 of nanoparticle surface) and the mean diameter of the nanoparticles.

Key Research Findings

The use of fluorescence in immunoassay for the detection of medically and biologically important analytes has become an important tool in diagnostics. Sun [7] showed the use of quantum dots as novel fluorescent probes for a glass chip-based sandwich immunoassay. Carboxyl-coated quantum dots were linked to antibodies via EDC chemistry. Glass chips were silanised for the immobilsation of capture antibodies and a sandwich assay was successfully developed on the chip, with detection using laser confocal scanning microscopy and array software. Luminescent quantum dot bioconjugates were also prepared using engineered poly-histidine terminated proteins. A recombinant single chain antibody fragment (scFv) specific for trinitrotoluene (TNT) was conjugated to CdSe-ZnS quantum dots through a carboxy terminal histidine tail and the conjugated scFv were used to detect TNT in a competitive immunoassay.

The use of nanoparticles to improve the performance and sensitivity of immunoassays is an emerging technology. Seydack [6] reported on the use of nanoparticles in immunoassays with improved detection limits, multiplexing of assays, reduction in photobleaching, signal amplification and improved sensitivity. Both dye-doped and metallic-enhancement nanoparticles are easily fabricated for use as fluorescent tags in immunosensing technologies. The preparation and characterisation of tetramethylrhodamine (TMR), ruthenium and fluorescein-doped nanoparticles was reported by Lian et al. [11] and the application of such molecules in solid-phase and biochip applications was shown. The applications of nanoparticles in immunoassay formats include direct and indirect binding assays for the detection hIgG, using avidin nanoparticles in direct comparison with Texas red and quantum dots, [11]. DNA microarray technology was also explored, using genomic DNA from *Pseudomonas aeringosa*. Dilutions of DNA were printed on gamma amino propyl silane (GAPS) slides and post-hybridisation labeling with avidin-nanoparticles versus Streptavidin–Cy5 was investigated. Clusters of arrayed DNA were imaged and under the same conditions the nanoparticle spots were much brighter. Lian et al. also investigated the use of nanoparticles in a protein microarray application with high detection sensitivity reported. The use of europium (III) chelate-doped nanoparticles as donors in homogenous proximity assays has also been reported. Antibody fragment-coated nanoparticles are prepared by activa-

tion of the carboxyl groups on the nanoparticles with EDC/NHS chemistry. Covalent linkage occurs between the activated carboxyl groups on the nanoparticle surface and amino groups on the Fab. Lochner et al. [12] show the principle of nanoparticle-enhanced fluorescence. This phenomenon occurs when the surface of a metallic nanoparticle is illuminated, generating an electromagnetic field. The interaction of this field with nearby fluorophores results in a fluorescent enhancement effect. Silanised plates were used to couple silver nanoparticles on the surface and Fc-specific antibody fragments were used to immobilise antigen-specific antibodies. Fluorescein-labelled-antigen was detected in the sample only in the presence of the silver colloid.

Tully et al. [13] described a fluorescence-based immunoassay for the detection of a *Listeria monocytogenes*-derived protein, Internalin B, using quantum dots as fluorescent labels. A polyclonal antibody-based competitive assay with a limit of detection of 12 ng/ml was developed. The multicolor sensitivity and stability of quantum dots makes them ideal for the analysis of complex samples for histology, pathology and cytology in immunostaining applications. Quantum dots are similar in size to organic dyes so can be substituted for current fluorescence-based techniques [6]. The main advantage of quantum dots for the immunostaining of *L. monocytogenes* is the ability to multiplex without the need for multiple excitation sources, thus facilitating double or triple immunostaining of bacterial cells surface components.

Future Directions for Research

Fluorophores can be covalently attached to macromolecules and the emission of these fluorescent probes can be from UV to NIR. Probes are available with short (nanosecond) to long (micro to millisecond) life-times. Future trends in fluorescent labeling for biological applications lie with a number of emerging technologies. Labels with better spectral properties such as larger Stoke's shift, greater stability, solubility in aqueous solution and high brightness are constantly being developed. The evolution of these tags coupled with advances in functionalisation methods for inorganic probes are giving rise to a new generation of sophisticated probes suitable for high throughput screening in diagnostics. Metallic nanoparticles and inorganic probes are highly complex, spectroscopically tailored tags that improve assay sensitivity, reproducibility and multiplexing capabilities. Easily functionalised nanoparticles, quantum dots and nanocrystals are consistently brighter and more robust and will provide important reagents in the future for fluorescence-based detection. Another key group of fluorescent tags are those genetically engineered into biological molecules through in vivo labeling and the cloning of naturally fluorescing moieties. Further development of existing tags and generation of novel probes, as outlined, will have a very significant influence in the area of fluorescence-based analysis in the near future.

Fluorescent Probes

Synonyms

Luminescent labels; Fluorophores

Definition

Fluorescent probes are relatively small molecules that are used to label biomolecules such as proteins, antibodies and nucleic acids. They contain functional groups and specific physical and chemical characteristics that confer suitability for their use as detection moieties. To date, thousands of fluorescent probes are known each with varying spectral properties. Fluorophores may be intrinsic or extrinsic in nature. Intrinsic fluorophores are naturally occurring whereas extrinsic fluorophores are added to generate a fluorescence signal to facilitate measurement of a specific target molecule. Fluorescent labels have provided excellent sensitivity for a range of assay systems that can be applied to the determination of almost any analyte.

Photoluminescence; Temperature measurement using fluorescence

Definition

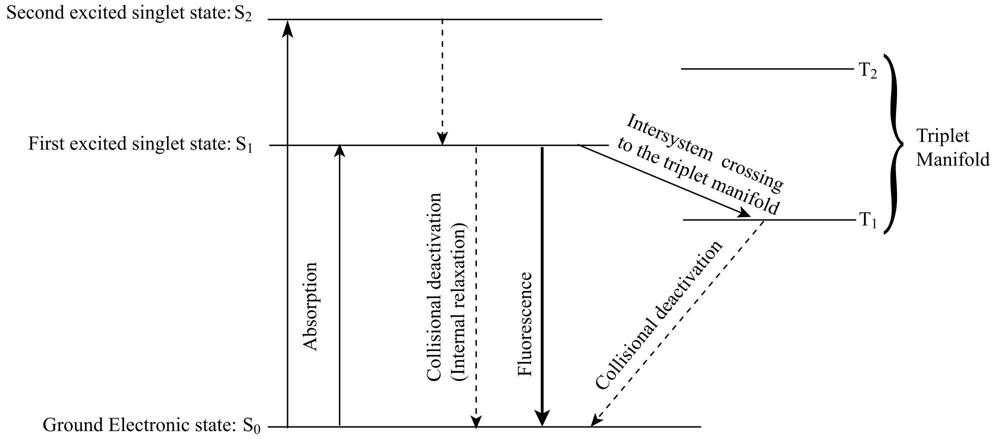
Fluorescent thermometry involves the use of a fluorescent dye, whose fluorescence intensity is a strong function of temperature, to infer the temperature of a fluid or surface. The dye is dissolved in a fluid of interest, or coated on a surface, and is excited to fluoresce by incident light. The fluoresced light is recorded with a ► CCD camera and variations in its intensity are proportional to variations in the local temperature.

Overview

There exists a growing demand for the development of advanced diagnostics for high-precision temperature measurements at the microscale. This demand is driven by the ever-increasing use of complex microfluidic devices such as micro-total analysis systems (μ-TAS) and μ-heat exchangers. Lab-on-a-Chip devices, which integrate multiple complex laboratory functions onto a single chip-sized substrate, often require precise temperature control to maximize the productivity of chemical operations like mixing, reactions and separations. Such control becomes especially critical when electrokinetic pumping is used for driving flow through these devices, as the current flowing through the buffer solution can result in significant internal heat generation, a phenomenon known as Joule heating. Since most microfluidic-based MEMS devices utilize very high heat and mass transfer rates, a thorough understanding of their thermal transport characteristics is paramount for optimizing their design for increased performance and reliability.

While several methods exist for measurement of fluid and/or surface temperature at the macroscale, the direct application of these methods to the microscale may not be possible. In particular, the accuracy of these techniques at the microscale can be compromised because dissipation of thermal gradients occurs over extremely short time scales due to high heat transfer rates and large surface area-to-volume ratios. Therefore, obtaining accurate measurements of fluid temperature at the microscale is still a challenge. Until recently, temperature measurements in microfluidic systems were limited to measurements of bulk fluid temperature at the inlet and outlet of microfluidic sections or measurements of the substrate's temperature itself. With regard to local temperature measurements, the use of high-precision thermocouple probes to measure fluid and/or substrate temperature is generally restrictive. In addition to being physically intrusive, these probes can suffer from poor spatial resolution since most probes have a characteristic size of a few microns. Alternatively, microfluidic devices can be fabricated with integrated microscale resistance temperature detectors (RTD's) embedded in the substrate with spatial extents on the order of a few microns (Wu et al. [11]). However, this fabrication procedure can be quite complex and, like thermocouple probes, RTD's suffer from poor spatial resolution which limits their ability to resolve local thermal gradients. Further, while these sensors are convenient for monitoring surface temperature, they do not provide a direct measure of local fluid temperature.

In contrast, fluorescent thermometry (a specific application of the more general ► laser-induced fluorescence



Fluorescent Thermometry, Figure 1 Schematic illustrating the energy levels of a diatomic molecule (adapted from Guilbault [3])

(LIF) technique) represents one of the most accurate temperature measurement techniques at the macroscale. In this technique, a fluorescent dye whose fluorescence intensity is a strong function of temperature is dissolved in a fluid of interest or is coated on a surface of interest. In the case of fluid temperature measurement, the fluid in a plane of interest is illuminated with incident light (typically a sheet of laser light) and the dye is excited to fluoresce. In the case of surface temperature measurement by fluorescence, the surface coated with the dye would be illuminated with incident light. In both cases, the fluoresced light is imaged with a CCD camera and the resulting image is converted to a temperature field using an a priori temperature calibration of the dye's fluorescence intensity. Unlike macroscale LIF where multiple directions of optical access are usually available, fluorescent thermometry at the microscale is often complicated by the fact that most microfluidic devices have only one principal direction of optical access, usually in a direction normal to the plane of the network. Therefore, illumination of the test section from this direction will inherently illuminate the entire depth dimension of the domain of interest. There is no adverse effect from volume illumination in the case of surface temperature measurement since presumably only the bottom surface of the device would be coated with the dye. However, in the case of fluid temperature measurement by fluorescence the dye is homogeneously dissolved in the solvent, meaning fluorescent molecules along the entire depth dimension are excited to fluoresce. As a result, fluid temperature measurements via fluorescence at the microscale often suffer from significantly more out-of-focus noise than similar measurements at the macroscale where sheets of laser light minimize the volume of fluid illuminated in the depth direction. Furthermore, the extremely small thermal transport time scales at the microscale render measurements of instantaneous and unsteady temperature fields much more difficult than similar measurements at the macroscale. Nevertheless, significant progress has been made in adapting fluorescent thermometry to the microscale and this contribution summarizes the state-of-the-art in this regard. Single- and two-dye techniques are discussed in detail and representative experimental results are summarized.

Basic Methodology

As illustrated in Fig. 1, when a photon of a given energy is absorbed by a fluorophore, the energy state of the molecule transitions from the ground state, S_0, to higher electronic states (S_1, S_2, etc.). Energy is subsequently dissipated at these excited states until the molecule reaches the lowest level of the first excited singlet state, S_1. Thereafter, the molecule at the first singlet state can return to the ground state in multiple ways. The process by which the excited molecule returns to the S_0 state by a radioactive decay process, wherein no further energy is dissipated by collisions and its return to the ground state occurs purely by the emission of energy, is referred to as ► fluorescence. In such a scenario, a portion of the remaining energy is lost by the molecule before the emission occurs, meaning that the emitted energy is of a longer wavelength than the energy it initially absorbed. The shift in wavelength of the fluoresced light relative to the absorption wavelength is known as ► Stokes shift.

While the emission of fluoresced light represents one possible path for the transition of a molecule from the first singlet state to the ground state, there exist other non-radiative processes, like internal conversions and intersystem crossings, by which an excited molecule can return to its ground state (Fig. 1). As such, the efficiency of the fluorescence

emission by a dye is often quantified by its ▶ quantum efficiency

$$\phi = \frac{k_r}{k_r + k_{nr}}, \tag{1}$$

where k_r is the rate of emission of photons via fluorescence and k_{nr} represents the rate at which non-radiative relaxation to the ground state occurs. Similarly, the efficiency of a dye can also characterized by the fluorescence lifetime of its excited species

$$\tau = \frac{1}{k_r + k_{nr}}, \tag{2}$$

which represents the average time the fluorophore remains in its excited state.

For a dye of concentration C (kg m^{-3}) illuminated with an incident light flux of intensity I_0 (Wm^{-3}), the fluorescence energy emitted per unit volume, I (Wm^{-3}), is

$$I = I_0 C \phi \epsilon, \tag{3}$$

where ϵ (m^{2}kg^{-1}) is the absorption coefficient of the dye. Variations in I with temperature are predominantly attributable to a dye's quantum efficiency, ϕ, which displays some degree of temperature dependence for most organic dyes. While this temperature sensitivity is small for most dyes (typically a fraction of a percent per K), there are some dyes that exhibit significantly more temperature dependence, like Rhodhamine B (2.3% K^{-1}). In contrast, ϵ has a very weak temperature dependence, usually of the order of 0.05% K^{-1} (Sakakibara and Adrian [9]). Therefore, by employing a dye whose quantum efficiency is highly-sensitive to temperature variations, the temperature distribution in a fluid or on a surface can be inferred from intensity variations in the light fluoresced by the dye.

Single-Dye Fluorescence

Temperature measurement using a single fluorescent dye is the simplest adaptation of fluorescent thermometry at the microscale. If the intensity of the illuminating light flux, I_0, is assumed constant in both space and time, then the ratio of the emitted fluorescence intensity measured at a temperature T to that measured at a reference temperature T_{ref} for a fixed dye concentration is given by the ratio of the quantum efficiencies of the fluorescent dye at these temperatures:

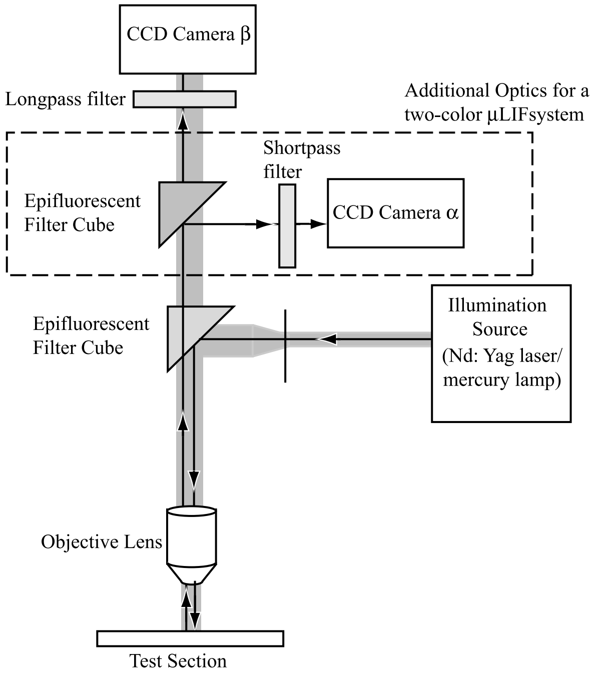
$$\frac{I}{I_{ref}} = \frac{\phi(T)}{\phi(T_{ref})} = f(T). \tag{4}$$

Therefore, assuming that the variation of the ratio of quantum efficiencies, or equivalently the ratio of the emitted fluorescence intensities, has been properly calibrated as a function of temperature, an estimate of the unknown temperature distribution is arrived at by comparing its fluorescence intensity to that given by the calibration. The spatial resolution of this measurement is defined by the imaging optics while the temporal resolution is defined either by the framing rate of the imaging camera or by the illumination time of the incident light (since the fluorescence lifetime, given by Eq. (2), is quite short for most dyes–typically a few ns to a few μs).

A schematic of the imaging configuration used for the measurement of temperature via single-dye fluorescence is presented in Fig. 2. Light from an illumination source, like an Nd:YAG laser, Argon-ion laser or a mercury arc lamp, is directed through an epi-fluorescent filter cube and through a microscope objective lens to excite the fluorescent dye molecules in the microfluidic device. The filter cube allows the relatively weak fluorescent signal to pass to a CCD camera while simultaneously blocking the intense illumination wavelength. Given the relatively weak fluorescent signal from the dye, the CCD camera employed must have very low noise levels and a high sensitivity to the emitted wavelength in order to maximize the signal-to-noise ratio of the measurement. A reference image is first acquired at a known, preferably uniform, temperature while a second image is acquired at an unknown, possibly non-uniform, temperature. A ratio of intensities is then obtained by dividing the intensity recorded at each pixel of the measurement image by the corresponding intensity at the same pixel of the reference image. This intensity ratio is then converted to temperature using an a priori calibration of the dye that tabulates the variation of the fluorescence intensity ratio with temperature (Eq. (4)).

Two-Dye Fluorescence

As outlined in Single-Dye Fluorescence, the fluorescence intensity measured by single-dye fluorescence depends solely on temperature only if the dye concentration and the incident light flux are constant. While maintaining a constant dye concentration is quite simple, sustaining a constant incident light flux is much more difficult since all illumination sources exhibit some degree of spatial and/or temporal variability in their intensity. As such, the measured fluorescence intensity not only embodies temperature variations through ϕ, but also variations in the illuminating intensity through I_0. Therefore, the accuracy of temperature measurements via single-dye fluorescence is strongly dependent on the stability and homogeneity of the illuminating light source. To alleviate such issues, a two-dye methodology was introduced



Fluorescent Thermometry, Figure 2 Representative schematic of the optical configuration for microscale fluorescence thermometry. The dashed box outlines the additional optics required for a two-dye fluorescence imaging

by Sakakibara and Adrian [9] to improve the accuracy of macroscale fluorescent thermometry. In this technique, spatial and/or temporal intensity variations within the illuminating light source are accounted for via a second fluorescent dye whose quantum efficiency exhibits little, or no, temperature dependence. Therefore, while the intensity of the fluoresced light from the temperature-dependent dye embodies both variations in temperature and illuminating intensity, any variations in the fluorescence intensity of the temperature-insensitive dye are directly attributable to variations in the illuminating intensity. Therefore, one can account for variable illumination intensity by simultaneously imaging the fluoresced light from each dye with separate CCD cameras and normalizing the fluorescence intensity of the emission from the temperature-sensitive dye by that of the temperature-insensitive dye.

Temperature measurement by two-dye fluorescence requires efficient separation of the two fluorescent emissions so that their emissions can be imaged separately over identical spatial domains at the same instant in time. Such separation is achieved by adding a second camera and additional spectral filters to the aforementioned single-dye optical arrangement (these additions are identified by the dashed bounding box in Fig. 2). In this optical arrangement, both dyes must have similar excitation wavelengths since the same illumination source is typically used to simultaneously excite both dyes. However, the dyes must have different emission spectra so that they can be effectively separated using low- and high-pass spectral filters just upstream of the cameras. If the emission from the two dyes, labeled A (temperature sensitive) and B (temperature insensitive), are separated perfectly into cameras α and β, the ratio of the fluorescence intensities recorded by both cameras is given by

$$\frac{V^{\alpha}}{V^{\beta}} = \frac{I_A}{I_B} = \frac{C_A \phi_A \varepsilon_A}{C_B \phi_B \varepsilon_B}\,, \tag{5}$$

where V^{α} and V^{β} are voltage outputs from the CCD's of cameras α and β, respectively. Note that this ratio depends on the temperature via ϕ_A/ϕ_B but is independent of the incident light flux, I_0. In practice, however, it is nearly impossible to obtain perfect separation of the two emissions, I_A and I_B, both because the emission spectra of most organic dyes are rather broad, meaning some overlap of their emissions is to be expected, and because spectral filters are inherently imperfect (filtering efficiencies of 90–95% are typical). Sakakibara and Adrian [9] considered the case of imperfect separation, wherein some fraction of the fluorescent intensity of the emission from dyes A and B are imaged by cameras β and α, respectively, and derived the expression

$$\frac{V^{\alpha}}{V^{\beta}} = \frac{I_A}{I_B} = \frac{C_A C'_B \phi_A \phi'_B V^{\alpha}_{C_B=0} + C_B C'_A \phi_B \phi'_A V^{\alpha}_{C_A=0}}{C_A C'_B \phi_A \phi'_B V^{\beta}_{C_B=0} + C_B C'_A \phi_B \phi'_A V^{\beta}_{C_A=0}}\,, \tag{6}$$

that accounts for this effect. Here, C'_A, ϕ'_A, $V^{\alpha}_{C_B=0}$ and $V^{\beta}_{C_B=0}$ are the measured parameters for fluorescent dye A with $C_B = 0$, and C'_B, ϕ'_B, $V^{\alpha}_{C_A=0}$ and $V^{\beta}_{C_A=0}$ are the measured parameters for fluorescent dye B with $C_A = 0$. In this context, $V^{\alpha}_{C_A=0}$, $V^{\beta}_{C_A=0}$, $V^{\alpha}_{C_B=0}$ and $V^{\beta}_{C_B=0}$ are constants for a given optical configuration. Therefore, the intensity ratio I_A/I_B is only a function of the concentration of the two dyes, C_A and C_B, and the temperature, T.

Apart from issues related to properly imaging the light fluoresced by the two dyes, accurate determination of the temperature distribution over the chosen spatial domain in the two-camera arrangement requires that both cameras have identical fields of view. Therefore, one must not only ensure that the magnifications of the two CCD cameras are identical but also that the cameras are aligned such that each pixel location in the two CCD arrays map back to the same physical coordinate in the measurement domain. This alignment is a crucial step in the two-dye methodology because one must divide the two intensity fields pixel-by-pixel, as outlined in Eq. (6), to determine the tempera-

ture distribution over the spatial domain of interest. Therefore, any misalignment of the two CCD cameras will prevent one from properly accounting for spatial variations in the illuminating intensity, thereby reducing the overall accuracy of the measurement.

Dye Selection

The fluorescent properties of an organic dye are governed by the chemical structure of the dye molecules and their interaction with the solvent molecules. In general, dyes whose molecules have rigid and planar structures display higher fluorescence efficiencies, meaning that their fluorescence can be imaged with very high signal-to-noise ratios. Unfortunately, such dyes seldom display a strong temperature sensitivity since the temperature dependence of a dye is often governed by the structural mobility of its functional groups. For instance, while Rhodamine 101 exhibits a temperature-insensitive quantum yield close to 100%, Rhodamine B (RhB), when dissolved in ethanol, has a quantum yield of roughly 40% at 25 °C that steadily decreases to only a few percent with increasing temperature. This RhB behavior is attributed to the increased mobility of its diethylamino groups with increasing temperature compared to the relatively rigidized diethylamino groups in Rhodamine 101. Therefore, one often must sacrifice some signal-to-noise ratio during imaging for strong temperature sensitivity. In addition, when measuring fluid temperature, the fluorescent properties of a dye can be highly dependent on the properties of the solvent itself. In most cases, solvents with higher viscosities increase the fluorescence efficiency of dyes since a higher viscosity not only restricts the mobility of the functional groups in the dye molecules, but also minimizes the energy transfer between these molecules by reducing the number of molecular collisions. Rhodamine B, for instance, exhibits a quantum yield of nearly 100% in viscous solvents like glycerol as compared to 40% in less-viscous ethanol. Further, the fluorescent efficiencies of most organic dyes also depend on other solvent properties in sometimes complicated fashions. For instance, although using water as a solvent can counteract inhomogeneities in the temperature distribution of the dye solution due to thermal energy released during the lasing process, water is known to enhance aggregation of dye molecules to form dimers and higher aggregates. These aggregates, which have different absorption spectra compared to the dye molecules themselves, can adversely affect the accuracy of the temperature measurement. Hence, the choice of fluorescent dyes and their solvents is highly dependent on the application under consideration (The reader is directed to Drexhage [1] and Guilbault [3] for a more detailed explanation of the structure and properties of fluorescent dyes).

For temperature measurement by single-dye fluorescence, the temperature sensitivity of a dye, specifically its quantum efficiency, effectively defines the temperature resolution of the measurement itself. Rhodamine B is the most-common temperature-dependent fluorescent dye used in both macro- and microscale liquid applications because of its relatively strong temperature sensitivity of 2.3% K^{-1} in water over a temperature range of 0 – 120 °C. This dye is also soluble in many other organic solvents, like ethanol, making it a practical choice in a variety of microfluidic applications. Moreover, its absorption spectrum is rather broad (470 – 600 nm with a peak at 554 nm), meaning it can be readily excited with conventional illumination sources like mercury arc lamps as well as Argon-ion (continuous) and Nd:YAG (pulsed) lasers. Further, its emission spectrum is also rather broad (centered at 575 nm) so a portion of its fluoresced light can be faithfully filtered from the illuminating wavelength. Pyrene is another fluorescent dye whose quantum efficiency exhibits relatively strong temperature dependence (0.9% K^{-1}) in the range 20 – 130 °C when dissolved in decane. This dye has an excitation peak at 330 nm and a broad emission spectrum centered at 475 nm. For a more comprehensive list of temperature-sensitive fluorescent dyes, the reader is referred to Lou et al. [5].

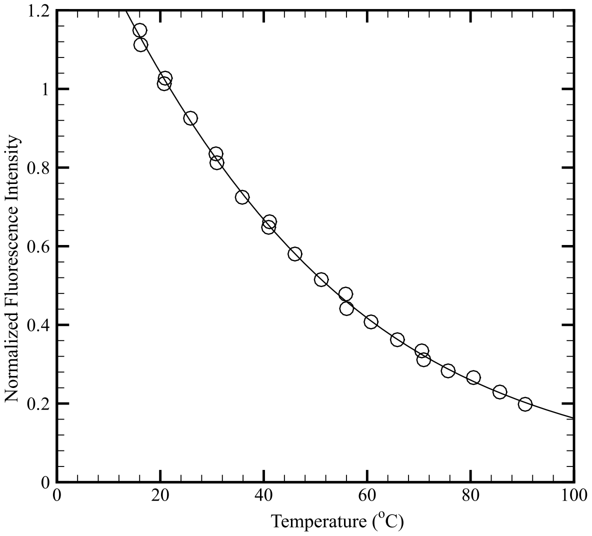
In the case of two-dye fluorescence, the ideal choice of dyes would include one dye that has strong temperature sensitivity and one that has strong temperature insensitivity. Such a combination will maximize the temperature sensitivity of the ratio of their quantum efficiencies as given by Eq. (6). However, one must also consider other constraints on the choice of dyes, particularly their absorption and emission spectra. As noted earlier, since the two dyes are typically excited by the same illumination source, both dyes should have similar absorption spectra. In addition, both dyes should exhibit strong Stokes shifts so that the relatively weak fluoresced light from both dyes can be efficiently separated from the more intense illuminating wavelength prior to imaging. However, it is also paramount that the dyes have as different emission spectra as possible so that they can be effectively separated from one-another prior to imaging. Finally, in the case of fluid temperature measurements both dyes must also exhibit good solubility characteristics in the chosen solvent, particularly homogeneity at the molecular scale.

As in the single-dye technique, RhB (absorption and emission peaks of 554 nm and 575 nm, respectively) is generally chosen as the temperature-sensitive dye in two-dye fluorescence because of its broad absorption and emission spectra as well as its solubility in a number

of commonly-used solvents. Rhodamine-110 (Rh110) is often chosen as the temperature-insensitive dye because it exhibits a weak temperature sensitivity of 0.13% K^{-1} in water and its emission peak of 520 nm is far enough from that of RhB to achieve efficient separation of the two emission signals. However, its absorption peak at 496 nm implies that its use is limited to cases where an Argon-ion laser, or an alternative illumination source of similar wavelength, is employed. In situations where an Nd:YAG laser is used for illumination (which emits at 532 nm), Nile Red (absorption and emission peaks of 553 nm and 620 nm, respectively) represents an alternative temperature-insensitive dye (0.1% K^{-1}), particularly since its emission spectrum can be effectively separated from that of RhB. Unfortunately, Nile Red is not soluble in water, although Nile Red and RhB are both soluble in ethanol. Rhodamine-101 (Rh101; absorption and emission peaks at 575 nm and 635 nm, respectively) and Rhodamine-6G (Rh6G; absorption and emission peaks at 520 nm and 566 nm, respectively), both of which are soluble in ethanol, can also be used as temperature-insensitive dyes. However, one must select a more compatible temperature-sensitive dye for use with Rh101 and Rh6G as the former has an absorption spectrum that overlaps the emission spectrum of RhB and the latter has an emission spectrum that significantly overlaps that of RhB. Finally, fluorescein, which is soluble in ethanol, represents another option as a temperature-insensitive dye because of its high quantum yield of 0.97 and its convenient absorption and emission peaks at 500 nm and 545 nm, respectively.

Temperature Calibration

The exact temperature dependence of the chosen dye(s) must be known before the measured intensity ratio fields, given by Eq. (4) for single-dye fluorescence and Eq. (6) for two-dye fluorescence, can be faithfully converted to temperature fields. In the context of single-dye fluorescence, this calibration is accomplished by isolating a fixed amount of the chosen dye at a known concentration in a well-insulated reservoir whose temperature is both known and precisely controlled. One then maintains the dye solution at a known temperature, begins illuminating the dye solution and acquires an ensemble of images of the light fluoresced by the dye using the same optical configuration outlined earlier (Fig. 2). The temperature of the dye is then varied slightly and a new ensemble of images is acquired at this new temperature. This procedure is repeated until image ensembles have been acquired at several known temperatures over the range expected in a given experiment. An average over each image ensemble and/or a spatial average over neighboring pixels is often performed at a fixed temperature to minimize variations in the intensity of the recorded fluorescence due to noise (attributable to variations in the intensity of the illuminating light as well as noise from the CCD array). This procedure yields a single, average intensity value associated with each temperature. These intensities are then normalized by the intensity of the fluoresced light at a reference temperature, yielding a calibration curve of intensity ratio (or equivalently quantum-efficiency ratio) versus temperature. A typical calibration curve of RhB dissolved in deionized water at a concentration of 1 mmol/l is shown in Fig. 3 (adapted from Ross et al. [8]). Note that the dependence of RhB's intensity ratio on temperature is quite non-linear.

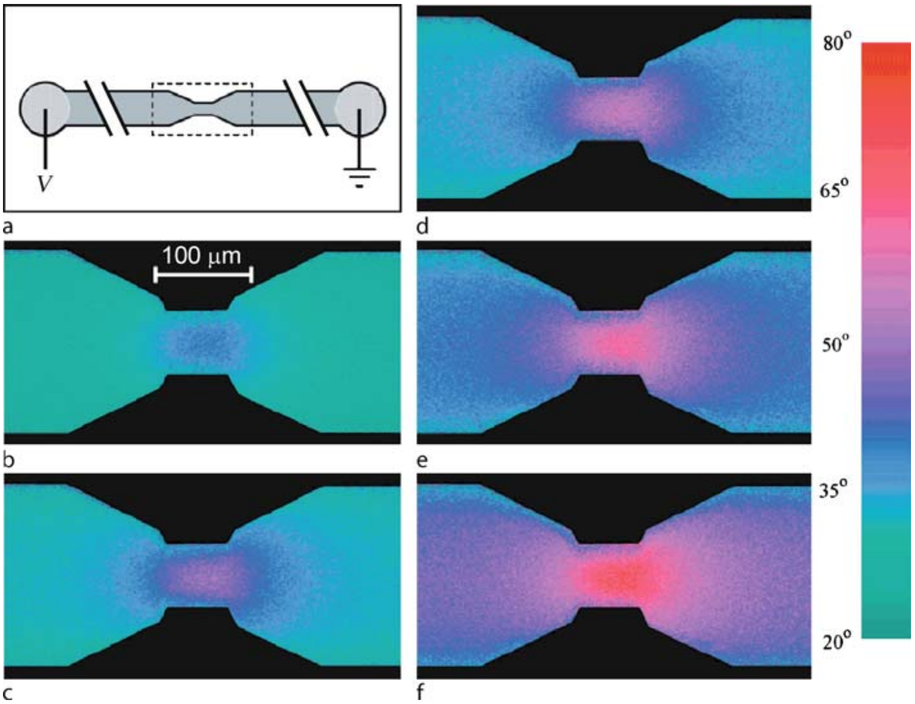


Fluorescent Thermometry, Figure 3 Representative calibration curve illustrating the dependence of Rhodamine B on temperature (adapted from Ross et al. [8])

In the context of two-dye fluorescence, the calibration methodology is identical except that one must now assess the temperature dependence of each dye. This calibration is accomplished by applying the procedure outlined above to the temperature-sensitive and temperature-insensitive dyes separately, yielding the temperature dependence of each dye's quantum efficiency as

$$\phi_{A(B)}(T) = \phi_{A(B)}(T = T_{\text{ref}}) \frac{I_{A(B)}(T)}{I_{A(B)}(T = T_{\text{ref}})} , \qquad (7)$$

where T_{ref} is a reference temperature at which the quantum efficiency of dye $A(B)$ is known.



Fluorescent Thermometry, Figure 4 (**a**) Schematic of a microfluidic circuit through which flow is driven by electrokinetic pumping. (**b**)–(**f**) Temperature fields through a constriction in the microfluidic circuit acquired 0.2, 0.4, 0.6, 1.4 and 3.8 s after the driving voltage was switched on (adapted from Ross et al. [8])

Photobleaching

As illustrated in Fig. 1, a fluorophore that is excited to higher energy levels often dissipates a portion of its energy that is in excess of the first excited singlet state, S_1. Ideally, the highest fluorescent efficiencies are obtained when a reverse transition from the S_1 state to the S_0 state occurs by the spontaneous emission of photons in the form of fluoresced light. However, there are other non-radiative processes that can act to compete with the emission of fluoresced light, thereby decreasing the fluorescent efficiency of the dye. These non-radiative processes include internal conversions, wherein non-radiative relaxation brings the energy state back to the ground state, S_0, and intersystem crossings, where the energy state is converted to the triplet state. As a consequence, molecules in the triplet state, as well as those that are at singlet states higher than the S_1 state, are susceptible to an irreversible alteration of their chemical structures that can yield non-fluorescent compounds. This decrease in the emitted fluorescent intensity as a result of the decay of fluorescent molecules is termed ►photobleaching.

Prolonged exposure of the fluorescent molecules to high-intensity incident light can raise the energy level of these molecules to energy states that are higher than the S_1 excited singlet state, thereby increasing the probability of degradation via the mechanisms detailed above. As such, minimizing the number of exposures and/or the exposure time to the incident illumination in conjunction with the use of lower excitation intensities and higher exciting wavelengths can aid in delaying the effects of photobleaching. In most measurements of fluid temperature, photobleaching effects are of little concern because the fluid in which the fluorescent dye is dissolved is typically moving through the measurement domain. In cases where the average time required for a dye molecule to enter and leave the image domain, τ_d, is small compared to the time between exposures (defined by the framing rate of the imaging system), photobleaching losses are minimal since, on average, each dye molecule will only be exposed to a single exposure of incident light. If, however, τ_d is large compared to the time between exposures, or $\tau_d \to \infty$ (i. e., the limiting case of a stationary fluid or dye coated on a stationary surface), photobleaching effects are inevitable and can severely compromise the accuracy of the temperature measurement. One can attempt to account for these losses by performing an a priori photobleaching calibration that embodies such effects.

Key Research Findings

Single-Dye Fluorescence

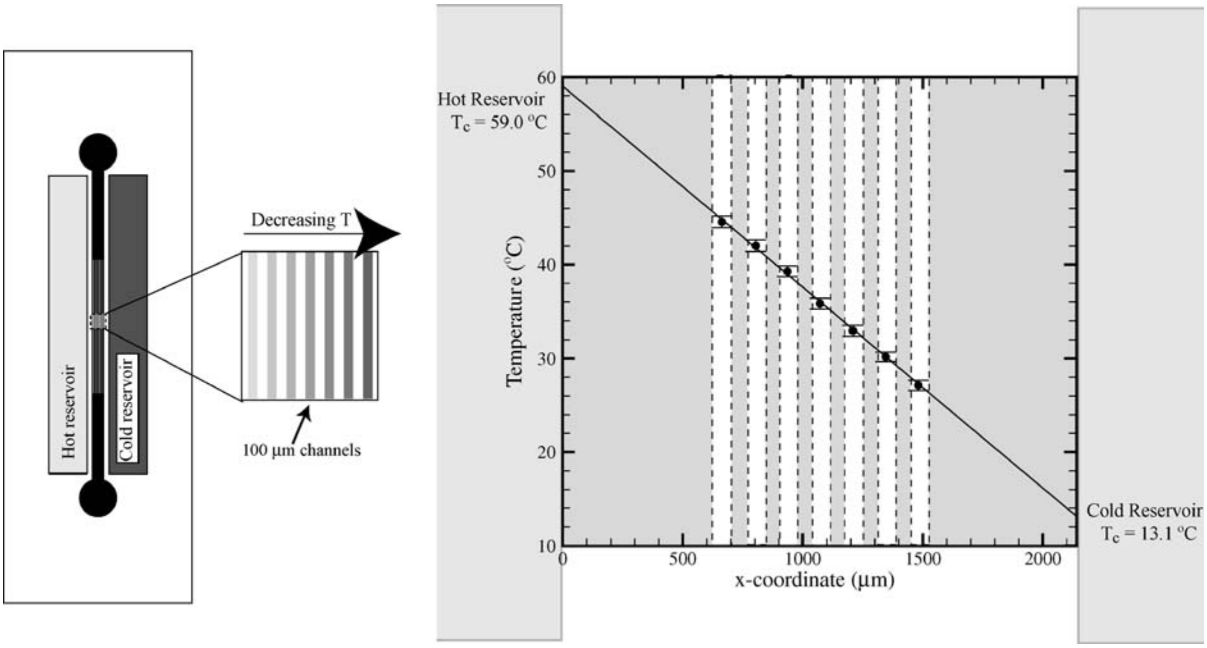
Temperature measurement at the microscale by single-dye fluorescence was first accomplished by Ross et al. [8] using RhB as the temperature-dependent fluorescent dye and a mercury arc lamp for illumination. Ross et al. [8] conducted measurements of fluid temperature distributions resulting from Joule heating in a microfluidic circuit (Fig. 4a) due to electrokinetic pumping. Figures 4b–f present a time series of fluid temperature fields acquired by Ross et al. [8] through a constriction in the microfluidic circuit. These temperature fields clearly highlight the drastic rise in fluid temperature that can occur in the presence of electrokinetic pumping. A spatial resolution of 1 μm and a temporal resolution of 33 ms were reported, yielding temperature uncertainties in the range 2.4 – 3.5 °C with no spatial or temporal averaging. Improved measurement uncertainties (as low as 0.03 °C) were achieved but at a significant cost in spatial and/or temporal resolution. This single-dye methodology was also employed by Erickson et al. [2] to examine Joule heating and heat transfer in electrokinetically-driven flows at the junctions of PDMS and PDMS/glass microfluidic devices. The temperature fields obtained with RhB excited by a mercury illumination source were found to agree with complementary numerical simulations to within ±3 °C. They also reported a repeatability of approximately ±2 °C and a noise level of ±1 °C. Improved noise levels were achieved by applying a Wiener-type filter to their raw image data.

Sato et al. [10] used single-dye fluorescence to study the two-dimensional surface temperature distributions associated with convective mixing in a T-shaped microchannel bound by a cover glass. Water at different temperatures was injected into the opposite inlets of their test section as a means of simulating a Hele–Shaw flow condition. Tris(bipyridine)ruthenium(II), with a temperature sensitivity of $-3\%\,K^{-1}$, was spin-coated on the interior of the cover glass of their test section and excited with a mercury illumination source as a means of measuring the wall temperature distribution. Sato et al. [10] reported a temperature resolution of 0.26 °C with a measurement uncertainty of 1.2 °C. They also acquired velocity fields in the same measurement domain using microscopic particle-image velocimetry (μPIV) which, in concert with the measured temperature fields, allowed direct evaluation of the heat fluxes due to conduction and convection. This analysis revealed that conduction effects were an order-of-magnitude larger than convective effects.

Two-Dye Fluorescence

Kim et al. [4] implemented the two-dye methodology to measure steady fluid temperature fields associated with thermal buoyancy in the interior of a 1 mm-wide closed test section at low Grashof–Prandtl numbers. Instead of employing a two-camera imaging arrangement, which requires accurate alignment of their fields of view, Kim et al. [4] instead used a single-camera arrangement to image the fluorescence emissions of RhB and Rh110 excited by a continuous Ar-ion laser. Separate imaging of the two emissions was achieved by alternating two band-pass filters just upstream of the camera, meaning that the RhB and Rh110 images were not acquired simultaneously but rather were separated in time by 50 ms as defined by the framing rate of the CCD camera. As such, this imaging setup limited their measurements to steady-state temperature variations. The measured fluid temperature fields were found to agree well with complementary numerical simulations of the same thermal system. Kim et al. [4] cited measurement uncertainties from 1.967 °C with a spatial resolution of 150×100 μm to 0.412 °C with a spatial resolution of 1200×800 μm. They also observed root-mean-square deviations of the measured temperatures from their computational predictions of 2.3 °C and 0.92 °C for spatial resolutions of 19 μm and 76 μm, respectively.

Most recently, Natrajan and Christensen [7] considered the development of a two-dye fluorescence method for temperature measurement using a pulsed, Nd:YAG laser as the illumination source. In this context, the Nd : YAG laser provided narrow pulse widths (~ 5 ns), enabling the measurement of instantaneous temperature fields. The experimental setup employed was a true dual-camera arrangement (identical to that illustrated in Fig. 2) implemented with two 12-bit, cooled CCD cameras with an effective chip area of 1392×1040 pixels (Photometric, CoolSnap HQ2). Rhodamine B and Sulforhodamine-101 were selected as the temperature-sensitive and temperature-insensitive dyes, respectively, yielding a sensitivity of 1.5 %/K for the dye mixture dissolved in ethanol. Natrajan and Christensen [7] validated this methodology via measurements of steady-state temperature in a microfluidic device specifically designed to maintain a linear temperature gradient. This device, designed in the spirit of the protocol outlined by Mao et al. [6], consisted of an array of seven parallel microchannels (width = 100 μm, depth = 100 μm; made of PDMS) spaced 100 μm apart that were fabricated between two large reservoirs (width = 3.2 mm, depth = 3.2 mm) spaced 2 mm apart. As illustrated in Fig. 5a, one reservoir acted



Fluorescent Thermometry, Figure 5 (**a**) Schematic of the microfluidic device used by Natrajan and Christensen [7] to obtain a one-dimensional, steady-state temperature gradient. (**b**) Variation of temperature across the microfluidic device shown in (**a**). The solid circles represent the mean temperatures obtained via two-dye LIF measurements while the solid line indicates the predicted linear temperature profile across the microchannel array. The span of the error bars represents twice the standard deviation for each mean temperature. Adapted from [7]

as a heat source and the other as a heat sink. Continuous circulation of heated and cooled water through the reservoirs ensured that they remained at constant temperatures. An independent measure of the temperature of the heated and cooled walls on either side of the channel array was obtained with two thermocouples inserted into the device through the hot and cold reservoirs. As reported by Mao et al. [6], such an arrangement generates a linear temperature gradient across the channel array which is filled with the dye mixture. When illuminated with the Nd : YAG laser, a measure of the temperature of the dye mixture in each channel was obtained by imaging the fluorescence emission from the dyes.

Figure 5b presents the measured variation of the steady-state temperature distribution across the microchannel array imposed by the hot and cold reservoirs computed from an ensemble of sixty instantaneous snapshots of the temperature field across the array as reported in [7]. Note that variations of fluid temperature *within* each microchannel were not resolved, so the spatial resolution of these measurements is 100 µm (i. e., the size of the microchannels). In this figure, the filled circles represent the mean temperatures of the dye mixture in the microchannel array obtained by averaging over the sixty samples, while the predicted linear temperature variation across the device (solid line in Fig. 5b) is obtained by fitting a line through the independently-measured wall temperatures of the hot and cold reservoirs. An estimate of the uncertainty in the measurements was obtained by computing the standard deviation of the data sets comprising the ensemble. Figure 5b illustrates that the mean temperature of the dye mixture in each of the seven microchannels of the microfluidics device is in very good agreement with the predicted temperature distribution (span of error bars represent two standard deviations). The maximum deviation of the LIF-measured mean temperatures from the linear prediction is 0.4 °C while the computed standard deviation lies in the range 0.5 – 0.63 °C. This range of standard deviations yields relative uncertainties (standard deviations normalized by measured temperatures) of 1.4 – 2.0%, with the relative uncertainty increasing with decreasing temperature. Natrajan and Christensen (2008) noted that these uncertainties are 2 – 3 times larger than those normally achieved in macroscale implementations of two-dye fluorescent thermometry, indicating that volume illumination can be a non-trivial source of error in LIF implementations at the microscale.

Future Research Directions

While significant progress has been made in adapting fluorescent thermometry to microfluidic applications, the

accuracy of the technique is still nearly an order of magnitude lower than similar implementations at the macroscale. This stark difference is attributable not only to the volume-illumination effect at the microscale but also to the relatively weak fluorescent signals that must be imaged with high signal-to-noise ratio. In the case of a stationary fluid (or equivalently a dye-coated stationary surface), the accuracy of the technique is further compromised by photobleaching effects. Therefore, significant effort must be put forth to solve such issues before fluorescent thermometry becomes a standard technique employed in a wide variety of practical applications. One promising path toward resolving the aforementioned issues involves the use of ► quantum dots as thermal markers, although researchers are just beginning to explore this intriguing possibility. Quantum dots are nanometer-scale semiconductors that are formed by confining the motion of electrons and/or holes (the absence of electrons) in all directions and can range in size from a few to a few hundred nanometers depending upon how they are fabricated (typically by molecular beam epitaxy or self assembly). Quantum dots behave similarly to fluorescent dyes in that they can be excited with an illumination source to fluoresce light with rather large Stokes shifts and their fluorescence intensity is strongly dependent upon temperature. However, quantum dots are superior to fluorescent dyes in several respects. First, they have extremely broad absorption spectra, meaning a wider variety of illumination sources can be employed (like diode lasers). In addition, the wavelength of the light fluoresced by a quantum dot is a function of its size, so one can tailor the spectral characteristics of the thermal marker by simply altering its size. In this regard, smaller dots fluoresce toward the blue end of the spectrum while larger dots fluoresce toward the red. This spectral behavior is attributable to the fact that larger dots are more efficient at absorbing weaker photons which tend to reside in the red portion of the spectrum. Finally, of critical importance is the fact that quantum dots display significantly higher quantum yields compared to fluorescent dyes and yet do not suffer from photobleaching effects. Therefore, not only is the signal-to-noise ratio of the fluorescence imaging greatly enhanced by using quantum dots as thermal markers but their viability is not compromised by continued exposure to illuminating light as is unfortunately the case with fluorescent dyes. All of these characteristics make quantum-dot-based fluorescent thermometry an intriguing possibility for applications ranging from meso-scale surface-temperature monitoring in electronics cooling, whereby the surface would be coated with a single layer of quantum dots, to temperature monitoring of microscale biological processes wherein precise temperature control is of critical importance.

Focused Ion Beam Milling (FIB)

Definition

This is a fabrication procedure used to machine or modify materials on the micro-scale. A focused beam of high-energy ions is targeted at a material and the impacting ions sputter atoms from the surface; a prescribed scanning of the ion beam thus has the effect of a milling procedure.

FOV – Field of View

Definition

Describes the extend of an image which is captured with the camera. The bigger the magnification of the optics the smaller is the field of view.

Free Boundary Reflection

Definition

A virtual boundary (interface) exists between a gas jet exhausting from a nozzle and the surrounding quiescent medium. Compression and/ or expansion pressure waves propagating within the jet will undergo a reflection at the virtual boundary in such a way as to maintain a continuity in pressure across the interface.

Frequency Response

Definition

The frequency response (although called transfer function) is a common function in signal analysis and control engineering when the dynamic behavior of a system must be analyzed. Therefore the input and output parameter of the system will be compared as a function of frequency. For example when the system is stimulated with a harmonic input signal of a certain frequency the system will answer with the same frequency, but with attenuated amplitude and a shifted phase. Since the amplitude attenuation and the phase shift are both functions of the stimulation frequency, it is common to plot them in Bode-diagrams, where the amplitude response and the phase response are displayed separately over the frequency.

Fuel Cell

Definition

Conceptually similar to a battery, a fuel cell is an electrochemical device that converts chemical energy stored in a fuel and an oxidant into electrical energy. The fundamental difference between a fuel cell and a battery is that fuel and oxidant are supplied from outside the reaction chamber and waste products are removed. The heart of the fuel cell contains an anode and a cathode, separated by an ion-conducting electrolyte. Its operation is conceptually straightforward. The fuel is oxidized at the anode, releasing protons (H^+ ions) and electrons. The protons travel through the electrolyte, which conducts ions but is electrically insulating, and recombine with the oxidant at the cathode. The electrons, that are required for the cathodic reaction, are conducted from the anode to the cathode through external wiring, thereby generating an electrical current used to drive a load. Most fuel cells operate at low temperatures and therefore require an electrochemical catalyst such as platinum to reduce the activation energy of the chemical reactions and generate useful electrical power.

Self-diffusion

Definition

Brownian motion is defined as the irregular motion of microscopic particles suspended in a fluid due to collisions with the surrounding fluid molecules. The mean square displacement of a particle executing Brownian motion is directly proportional to the temperature of the fluid and inversely proportional to the viscosity of the fluid and the diameter of the particle.

Chemical and Physical Principles

In the latter half of the nineteenth century and the beginning of the twentieth century, Brownian motion played an important role in the debate about the molecular reality of nature. The random movement of microscopic particles suspended in a liquid is named after the botanist Robert Brown, who discovered this phenomenon while observing pollen grain suspended in water. Though Brown himself states that this motion was observed by other researchers before him such as Leeuwenhoek (1632–1723), Buffon (1800s), Spallanzani (1800s), and Bywater (1819), he is credited with conducting the first systematic experiments to study the nature of this motion. He observed that both organic and inorganic particles exhibited this motion and that it was not caused by local currents in the fluid or any other such disturbances; he concluded that the motion originated in the particles themselves and called them *active molecules*.

Several investigations [1] were carried out to study this motion between 1860 and 1900 and it was established that external factors such as vibration, temperature, surface

tension, and incident light were not the cause of Brownian motion. It was proposed that the random movement of these particles was caused due to the bombardment by the molecules of the fluid, as predicted by kinetic theory. This hypothesis was open to a simple test. On the basis of the law of equipartition of energy, it was known that the mean kinetic energy of the molecules in a fluid in any one direction was

$$\frac{1}{2}m\left\langle v_x^2\right\rangle = \frac{1}{2}kT\,, \tag{1}$$

where m is the mass of a molecule, v_x is the velocity of a molecule in the x-direction, k is Boltzmann's constant, and T is the temperature of the fluid. On the basis of statistical mechanics, it was proposed that a particle suspended in a fluid should have the same kinetic energy. Several experiments were attempted to verify this theory, but the values of the kinetic energy differed by a factor of up to 100,000 [2].

The theoretical explanation of Brownian motion was derived independently by Einstein [3] and Smoluchowski around the same year. Later, Paul Langevin [4] derived the same expression through a completely different approach. Einstein's derivation will be discussed in the following section.

Einstein's Derivation

In the first part of the argument, Einstein derived a relationship between the diffusion coefficient and other physical quantities. On the basis of the molecular kinetic theory of heat, he asserted that particles suspended in a liquid will experience the same osmotic pressure that molecules do. If an external force K acts on a suspension of Brownian particles, then in equilibrium this force will be balanced by osmotic-pressure forces given by the relation

$$K = kT\frac{\nabla \cdot c}{c}\,, \tag{2}$$

where c is the number of particles per unit volume. Here, the force K can be any external force, such as gravity. The Brownian particles moving in the fluid because of this force will experience a resistance from the fluid of the form

$$\frac{K}{m\beta}\,, \tag{3}$$

where β is a constant with dimensions of frequency, and m is the mass of the particle. Therefore the number of particles that pass through a unit area per unit time owing to the action of the force K is given by

$$\frac{cK}{m\beta}\,. \tag{4}$$

The number of particles that pass through a unit area per unit time t owing to diffusion is given by the diffusion equation

$$\frac{\partial c}{\partial t} = D(\nabla \cdot c)\,. \tag{5}$$

Since the system is in dynamic equilibrium, the number of particles displaced owing to K will be restored by diffusion, giving the relation

$$\frac{cK}{m\beta} = D(\nabla \cdot c)\,. \tag{6}$$

Using (2) and (6), K and c can be eliminated, giving the relation

$$D = \frac{kT}{m\beta}\,. \tag{7}$$

If the Brownian particles are spheres of radius a, then the frictional resistance is given by Stokes's theory as

$$m\beta = 6\pi\eta a\,, \tag{8}$$

where η is the dynamic viscosity of the fluid. Combining (7) and (8), we obtain Einstein's equation for the diffusion coefficient,

$$D = \frac{kT}{6\pi\eta a}\,. \tag{9}$$

In the second part of his argument, Einstein relates the diffusion coefficient to a measurable property of Brownian motion such as the mean displacement of the particles. Let $c(x, t)$ denote the probability for a Brownian particle to be at position x at time t. By following a probabilistic argument, the spatial and temporal changes in the concentration of the particles were shown to be related to the diffusion coefficient by

$$\frac{\partial c}{\partial t} = D\frac{\partial^2 c}{\partial x^2}\,. \tag{10}$$

This equation was established by Adolf Fick, but was reinterpreted and applied to the problem of Brownian motion by Einstein. Integrating (10), we obtain

$$c(x, t) = \frac{n}{\sqrt{4\pi D}}\frac{e^{-\frac{x^2}{4Dt}}}{\sqrt{t}}\,, \tag{11}$$

where n is the total number of particles suspended in the fluid. The mean square of the displacement $\langle x^2 \rangle$ of the particles along the x-axis in a time Δt can be obtained by solving the integral equation

$$\left\langle x^2 \right\rangle = \left(\frac{1}{n}\right) \int_{-\infty}^{+\infty} x^2 c(x,t)\mathrm{d}x\,, \tag{12}$$

which gives the final result,

$$\left\langle x^2 \right\rangle = 2D\Delta t\,. \tag{13}$$

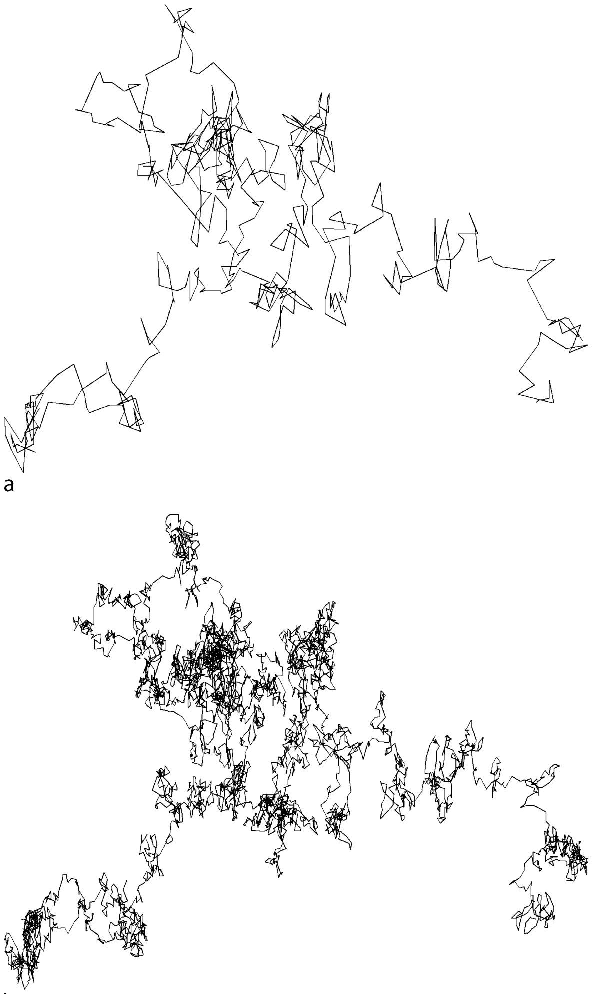
If the displacements along all three dimensions are considered,

$$\left\langle r^2 \right\rangle = \left\langle x^2 + y^2 + z^2 \right\rangle = 6D\Delta t\,. \tag{14}$$

Mathematical Foundation

The theory of Brownian motion has grown far beyond the domain of its initial application and has benefited enormously from the contributions made by mathematicians. An interesting aspect of Brownian motion is its interpretation as a particular limiting case of a random walk, which is the motion generated by taking successive steps, of a fixed length, in a random direction. Hence Brownian motion is often stated to be the random-walk motion of small particles suspended in a fluid due to bombardment by molecules obeying a Maxwellian velocity distribution. Such a motion can be easily demonstrated experimentally by taking a sequence of images of a Brownian particle. Figure 1 shows a simulated random walk of a particle undergoing Brownian motion in two dimensions. Figure 1a shows the motion of a particle on a large timescale and Fig. 1b shows the same motion recorded on a smaller timescale. It can be seen that the path of the Brownian motion contains fine details. More and more details emerge as smaller timescales are chosen to sample the data. The assumption that the mean square displacement of the particles is proportional to the time interval becomes invalid at very small timescales [5]. As soon as a particle receives momentum from the fluid molecules, the fluid in the immediate vicinity of the particle is disturbed. Owing to the inertial effect of the surrounding fluid, there is a time delay in the transition from ballistic motion to a purely diffusive motion. This effect is called the hydrodynamic memory effect and becomes important at timescales much less than 1 μs [6, 7].

In a strict mathematical sense, Brownian motion can be classified as a Weiner process. A Weiner process is a class of stochastic processes which satisfies the following conditions [8]:



Fundamentals of Diffusion in Microfluidic Systems, Figure 1 Simulated paths of a Brownian particle. (**a**) Path recorded on a large timescale and (**b**) same path recorded on a smaller timescale. More details emerge as we use smaller time scales

1. $X(0) = 0$;
2. $\{X(t),\, t \geq 0\}$ has stationary and independent increments;
3. For every $t > 0$, $X(t)$ is normally distributed with mean 0 and variance $\sigma^2 t$.

This definition shows that Brownian motion is closely linked to the Gaussian/normal distribution. The formalism of Weiner processes opens stochastic processes to rigorous mathematical analysis and has enabled the use of Weiner processes in the field of stochastic differential equations. Stochastic differential equations are analogs of classical differential equations where the coefficients are stochastic variables rather than constants or deterministic variables. The field of stochastic differential equations finds wide application in many practical situations where mod-

eling using stochastic models becomes a necessity. Examples of such situations include population growth models where *noise* is present, and electrical circuits with noise. The non-differentiability of the Weiner process requires the introduction of concepts of white noise; an appropriate text may be referred to for a deeper understanding [9].

Key Research Findings

Influence of Brownian Motion on Particulate Flows

In the past two decades, the biological and medical fields have seen great advances in the development of biochips capable of characterizing and quantifying biomolecules. Biochips, also known as labs on a chip or μTAS (micro-total analysis systems), are microscale systems that interact with biological components on their characteristic length scale. Many biochips work with *particles* (cells, bacteria, DNA, etc.) suspended in fluids.

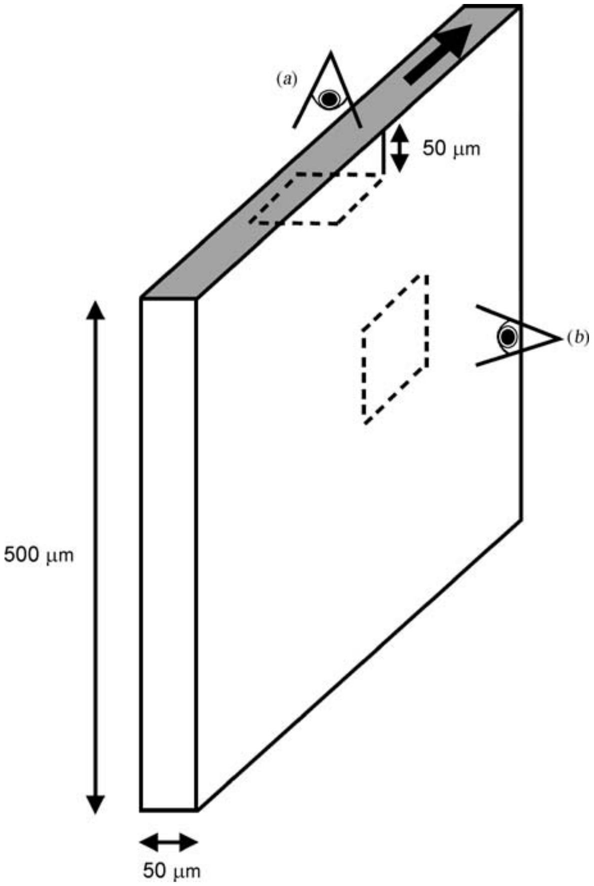
Generally, two major phenomena act on suspended neutrally buoyant particles to determine their spatial distribution: particle migration due to hydrodynamic forces, and Brownian motion. Bulk migration of particles has been shown in non-Brownian suspension flows both theoretically and experimentally in many studies since Segré and Silberberg's pioneering reports [10, 11] on the inertial migration of particles in tube flow and Leighton and Acrivos's report [12] on particle–particle interaction in concentrated suspensions. Considering the characteristic length scale (several microns or less) of biological components and their typical speed in both biomedical devices, Brownian motion cannot be neglected.

Concentrated Suspensions

Frank et al. [13] investigated particle migration in concentrated Brownian suspensions both by experiment and by modeling of flow in a mixer. The flow rate was quantified by the dimensionless Péclet number, which, conceptually, is the ratio of the time required for Brownian diffusion to move a particle by its own size, $a^2/D = a^2/(kT/6\pi\eta a)$, to the time required for shear flow to move it by the same distance, γ^{-1} (where γ is the shear rate of the surrounding flow field), yielding

$$\mathrm{Pe} = \frac{6\pi\eta\gamma a^3}{\kappa T} . \qquad (15)$$

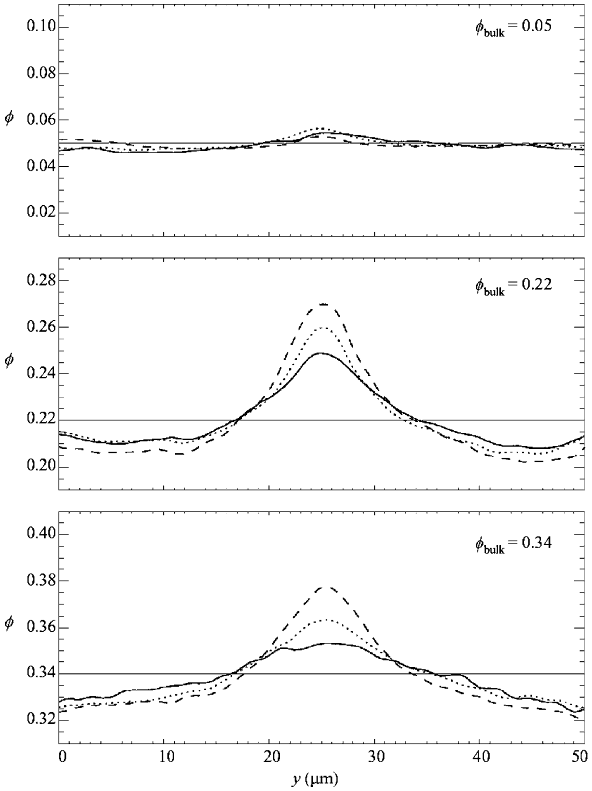
Confocal microscopy was used to study the flow of Brownian particles experimentally by directly imaging the particle motion and concentration. The experimental setup was a long, rectangular glass channel of cross section $50 \times 500\,\mu\mathrm{m}^2$, connected on each side to a Teflon tube. Concentration profiles were measured across the narrow dimension of the glass channel as shown in Fig. 2. The results are shown in Fig. 3. It can be seen that there is an increase in concentration in the center, which shows that at high volume fractions particles migrate toward the centerline, with the migration becoming progressively stronger as Pe increases. Comparisons of the experimental data with the modeling indicate that the dependence of the extent of migration on Pe is captured well but that discrepancies arise, at least in part because the assumption of fully developed flow is not valid for these experiments.



Fundamentals of Diffusion in Microfluidic Systems, Figure 2 Sketch of an experimental flow chamber; the bold arrow indicates the flow direction. Concentration profiles were obtained by looking through the top (**a**) at a fixed distance (50 μm) from the top wall. Velocity profiles were taken by scanning a horizontal plane through the side (**b**) of the chamber, across the 50 μm width of the channel

Dilute Suspensions

In Poiseuille flow, rigid, spherical, non-Brownian particles are subjected to lateral forces that result in migration to an equilibrium radial region located at approximately 60% of the distance from the tube axis to the tube wall, which



Fundamentals of Diffusion in Microfluidic Systems, Figure 3 Plots of the local volume fraction ϕ as a function of the distance across the channel for an average volume fraction $\phi_{bulk} = 0.05$, 0.22, and 0.34 at flow rates of 0.125 μl min^{-1} (solid line, Pe = 69), 1.0 μl min^{-1} (dotted line, Pe = 550), and 8.0 μl min^{-1} (dashed line, Pe = 4400) [13]

is called the *Segré and Silberberg effect* [10, 11]. The migration of Brownian particles in a Poiseuille flow for a range of particle volume fractions ϕ much less than 0.01 has been investigated using epifluorescent microscopy and microparticle image velocimetry [14]. When Pe is smaller than 1000, particles migrate away from the channel wall, with a nearly uniform particle concentration everywhere else in the channel, as shown in Fig. 4. When Pe is greater than 1000, the Segré and Silberberg effect is observed: particles move toward a preferred position, with the migration effect becoming progressively stronger as Pe increases, which results in an increase in the concentration profile between the channel center and channel wall.

Influence of Brownian Motion on Velocity Measurements

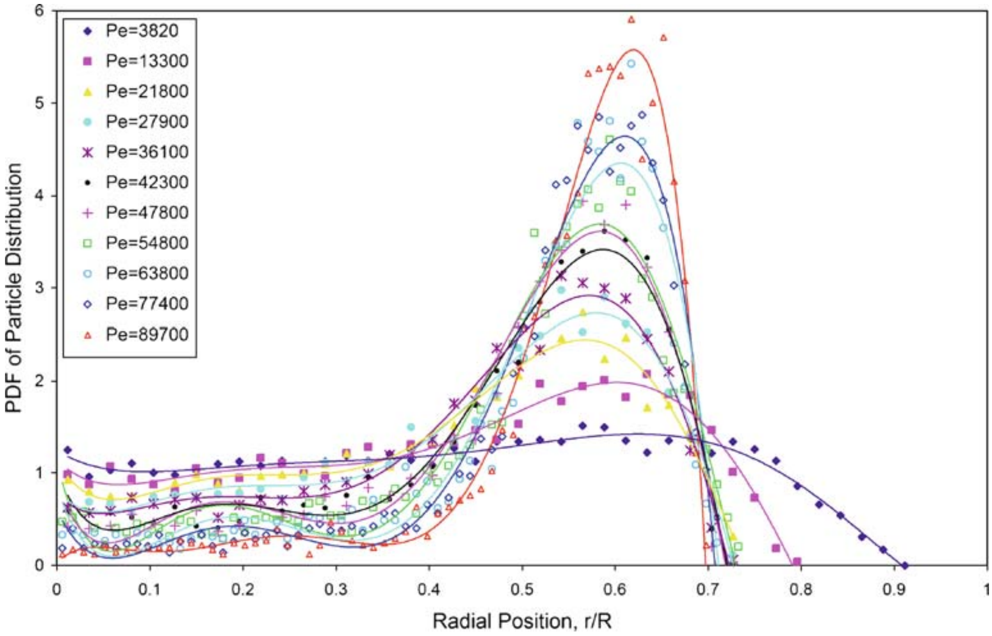
In typical particle image velocimetry (PIV) analysis, the correlation of an image with itself is called an autocorrelation, and the correlation of an image with another image is called a cross-correlation. The location of the correlation peak gives the average displacement of the particles, and the shape of the correlation peak depends on the particle size and on the imaging optics. It has been observed that for low velocities (< 10 μm/s), the submicron-sized particles used to seed the flow undergo enough Brownian motion to introduce significant errors in velocity measurements made by microparticle image velocimetry (μPIV) [15]. This uncertainty in locating the peak center was, however, substantially minimized through ensemble averaging over multiple images. This had the effect of causing a widthwise spreading of the correlation function. The effect of Brownian motion on the cross-correlation function is illustrated in Fig. 5. Figure 5a shows a typical autocorrelation peak, Fig. 5b shows a typical cross-correlation peak without any Brownian motion, and Fig. 5c shows a typical cross-correlation peak in the presence of Brownian motion. It can be seen that the peak width of the correlation function in the presence of Brownian motion is broader and the peak is lower than for the correlation function without any Brownian motion.

Olsen and Adrian [16] performed a theoretical study of the effect of Brownian motion on the μPIV correlation signal peak and derived a function quantifying the broadening of the correlation function. They postulated that this widthwise broadening of the correlation function could be used to calculate the temperature of the fluid, since Brownian motion has a direct dependence on temperature. This method would utilize the same data as that obtained for making μPIV measurements, eliminating the need to set up an entirely different experiment for measuring the temperature [15]. This idea was further developed by Hohreiter et al. [17], where the measurement technique was demonstrated with an experimental uncertainty of ±3 °C.

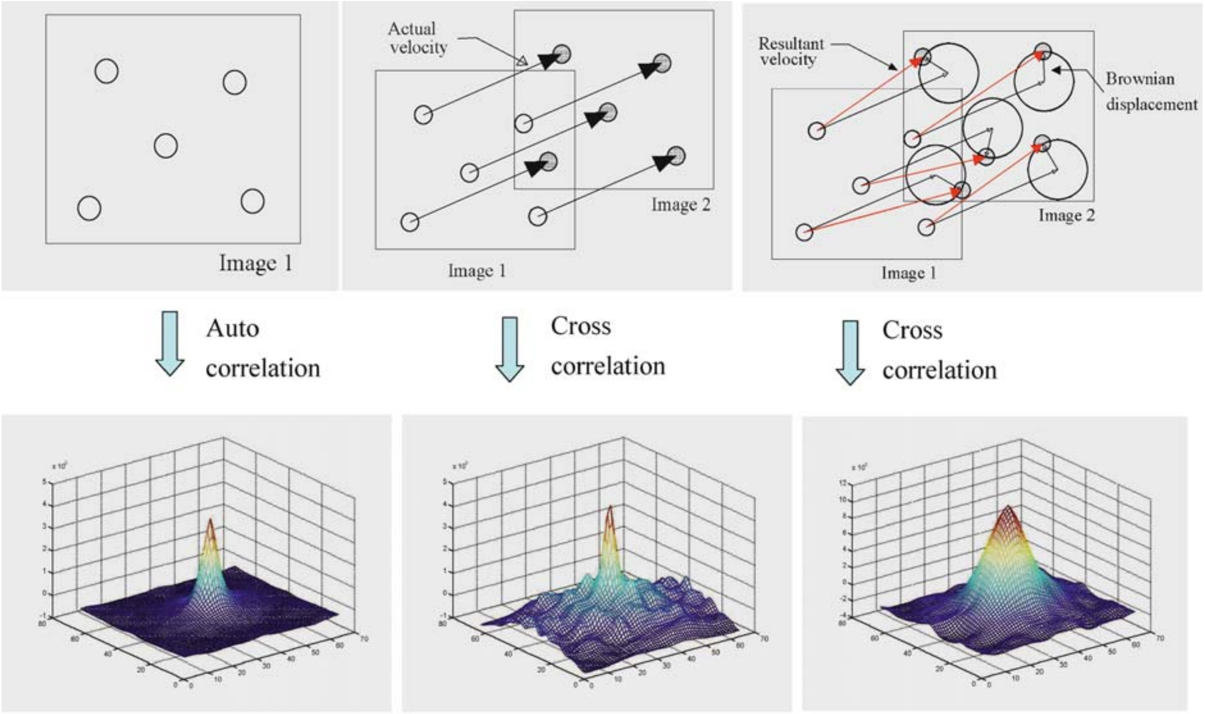
Measurement of Brownian Motion

Several attempts have been made to experimentally verify the theory of Brownian motion proposed by Einstein. Svedberg's results [18] were close to the expected values, but several researchers remained skeptical. Henri [19] used the recently invented film camera, attached to a microscope, to record the trajectories of latex particles suspended in water, but could not find quantitative agreement with Einstein's formula. The theory was finally verified by Perrin [20] by a series of experiments. In these experiments, the data was obtained using a microscope and a camera, while the displacements and the number of particles were measured manually.

At present, several different methods can be used to measure diffusion. The commonly used techniques to measure Brownian motion are briefly discussed below.



Fundamentals of Diffusion in Microfluidic Systems, Figure 4 Plot of the relative concentration (probability density function of the particle distribution) as a function of the radial position in a round capillary tube



a $\Delta s_{o,a} = \sqrt{2d_e^2/\beta^2}$ b $\Delta s_{o,c} = \sqrt{2d_e^2/\beta^2}$ c $\Delta s_{o,c} = \sqrt{2(d_e^2 + 8M^2\beta^2 D\Delta t)}$

Fundamentals of Diffusion in Microfluidic Systems, Figure 5 Broadening of cross-correlation function in the presence of Brownian motion. (**a**) Auto-correlation function. (**b**) Cross-correlation function. (**c**) Cross-correlation function with Brownian motion

Light Scattering

When a beam of light is incident on a particle, it is partially reflected, refracted, and transmitted, depending on the size and properties of the particle. Light scattering can be broadly classified into classical light scattering and dynamic light scattering. In classical light scattering, if the particle size is of the order of or smaller than the wavelength of light, the light is scattered in all directions (Rayleigh scattering) and is a function of the molar mass and of the size of the particle. If the particle size is much greater than the wavelength of light, the intensity of the scattered light is dependent on the angle (Mie scattering). Classical light-scattering techniques are commonly used to study the size, shape, and structure of biological molecules in cells.

Dynamic light scattering involves the study of time-dependent fluctuations in the intensity of scattered light which are the result of the Brownian motion of the particles. The random movement of the particles causes the distances between the particles to fluctuate, causing constantly varying constructive and destructive interference patterns. This time-dependent fluctuation in the intensity can be correlated with itself to obtain the diffusion coefficient of the particles. This method is also called photon correlation spectroscopy (PCS) and quasi-elastic light scattering (QELS) [21, 22].

Fluorescence Correlation Spectroscopy

In fluorescence correlation spectroscopy (FCS), the fluorescence intensity of molecules within a small volume is statistically correlated to measure the concentration and the particle size. Typically, the sample is illuminated with a laser beam and the intensity, which is dependent on the number of fluorescent molecules, is measured. Since these fluorescent molecules exhibit Brownian motion, the number of particles present in the region will be constantly changing, resulting in a fluctuating intensity signal. If the time series of the intensity is correlated with itself, the resulting plot gives a measure of the number of fluorescent molecules present in that volume, as well as the diffusion coefficient of the molecules. By using a ▶confocal microscope, the background noise can be eliminated and the fluorescence intensity of a single molecule can be measured [23].

Fluorescence Recovery After Photobleaching (FRAP)

If a fluorescent molecule is irradiated with a high-intensity laser, the molecule undergoes a permanent chemical reaction, as a result of which it loses its fluorescent capability. This phenomenon is called photobleaching. In this method, high-intensity laser light is used to photobleach a small volume of the sample and low-intensity laser light is used to image the sample. Immediately after photobleaching, there is a dark region, where the fluorescent molecules have been inactivated, surrounded by a bright region containing unaffected fluorescent molecules. But, as time progresses, the fluorescent molecules from the bright region diffuse into the dark region. By measuring this fluorescence recovery after photobleaching, the mobile fraction and the rate of motion of the molecules in a region can be measured. The rate of motion can be used to calculate the diffusion coefficient.

The spatial resolution in FRAP (also known as fluorescence photobleaching recovery, FPR) measurements is limited by the minimum diffraction-limited size of the laser beam [24, 25].

Single-Particle Tracking

The most straightforward method of measuring diffusion is by tracking the movement of individual particles. Particles executing Brownian motion are imaged at fixed time intervals with the help of a video camera or CCD camera attached to a microscope. The images are then processed to locate the centers of the particles and to measure the distance that each particle travels within each time interval. The diffusion coefficient is obtained directly by plotting the mean square of the displacement as a function of time, as given by (14).

Several researchers have studied the Brownian motion of submicron-sized particles suspended in a fluid using digital video microscopy. Crocker and Grier [26] made use of optical tweezers to study the hydrodynamic correction to Brownian motion in the case of two spheres in close proximity. They argued that with careful experiments, diffusion coefficients can be experimentally measured to an accuracy of $\pm 1\%$. Nakrohis et al. [27] measured Boltzmann's constant, and Salmon et al. measured Avogadro's number by studying the Brownian motion of submicron-sized particles. Park et al. used optical serial-sectioning microscopy (OSSM) to measure Brownian particle displacements in all three dimensions and deduced temperature information with uncertainty differentials of 5.54%, 4.26%, and 3.19% for the 1D, 2D, and 3D cases. Kihm et al. used 3D ratiometric total internal reflection fluorescence microscopy (3D R-TIRFM) to measure Brownian displacements near a wall and calculated the hindered diffusion constant of 200 nm particles in the lateral and normal directions relative to the wall.

Examples of Application

Brownian motion is a rich field in terms of the attention it has received from both physicists and mathematicians,

and various models exist which incorporate other physical features. The study of Brownian motion is now being applied in fields as varied as financial modeling, protein–DNA interactions, fractal analysis in medical imaging, and estimation of floods.

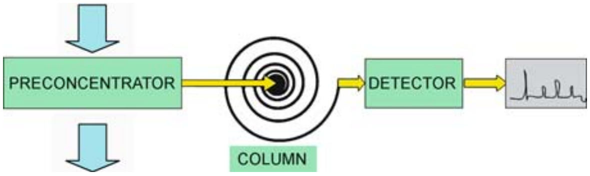
Definition

Gas chromatography (GC) is a chemical analysis technique for separating chemicals in a complex sample. In a gas chromatography setup, the sample is passed through a narrow tube known as the *column*, through which different chemical constituents of a sample pass in a gas stream (carrier gas, *mobile phase*) at different rates depending on their various chemical and physical properties and on their interaction with a specific column filling, referred to as the *stationary phase*. Interaction of the analytes with the stationary phase causes each one to exit the column at a different time (*retention time*). Separated chemicals are detected and identified at the end of the column. Miniaturization of GC systems can lead to small size and extremely low power consumption.

Overview

In the 50 years since its introduction, the use of GC by the petroleum industry has helped foster many breakthroughs in GC instrumentation. Open-tubular GC columns and the theory that describes them were first introduced by Golay and Ettre in the mid-1950s. The further development of open-tubular capillary columns was done by Desty of British Petroleum, and with subsequent refinement, this technique is now the standard method for most GC applications. The use of GC for sample analysis was also quickly adopted by the pharmaceutical and food industries and is used for fundamental studies of reaction kinetics and physiochemical measurements. Today the use of GC for the analysis of complex samples such as serum proteins, natural products, essential oils, and environmental samples has become routine with multidimensional separation techniques and multivariate *chemometric* analysis providing identification and quantification of trace analytes from complex samples in the sub-ppb range. A GC system usually consists of the following elements (Fig. 1):



Gas Chromatography, Figure 1 Schematic of a GC system

Injector/Preconcentrator

Most common injectors are microsyringes, solid-phase microextraction fibers, or a gas source switching system.

Column

Two types of columns are used in GC:

Capillary Columns

Conventional capillary columns have a very small internal diameter, of the order of a few tenths of millimeters, and lengths between 25 and 60 m. The inner column walls are coated with a thin layer of stationary phase material. Most capillary columns are made of fused silica with a poly-

imide outer coating. These columns are flexible, so a very long column can be wound into a small coil.

Packed Columns

Conventional macroscale packed columns are 1.5–10 m in length and have an internal diameter of 2–4 mm. The tubing is usually made of stainless steel or glass and contains a *packing* of finely divided, inert, solid support material (e. g. diatomaceous earth) that is coated with a liquid or solid stationary phase.

Detector(s)

A detector is used to monitor the outlet stream from the column; thus, the time at which each component reaches the outlet and the amount of that component can be determined. Generally, substances are identified by the order in which they emerge (elute) from the column and by the retention time of the analyte in the column.

The most common are the flame ionization detector (FID) and the thermal conductivity detector (TCD). Both detectors are sensitive to a wide range of components, and both work over a wide range of concentrations. While TCDs are essentially universal and can be used to detect any component other than the carrier gas, FIDs are sensitive primarily to hydrocarbons, and are more sensitive to them than TCDs.

Gas chromatographs are often connected to a *mass spectrometer* (MS) which acts as the detector. The setup, known as *GC/MS*, is powerful because the MS can identify compounds by mass giving another dimension to the separation.

Additional Parameters

Because molecular adsorption and the rate of progression along the column depend on temperature, the column temperature is carefully controlled during the separations. Temperature can also be ramped during the separation to obtain faster and more efficient separations. This is referred to as temperature programming.

Typical carrier gases include helium, nitrogen, argon, hydrogen, and air. Which gas to use is usually determined by the detector being used, the sample's matrix, or based on safety and availability.

Basic Methodology

Conditions in which the gas separations are done need to be optimized for a desired analysis. During the analysis, the following conditions can be varied: inlet temperature, detector temperature, column temperature, temperature program, carrier gas and carrier gas flow rates, the column's stationary phase, diameter and length, inlet type and flow rates, sample size, and injection technique.

The column temperature is selected as a compromise between the length of the analysis and the level of separation. Separations that are done at the same temperature for the entire analysis are called *isothermal*. Most of the time, to obtain a better separation, temperature is increased during the analysis. The initial temperature, rate of temperature increase (the temperature *ramp*), and final temperature are referred to as the *temperature program*. A temperature program shortens the time it takes for late-eluting analytes to pass through the column while allowing analytes that elute early in the analysis to separate well.

Key Research Findings

In the past few years there has been a considerable development in microscale gas chromatography. Several portable instruments are commercially available (by Varian, Agilent, Electronic Sensor Technology). These are not fully microfabricated instruments so as not to be confused with chip-based GC instruments often referred to as μGC instruments. The first microfabricated GC device was reported by Terry et al. [1]. The only commercially available fully integrated μGC system is being advertised by SLS Micro Technology (http://www.slsmt.de/). It consists of a gas chromatography module of the size of a credit card integrated on multilayer printed circuit board with standard gas connectors, a micro-injection system, a micromachined separation column, and μTCD for detection. The column is only 0.86 m in length and can use temperature programming, maximum temperature of 250 °C, for analysis times that are typically less than 60 s. The instrument is capable of high sensitivity of measurement, fully automated operation as well as stand-alone interpretation and rapid transmission of results.

In recent years several advances in μGC technology have been made in the following areas.

Column Channel Design and Fabrication

Typical materials used for μGC include silicon, metal, and a variety of polymers etched for column configuration. Typically, rectangular channels are etched using deep reactive ion etching, wet chemical etching, and high-energy laser etching. Recent work by Spangler [2, 3] has updated the model for chromatographic theory from that used for traditional round column GC to the rectangular channel dimensions of μGC systems. Some of the examples of published μGC systems include the packed-bed μGC system incorporated as part of the μChemLab project at Sandia [4] and work by Lambertus et al. [5] where they used

a square spiral design and commercial dimethylpolysiloxane stationary phase.

Novel Stationary Phases

New efficient and robust stationary phases for μGC are essential because traditional polymer GC stationary phases in the angular cornered channels of the μGC do not result in a uniformly thick stationary phase, i. e. the polymer phase tends to be significantly thicker in the corners of the channel, introducing unwanted band broadening. Nanostructured materials are being explored for this purpose such as monolayer protected gold nanoparticles [6], carbon nanotubes [7], and others.

Thus, research on ways to refine the use of polymer stationary phases within the μGC channel design also continues. Examples include using UV photopolymerization of gas-phase monomers for thin-film deposition [8] and plasma polymerization [9].

Interconnects/Interfaces

With the desire for high-speed separations on short columns, μGC systems must be carefully designed in order to minimize sources of extra-column band broadening such as dead volumes at connection points and within detectors, large injection pulses, and non-uniform flow patterns. The interface of the chip with instrumental components is extremely important and integration of all of the components directly with the column is preferred.

Future Directions for Research

One of the most active areas in the development of true microscale gas analyzers (chip based) has been motivated by the desire to build extremely small and fast gas analyzers for military use. DARPA is currently funding a micro gas analyzers (MGA) program. The goal of the MGA program is to attain tiny separation analyzer-based chemical warfare agent (CWA) sensors capable of orders of magnitude reductions in analysis time, detection limit, and power consumption, over equivalent bench top systems, while maintaining the true to false alarm ratios on a par with benchtop GC/MS systems. By harnessing the advantages of microscale miniaturization, the MGA program is expected to yield chip-scale gas analyzers with the following performance characteristics:

- An ability to identify all relevant CWAs against plausible background mixtures of more than 30 different species, including fuels with true to false alarm ratios on par with GC/MS systems, which are the gold standard of gas analysis.
- Overall size less than 2 cm^3 not including the power source, but including control electronics and any fluid transport, pre-concentration, and detection mechanisms, whichever used.
- Detection limit better than 1 ppt.
- Total analysis time less than 4 s, to include the time needed for any pre-concentration, separation, and detection steps.
- Energy per analysis less than 0.5 J (less than 1 J for full GC/MS).

Research topics and activities relevant to the implementation of MGA include:

- fast microscale pre-concentration;
- strategies for suppression of unwanted species;
- micro- or nanoengineered separation methods, such as ultrathin chromatographic columns;
- nanoengineered stationary phases;
- methods for fluid transport, including pumpless strategies;
- microscale thermal isolation for low power operation; and
- micro- or nanoengineered detectors with unprecedented sensitivity.

MGA-enabled devices with characteristics similar to those listed above and fabricated via low-cost, batch fabrication methods are expected to enable a myriad of strategic capabilities. In particular, the sheer portability of the CWA sensors sought by the MGA program should introduce a host of new applications and deployment scenarios, including wearable sensors for dismounted warriors, projectile-delivered sensors for remote detection applications, and unattended ground sensors for perimeter protection and advanced warning purposes. Although the small size and power consumption sought by MGA are obvious enablers for wearable CWA sensors, it is actually the MGA program's pursuit of false alarm rates on a par with tabletop GC/MS systems that makes possible this sort of *per soldier* deployment strategy. Presently that kind of deployment is hindered by the unacceptably high incidence of false positives exhibited by current fielded portable CWA sensors. In addition, the fast analysis speed and tiny size (for resilience against high g forces) targeted by the MGA program, together with miniature wireless technologies targeted by other DARPA programs (e. g. NMASP), will enable projectile-deployed MGAs for remote detection of distant CWAs, effectively allowing miniature point detectors to operate in a stand-off-like fashion. Furthermore, MGA-enabled low power and low false alarm rates should greatly facilitate the deployment of unattended sensor networks for first warning perimeter applications, as well as environmental monitoring applications in both military and civilian sectors. By enabling an expansion of applica-

tions, as illustrated above, miniaturization via MGA technology is expected to generate a need for high-volume manufacturing that, together with wafer-level batch fabrication methods enabled by MEMS technology, should substantially lower the cost of GC/MS-equivalent systems, and thus further fuel expansion of the application suite for MGA technology.

Synonyms

Internal rarefied gas flows; Slip flow regime; Transitional regime; Free molecular regime

Definition

Gas flow in nanochannels is distinguished by the regime when a characteristic size of a channel is comparable with the mean free path of gaseous molecules.

Mean free path is the average distance traveled by a gaseous molecule between two successive collisions.

Knudsen number is the ratio of mean free path of gaseous molecules to a typical dimension of gas flow.

Mass flow rate is the mass quantity of gas flowing through a cross-section of channel per unit time.

Overview

A typical magnitude of the mean free path ℓ in equilibrium air under standard conditions is about 5×10^{-8} m. Thus, if a channel has a cross-section size a in the range from 10^{-9} m to 10^{-7} m, then the *Knudsen number* $\mathrm{Kn}=\ell/a$ is not so small in order to use the approach based on continuum mechanics. In this case, gas flows must be considered on the kinetic level, i. e. the methods of ▶ rarefied gas dynamics based on the ▶ Boltzmann equation must be used. The advantage of the kinetic approach is that it is applicable for any value of the *Knudsen number*, namely for very small values ($\mathrm{Kn}\ll1$) corresponding to the channel size larger than 10^{-6} m (microchannels), for transitional values ($\mathrm{Kn}\sim1$) when the size a is about 10^{-8} m, and for large values ($\mathrm{Kn}\gg1$) if the channel size is close to 10^{-9} m (nanochannels). Thus, the kinetic equation is a tool allowing us to have a unique approach to micro- and nanochannels.

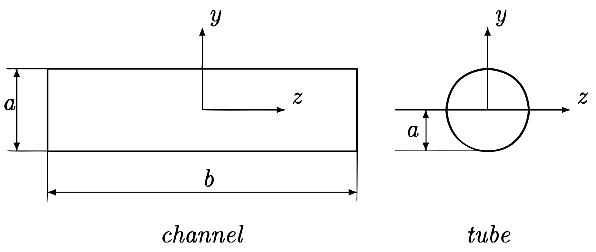
As is known, Poiseuille flow, i. e. gas motion due to a pressure gradient, is a typical phenomenon in all kinds of channels. However, a new phenomenon arises in nanochannels, namely ▶ thermal creep, i. e. gas flow due to a temperature gradient from a cold region to a hot one. In the transitional regime, i. e. when $\mathrm{Kn}\sim1$, this phenomenon is significant and should be taken into account together with the Poiseuille flow. Note that under the standard conditions the transitional regime is realized if the cross-section of channel a is about 10^{-8} m. Thus, if a nanochannel is non-isothermal then the two driving forces, such as pressure and temperature gradients, must be considered.

A numerical solution of the exact ▶ Boltzmann equation requires great computational effort that is not justified in practical and engineering calculations. That is why the so-called ▶ model equations allowing one to reduce the effort are widely used in practice.

In the open literature one can find reliable results on gas flows through long tubes, long rectangular channels and thin orifices over the whole range of the *Knudsen number*. Such flows were calculated for both driving forces, i. e. for pressure and temperature gradients. Numerical calculations were carried out on the basis of the model equations and also applying the exact Boltzmann equation itself. A consequence of the non-complete accommodation of the gaseous molecules on nanochannel walls was also intensively studied. Most of the published results can be applied directly to numerical simulations of microfluidics.

Basic Methodology

Here, long channels with two types of cross-section are considered: rectangular with a height a and width b and cylindrical with a radius a as is shown in Fig. 1. Further, the rectangular channel will be referred to as just *channel*, while the channel with the cylindrical cross-section will be called *tube*. It is assumed the channel/tube length L to be significantly larger than its cross-section size. i. e. $L\gg a$ and $L\gg b$. A rarefied gas moves along the channel/tube due to small longitudinal gradients of pressure P and temperature T denoted as



Gas Flow in Nanochannels, Figure 1 Cross-sections and coordinates

$$\xi_{\mathrm{P}}=\frac{a}{P}\frac{\mathrm{d}P}{\mathrm{d}x},\qquad \xi_{\mathrm{T}}=\frac{a}{T}\frac{\mathrm{d}T}{\mathrm{d}x},\tag{1}$$

respectively. Here, x is the longitudinal coordinate. In practice, one is interested in the mass flow rate $\dot{M}$ defined as

$$\dot{M}^{\mathrm{ch}}=\int_{\frac{-b}{2}}^{\frac{b}{2}}\int_{\frac{-a}{2}}^{\frac{a}{2}}\rho u_x(y,z)\,\mathrm{d}y\,\mathrm{d}z\tag{2}$$

for channel and

$$\dot{M}^{\mathrm{tb}}=2\pi\int_0^a\rho u_x(r)r\,\mathrm{d}r,\qquad r=\sqrt{y^2+z^2}\tag{3}$$

for tube, where ρ is the mass density and u_x is the bulk velocity of the gas. Since the gradients ξ_{P} and ξ_{T} are small the mass flow rate depends linearly on them, i. e.

$$\dot{M}^{\mathrm{ch}}=\frac{abP}{v_0}\left(-G_{\mathrm{P}}^{\mathrm{ch}}\,\xi_{\mathrm{P}}+G_{\mathrm{T}}^{\mathrm{ch}}\,\xi_{\mathrm{T}}\right)\tag{4}$$

for channel, and

$$\dot{M}^{\mathrm{tb}}=\frac{\pi a^2P}{v_0}\left(-G_{\mathrm{P}}^{\mathrm{tb}}\,\xi_{\mathrm{P}}+G_{\mathrm{T}}^{\mathrm{tb}}\,\xi_{\mathrm{T}}\right)\tag{5}$$

for tube. Here, v_0 is the most probable molecular speed

$$v_0=\left(\frac{2k_{\mathrm{B}}T}{m}\right)^{\frac{1}{2}},\tag{6}$$

$k_{\mathrm{B}}=1.380662\times10^{-23}$ J/K is the Boltzmann constant and m is the molecular mass of the gas in kg. The coefficient G_{P} corresponds to the gas flow induced by a pressure gradient and it is called the ▶ Poiseuille coefficient.

Note that if the super-index ch or tb is omitted the quantity is referred to both channel and tube. The coefficient G_T describes a gas flow due to a temperature gradient and it is called the ▶ thermal creep coefficient. The coefficients G_P and G_T are introduced so that they are always positive. They are calculated from the kinetic equation and determined by the ▶ rarefaction parameter

$$\delta = \frac{Pa}{\mu v_0}, \tag{7}$$

where μ is the gaseous viscosity in Pa s. Moreover, the coefficients G_P and G_T are affected by the gas-surface interaction law.

A moderate gas rarefaction, say $5 \leq \delta \leq 100$, can be taken into account applying the Navier–Stokes equation with the velocity slip boundary conditions. This is the so-called *slip flow regime*. In practice, the slip boundary conditions mean that the bulk velocity is not equal to zero on the wall, but its tangential component u_t is proportional to its normal gradient

$$u_t = \sigma_P \, \ell \, \frac{\partial u_t}{\partial x_n}, \quad \text{at} \quad x_n = 0, \tag{8}$$

where σ_P is the ▶ viscous slip coefficient, x_n is the coordinate normal to the surface directed toward the gas, and $\ell = \mu v_0 / P$ is the ▶ equivalent mean free path. Since a rarefied gas flow is induced by a temperature gradient too, then the tangential velocity is proportional to the longitudinal temperature gradient, i. e.

$$u_t = \sigma_T \frac{\mu}{\rho} \frac{\partial \ln T}{\partial x_t}, \quad \text{at} \quad x_n = 0, \tag{9}$$

where σ_T is the ▶ thermal slip coefficient and x_t is the tangential coordinate. The detailed technique of calculations of the slip coefficients σ_P and σ_T on the basis of the kinetic equation and their numerical values can be found in many papers (e. g. [5, 8, 13]).

The values recommended in practical calculations are as follows:

$$\sigma_P = 1.018, \qquad \sigma_T = 1.175, \tag{10}$$

which were obtained under an assumption of the diffuse scattering of gaseous particles on the surface. In most practical situations this assumption is fulfilled. Only in some special situations, the deviation from the diffuse scattering can be significant (e. g. [9]). If one deals with such a situation, then the expression

$$\sigma_P(\alpha_t) = \frac{1}{\alpha_t} \left[1.016(2 - \alpha_t) - 0.2640(1 - \alpha_t) \right] \tag{11}$$

should be used, which was obtained as an interpolation of the numerical data [13] based on the kinetic equation and ▶ gas–surface scattering kernel obtained by Cercignani and Lampis. Here, α_t is the tangential momentum accommodation coefficient. Numerical data of the slip coefficients σ_P and σ_T for gaseous mixtures can be found in [16, 17], respectively.

However, in the transitional regime, i. e. when the rarefaction parameter is intermediate ($\delta \sim 1$), the slip solution is not valid. Such a situation is realized when the channel/tube size a is less than 2×10^{-7} m. In this case the kinetic ▶ Boltzmann equation is applied to calculate the coefficients G_P and G_T. In the free-molecular regime, i. e. when the rarefaction parameter is very small ($\delta \ll 1$), the intermolecular collisions can be neglected and the ▶ Boltzmann equation is significantly simplified. This happens if the channel/tube size a is smaller than 10^{-9} m.

For brief information about the calculations of G_P and G_T see in ▶ micro- and nanoscale gas dynamics. The details of such calculations and recommended data on the coefficients G_P and G_T can be found in [18]. Below, some of these data and examples of their applications are given.

Key Research Findings

Free-Molecular Regime

In the free-molecular regime ($\delta = 0$) assuming the diffuse gas–surface interaction on the channel/tube wall, the coefficients G_P and G_T can be calculated directly without numerical solution of the kinetic equation. In the case of the channel the ▶ Poiseuille coefficient G_P^{ch} is given by the following double integral:

$$G_P^{ch} = \frac{1}{\sqrt{\pi}} \frac{a}{b} \int_0^{b/a} \int_0^1 \left[\zeta \ln \frac{C + \eta}{C - \eta} + \eta \ln \frac{C + \zeta}{C - \zeta} \right] d\eta \, d\zeta,$$
$$C = \sqrt{\eta^2 + \zeta^2}. \tag{12}$$

The numerical values of G_P^{ch} for some aspect ratios are given in Table 1. If the channel is sufficiently wide, i. e. $b \gg a$, then the expression given above is simplified as

$$\lim_{b/a \to \infty} G_P^{ch} = \frac{1}{\sqrt{\pi}} \left(\ln \frac{2b}{a} + \frac{1}{2} \right). \tag{13}$$

In the case of a tube the expression of the ▶ Poiseuille coefficient G_P^{tb} is quite simple:

$$G_P^{tb} = \frac{8}{3\sqrt{\pi}}. \tag{14}$$

Gas Flow in Nanochannels, Table 1 Coefficients $G_P^{ch}(\delta = 0)$, H, and S vs. aspect ratio b/a

b/a	G_P^{ch} $(\delta = 0)$	H	S
1	0.839	0.422	0.562
10	1.99	0.937	0.949
20	2.37	0.968	0.975
∞	∞	1.0	1.0

The ▶ thermal creep coefficient G_T in both channel and tube is given by

$$G_T = \frac{G_P}{2}. \tag{15}$$

Slip Flow Regime

To calculate the ▶ Poiseuille coefficient G_P in the slip flow regime ($5 \leq \delta \leq 100$) the Navier–Stokes equation is solved with the velocity slip boundary conditions (8). Then for the channel the flow rate reads

$$G_P^{ch} = \frac{\delta}{6} H + \sigma_P S,$$
$$H = 1 - \frac{192}{\pi^5} \frac{a}{b} \sum_{i=0}^{\infty} \frac{\tanh\left(\pi\left(i+\frac{1}{2}\right)\frac{b}{a}\right)}{(2i+1)^5} \tag{16}$$

The coefficients H and S are calculated numerically (see [12]). They depend only on the aspect ratio and can be used with any ▶ viscous slip coefficient σ_P including that obtained for the non-diffuse gas–surface interaction (11) and for gaseous mixtures [16]. The numerical values of H and S are given in Table 1. If the channel is wide, i. e. $b \gg a$, then the expression (16) is reduced to

$$\lim_{b/a \to \infty} G_P^{ch} = \frac{\delta}{6} + \sigma_P. \tag{17}$$

For tube the expression of the ▶ Poiseuille coefficient G_P reads

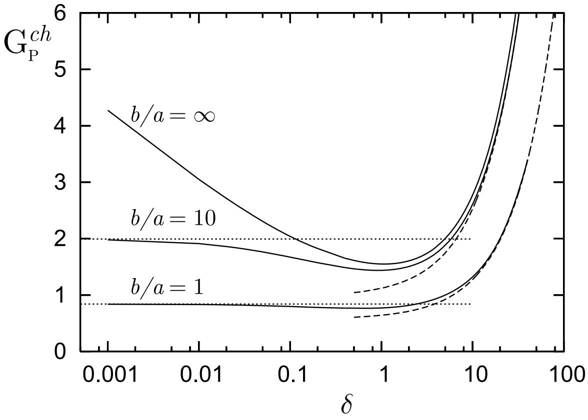
$$G_P^{tb} = \frac{\delta}{4} + \sigma_P. \tag{18}$$

The ▶ thermal creep coefficient G_T is also obtained from the Navier–Stokes equation, but applying the thermal slip boundary condition (9). It is verified that this coefficient does not depend on the type of the cross-section in the slip flow regime, but in any case considered here it takes the form

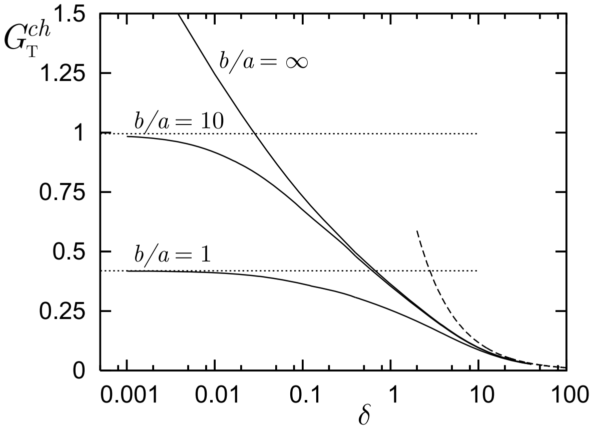
$$G_T = \frac{\sigma_T}{\delta}. \tag{19}$$

Transitional Regime

To calculate the coefficients G_P and G_T in the transitional regime ($\delta \sim 1$) the kinetic equation is applied. The coefficients G_P^{ch} and G_T^{ch} for the channel flow obtained in [11] assuming the diffuse scattering are presented in Figs. 2 and 3, respectively. For all values of the aspect ratio b/a the ▶ Poiseuille coefficient G_P^{ch} has the Knudsen minimum near the point $\delta \approx 1$. For the square channel ($b/a = 1$) the minimum is rather shallow. Since the variation of G_P^{ch} near the free molecular regime is small its free molecular value can be used for practical calculations in the range $0 \leq \delta \leq 5$. Then for $\delta > 5$ the hydrodynamic solution (16) with the slip boundary condition can be used. Such an approximation works with a precision of 10%. However,



Gas Flow in Nanochannels, Figure 2 Poiseuille coefficient G_P^{ch} vs rarefaction parameter δ: solid lines – kinetic equation solution [11], pointed line – free molecular value based on Eq. (12), dashed line – Navier–Stokes solution Eq. (16)



Gas Flow in Nanochannels, Figure 3 Thermal creep coefficient G_T^{ch} vs rarefaction parameter δ: solid lines – kinetic equation solution [11], pointed line – free molecular value based on Eqs. (12) and (15), dashed line – Navier–Stokes solution Eq. (19)

for large values of the aspect ratio, i. e. at $b/a \geq 10$, the Knudsen minimum is deep and reliable results can be obtained only by solving the kinetic equation. The ▶ thermal creep coefficient G_T^{ch} vanishes in the hydrodynamic regime ($\delta \to \infty$) in accordance with Eq. (19) and in the free-molecular regime it tends to a constant value given by Eqs. (12) and (15). Note that both coefficients G_P^{ch} and G_T^{ch} have a singularity, i. e. they tend to infinity, at $\delta \to 0$ and $b/a \to \infty$, which is related to the degenerated geometry. However, in practice the aspect ratio b/a is always finite, so the flow rate is never infinite.

The coefficients G_P^{tb} and G_T^{tb} for the tube flow reported in [18] are presented in Figs. 4 and 5, respectively. Like for the channel, the ▶ Poiseuille coefficient G_P^{tb} also has a small minimum in the transition regime ($\delta \sim 1$). Its variation near the free molecular regime is very small. For large values of the ▶ rarefaction parameter δ the numerical solution tends to the analytical expression (18). The ▶ thermal creep coefficient G_T^{tb} vanishes in the hydrodynamic limit ($\delta \to \infty$) according to Eq. (19) and it tends to the constant value given by Eqs. (14) and (15) in the free molecular regime.

To show how the gas–surface interaction affects the flow rates, some values of G_P^{tb} and G_T^{tb} for the Cercignani–Lampis ▶ gas–surface scattering kernel obtained in [14] are given in Tables 2 and 3 (reprinted from [14] with permission from Elsevier), respectively. In all regimes the influence of the energy accommodation coefficient α_n on the ▶ Poiseuille coefficient G_P^{tb} is weak, while the momentum accommodation coefficient α_t affects significantly this coefficient in the transition ($\delta = 1$) and near the free molecular ($\delta = 0.01$) regimes. Both accommodation coefficients α_n and α_t moderately affect the ▶ thermal creep coefficient G_T^{tb} in all regimes of the flow. Since both transitional and free molecular regimes usually occur in nanochannels, a correct consideration of the gas–surface interaction and reliable data on the accommodation coefficients are very important.

To illustrate the application of the results given above let us consider helium flowing through a channel with height $a = 2.17 \times 10^{-8}$ m and width $b = 2.17 \times 10^{-7}$ m, i. e. the aspect ratio b/a is equal to 10. Let us assume the pressure to be $P = 10^5$ Pa and the temperature to be $T = 293.15$ K,

i. e. 20 °C. Under such conditions the gas viscosity is $\mu = 19.73 \times 10^{-6}$ Pa s and the most probable speed is $v_0 = 1.10 \times 10^3$ m/s. Substituting these values into Eq. (7) the ► rarefaction parameter is obtained as $\delta = 0.1$. According to Figs. 2 and 3 the coefficients G_P^{ch} and G_T^{ch} are equal to 1.67 and 0.68, respectively. If the gas flow is induced by the pressure gradient $\xi_P = 0.01$ and by the temperature gradient $\xi_T = 0.01$, then from Eq. (4) the mass flow rate is obtained as $\dot{M}^{ch} = 4.24 \times 10^{-15}$ kg/s. Considering a gas flow under the same conditions through a tube of radius $a = 2.17 \times 10^{-8}$ m with the help of Figs. 4 and 5 we obtain $G_P = 1.41$ and $G_T = 0.62$ at $\delta = 0.1$. Then the mass flow rate is calculated from Eq. (5) as $\dot{M}^{tb} = 1.06 \times 10^{-15}$ kg/s. If the drops of pressure and temperature are large then the technique elaborated in [10, 18] must be used. In the case of isothermal flow, i. e. $\xi_T = 0$, the following simple formulas are obtained for the mass flow rate:

$$\dot{M}^{ch} = \frac{ab\mu}{L} \int_{\delta_1}^{\delta_2} G_P^{ch}(\delta)\, d\delta, \tag{20}$$

$$\dot{M}^{tb} = \frac{\pi a^2 \mu}{L} \int_{\delta_1}^{\delta_2} G_P^{tb}(\delta)\, d\delta, \tag{21}$$

where δ_1 and δ_2 are ► rarefaction parameters on the channel/tube ends.

Numerical results on the capillary flow of polyatomic gases can be found in [4]. Comparing these results with the data presented here it is concluded that the ► Poiseuille coefficient G_P is slightly affected by the internal structure of molecules. The ► thermal creep coefficient G_T for polyatomic gases differs from that for monatomic gases.

A methodology of calculation of gaseous mixtures flowing through long nanochannels is described in [6, 7, 15]. From these data it is concluded that if the molecular masses of species are close to each other then the results for a single gas are applicable to this mixture. If the masses are quite different then calculations based on the kinetic equation should carried out for every specific mixture.

Future Directions for Research

Calculations of mass flow rate through a short channel, i. e. when the length L, width b and height a are arbitrary, would be useful in practice. In many applications, e. g. micropumps, the channels/tubes have a spiral form. Thus, calculations of gas flow through curve channels is needed. Until now, only some simple flows of polyatomic gas and gaseous mixtures were calculated. A further investigation in this direction would be interesting.

Genosensors

Definition

Biosensors are bioanalytical systems defined by the integration of the four key components of: sample presentation, biotransduction, instrumentation and data output. Central to the biosensor system is the biotransducer that converts the activity (concentration) of the targeted analyte into a proportionate signal via an intimate combination of a biological recognition membrane layer and a physico-chemical transducer. The biological recognition membrane is to provide its specificity by the use of biomolecules such as DNA, RNA, PNA, enzymes, antibodies, enzyme-linked antibodies and receptors, and may

be sub-cellular fragments such as mitochondria, cell membranes components (receptors), or whole cells (bacteria or mammalian cells), and/or tissue slices (liver, brain, etc.). An impedimetric biosensor is constructed by immobilizing biological recognition elements onto an electrode surface. It reports, through measurement and/or monitoring, the targeted analyte through the output of an electrical impedance signal made proportional to analyte activity.

Bonding of non-metallic inorganic surfaces and polymers

Definition

A ►polymer is a material composed of large macromolecules. These macromolecules are formed by chains of hundreds or thousands of connected (polymerized) monomer molecules. The three main classes of polymers are thermoplastics, elastomers and thermosets. They differ in the degree of cross-linking of their macromolecules – from no cross-linking (thermoplastics) to moderate cross-linking (elastomers, rubbers) to high cross-linking (thermosets).
A non-metallic inorganic material can be a bulk material (e. g., a glass chip, a quartz chip or a silicon chip which possesses a natural silicon oxide layer similar to glass) or a coating (e. g., a dielectric transition metal oxide coating on a chip).
The gage ►pressure is the pressure difference between the measured absolute pressure and the normal atmospheric pressure (101,325 Pa).

Overview

Polymers have become established materials in microfluidics. They offer a good potential for cost-efficient mass fabrication of microfluidic systems. For pure polymer microfluidic systems, the sealing of the microchannels can be accomplished using well-known techniques. For example, the most established sealing techniques for thermoplastic-thermoplastic bonding include lamination, ultrasonic welding or thermo-compression bonding (diffusion bonding). Thermo-compression bonding can be enhanced by solvent or plasma treatment.
However, there are applications when polymer microfluidic channels have to be bonded to a glass chip, a quartz chip, a silicon chip or a chip coated with a dielectric oxide ceramic layer. This is the main focus of the present article. One example is a glass or silicon chip with photolithographically defined electrodes for electrochemical detection. Other examples include a variety of microfluidic sensor chips for label-free detection, e. g., evanescent light based wavelength interrogated optical systems (WIOS) or surface plasmon resonance (SPR) chips. WIOS chips usually consist of a glass substrate coated with an amorphous transition metal oxide layer, e. g., tantalum oxide or titanium oxide. SPR chips can be glass chips coated with a gold layer (or silver, depending on the light source) and additionally also with a dielectric layer like the oxides mentioned before or hafnium oxide. There is a trend to combine SPR or WIOS sensors with mass spectroscopy for a more complete analysis of proteins. This can be done either by eluting the captured proteins from the SPR sensor chip surface, or by transferring the sensor chip with the captured and precipitated proteins to a mass spectrometer. In the latter case, the glass-thermoplastic bonding has to be reversible.
Another application includes glass or silicon chips for DNA or protein detection where the biochemical immobilization of capture (probe) molecules on the chip surface is based on a particular surface chemistry. The most common surface chemistries on biochips are thiol and silane chemistries. With silane chemistry the probe molecules are immobilized directly on the silicon or glass substrate. With thiol chemistry the probe molecules are immobilized on metal spots or electrodes (e. g., gold) which are fabricated by photolithography on glass or silicon chips. There are also surface chemistries for silicon or glass chips based on very reactive organic double (alkene) and triple (alkyne) bonds.

Further applications comprise glass chips with photolithographic electrodes for dielectrophoresis or for flow cytometry based on impedance spectroscopy, which are bonded to polymer fluidic scaffolds.

Chemically, a glass surface, a quartz surface, a silicon surface with a natural silicon oxide layer and an oxide ceramic coating surface are similar. Hence the methods for bonding polymer microfluidic scaffolds to them are similar. For simplicity, in the following subchapters the term *glass* stands for all these ► non-metallic inorganic materials.

In the following subchapters of the overview, glass-polymer bonding strategies are sketched for all three polymer classes. Glass-thermoplastic bonding strategies, which are particularly interesting from the market perspective because of the potential of low-cost mass fabrication of thermoplastic microfluidic scaffolds, are discussed in more detail in the chapter *Key Research Findings*.

Glass–Thermoset Bonding

In a thermoset, the cross-linking degree of the macromolecules is very high resulting in a stiff material which cannot "melt". Thermosets include e. g., negative-tone photoresists where the high degree of cross-linking is achieved by curing with heat or ultraviolet (UV) light. Therefore, thermosets are materials well-known and widely used in clean-room microfabrication. A good overview on the bonding of silicon with thermosets like BCB (benzocyclobutene) or photoresists used in clean-room microfabrication is given in [1]. For microfluidic channel fabrication, negative photoresists like SU-8 and photosensitive polyimide (PI) are used. Before structuring the microchannels, electrodes can be integrated on the glass substrate using a lift-off process. The adhesion bond of the SU-8 and polyimide channels on the glass substrate is good.

The advantage of this bonding strategy is the precise alignment of the microchannels with respect to the glass chip and the electrode or sensor structures on which they are made by photolithography. After curing of the photoresist on the glass substrate, the channels can be sealed with PDMS or a photoresist laminate. For some applications, the microfluidic channels have to be sealed with a glass cover which may also contain metal electrodes, e. g., for impedance spectroscopy or dielectrophoretic separation. In the case of SU-8, two glass chips with electrodes and soft baked microfluidic channels can be bonded in a final curing process under pressure. Sealing of SU-8 channels has also been demonstrated by lamination with a glass chip carrying a layer of uncured SU-8 [2], or a glass substrate laminated with uncured PMMA [3]. In the case of PI channels, the laminate can be a glass substrate coated with soft-baked PI. The final cure of the laminate for sealing is done under contact pressure [4]. The disadvantage of fabricating microfluidic channels in photoresist is the cost of the photolithography step. Further, the high temperatures involved in the final curing step do not allow the pre-deposition of bio-molecules in the microfluidic channels before bonding.

Another approach to form sealed microfluidic channels on glass substrates is derived form stereolithography. Photocurable thermoset is built up layer by layer between two plates. After curing, due to the surface properties of the plates, the adhesion to one plate is strong and weak to the other plate, allowing for separation there to build up the next layer. The integration of metallic electrodes is also possible. The thermoset properties can be adapted by mixing additives to it [5].

Glass–Elastomer Bonding

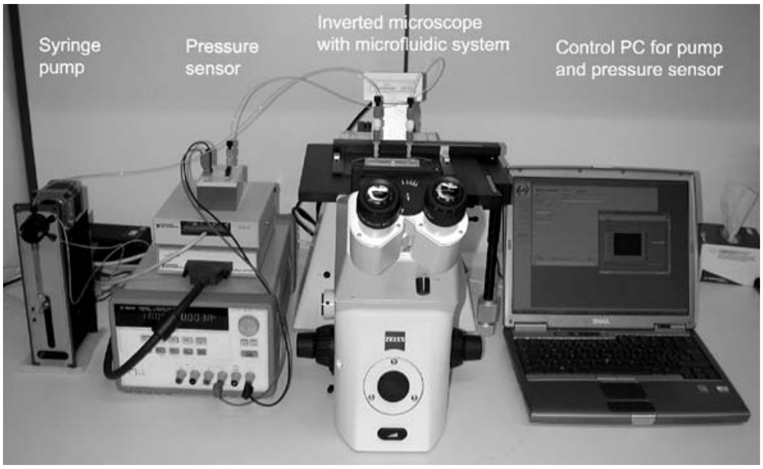
In an elastomer (rubber), the macromolecules are cross-linked. The cross-linking degree is moderate so that elastomers can be stretched easily. A transparent elastomer widely used in microfluidics is the silicone rubber polydimethylsiloxane (PDMS).

Glass-PDMS bonding is one of the most common methods in microfluidics research. Usually, the PDMS contains microfluidic channel structures replicated by polymerizing and cross-linking the PDMS on a master, e. g., a deep reactive ion etched (DRIE) master wafer or a master with SU-8 structures. The PDMS can be bonded to the glass reversibly by simply placing it onto the glass chip after some simple cleaning and pre-treatment steps (self-sealing), or irreversibly after an oxygen (or air) plasma treatment. The plasma treatment results in a replacement of the methyl ($\equiv \mathrm{Si}-\mathrm{CH_3}$) groups on the PDMS surface with hydroxyl ($\equiv \mathrm{Si}-\mathrm{OH}$) groups [6]. The hydroxyl groups on the PDMS and on the glass surface interact forming a strong bond ($\equiv \mathrm{Si}-\mathrm{O}-\mathrm{Si}\equiv$) and a water molecule ($H_2O$, condensation).

PDMS as a channel material has the disadvantage that bio-molecules tend to be adsorbed on it and to diffuse into it.

Glass–Thermoplastic Bonding

In a thermoplastic, the macromolecules are not cross-linked so that the material can "melt", i. e. above the glass transition temperature the material begins to soften. Thermoplastics can be amorphous or semi-crystalline. In microfluidics, amorphous polymers are often preferred because of their optical transparency. Amorphous polymers include polymethylmethacrylate (PMMA), polycar-



Glass-Polymer Bonding, Figure 1 Experimental setup for leak tests. The bonded chip is mounted on top of an inverted light microscope for optical leak detection. The pressure is generated with a syringe pump at the chip inlet side and measured at the outlet side with a MEMS gage pressure sensor

bonate (PC), polystyrene (PS), and cyclic olefin polymers (COP) and copolymers (COC). COP and COC, unlike most other polymers, are also transparent for UV light.
Thermoplastics are a particularly attractive material class because they have the potential for cost-efficient mass fabrication of microfluidic scaffolds, e. g., by injection molding. Therefore, the chapters *Basic Methodology* and *Key Research Findings* are devoted entirely to discussing glass-thermoplastics bonding strategies in detail.

Basic Methodology

Glass-thermoplastics bonding can be accomplished reversibly or irreversibly. Reversible approaches include clamping using microfabricated gasket membranes. Irreversible approaches include microstructured double-sided adhesive tape gaskets and gluing. These bonding strategies will be described and evaluated in more detail in the chapter *Key Research Findings*.

Typical Pump Pressures in Microfluidic Systems

For the evaluation of the bonding quality, it is important to know which pump pressures are typically involved in microfluidics. Table 1 gives a brief overview.

Leak Test Setup for Bond Quality Evaluation

For evaluation of the bonding quality obtained with the different bonding strategies, each approach was subjected to a series of leak tests. The following setup was used for this purpose. The bonded test system consisting of a glass chip bonded to a PMMA microfluidic scaffold was mounted onto an inverted microscope. In an inverted microscope, the objectives are below the observed object allowing easy access for fluidic connections to the microfluidic system from above. The microscope was used to observe possible leaks in the system. For this purpose, it was operated in the bright field mode and DIC (differential interference contrast) mode. The fluorescence mode was not used because of the auto-fluorescence of the PMMA.
On the inlet side, the microfluidic system was connected to a syringe pump with a 100 µl syringe. The pump generated a gage pressure of about 33,000 Pa covering the pressure range generated by typical microfluidic pumps (Table 1). On the *dead-end* outlet side, a MEMS gage pressure sensor measured the pressure in the system both to obtain quantitative data and to have a second means for possible leak detection. The experimental setup is shown in Fig. 1.

Glass-Polymer Bonding, Table 1 Typical pump pressures in microfluidic systems [7]

Pump type/actuation	Typical maximum pump pressure Δp_{max}/Pa
Piezoelectric	6000 – 17,000
Electrostatic	29,000
Thermopneumatic	3000 – 16,000
Pneumatic	2000 – 35,000
Shape memory alloy	530
Electromagnetic	5000 – 10,000
Electrowetting	700
Electrohydrodynamic	250 – 780
Electroosmotic (micromachined channels)	5000 – 33,000
Magnetohydrodynamic	170

Biocompatibility Issues

Another important issue for many hybrid glass-polymer bonding applications is biocompatibility. This includes both the materials involved in the bonding process and the bonding process parameters. Material biocompatibility means that the bio-molecules are not degraded or do not become dysfunctional after contact with the chip or bonding materials. On the other hand, the bonding process itself may have to be biocompatible. For example, capture (probe) bio-molecules are sometimes already attached to the chip surface before the chip is bonded and sealed with the microfluidic scaffold. That requires the bonding process to be compatible with the bio-molecules, e. g., in terms of bonding temperature, exposure to radiation or chemical environment. All used adhesive tapes and the glue where medical grade, i. e. biocompatible. No UV or thermal curing step was required for the glue. PDMS gaskets are also compatible with many bio-molecules. In addition, the contact area with the PDMS gasket channel side walls is very small. If necessary, the PDMS gasket channel walls can be passivated prior to a bioassay.

Key Research Findings

The following glass-thermoplastic bonding strategies will be discussed in this chapter:

- Clamping with microfabricated rubber gaskets (reversible bond)
- Bonding with microstructured double-sided adhesive tapes (not a truly reversible bond, but also not strictly irreversible)
- Gluing (irreversible bond)
- Bonding with heat and pressure (irreversible bond)

Glass–Thermoplastic Bonding by Clamping With Microfabricated Gaskets

Clamping is a reversible bonding method. The glass chip and the thermoplastic microfluidic scaffold are pressed together by a mechanical clamping system. Reversible sealing is interesting if the sensor chip or the microfluidic scaffold are used more than once, e. g., if a complex fluidic system with valves or actuators has to be re-used after cleaning. It is also of interest if bio-molecules are captured and precipitated or crystallized on certain sensor or detection sites on a glass chip and in a next step analyzed by mass spectroscopy. In this case, the glass chip with the captured bio-molecules can be separated from the microfluidic scaffold after the capturing the bio-molecules and transferred to a mass spectrometer.

To achieve a good sealing between glass chip and thermoplastic microfluidic scaffold, an elastic membrane, e. g., a silicone rubber, should be used as a gasket. The gasket membrane usually contains the microfluidic channel leading to the sensor. In the scaffold, the channel can go up a level to connect to a manifold of microfluidic inlet and outlet channels, mixers or other microfluidic elements. In microfluidics, the membrane gaskets forming the channels are usually only 30 – 100 μm high. The channel width is typically smaller than a millimeter. Therefore, the manufacturing of gasket membranes forming these miniature channels requires microfabrication.

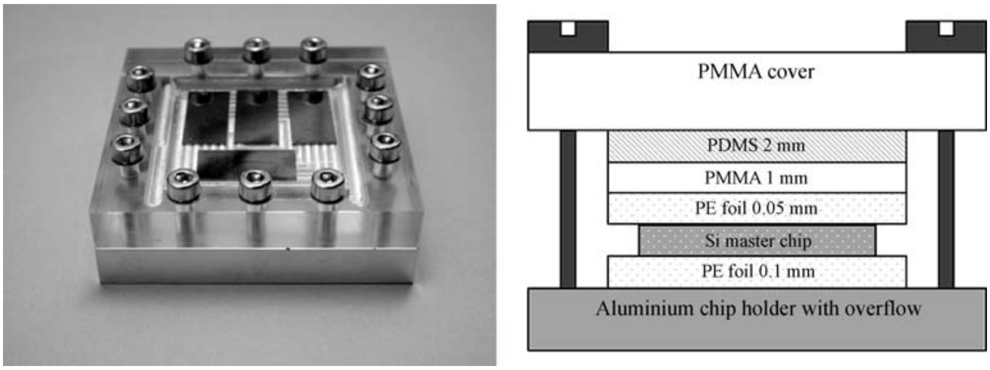
Gasket Microfabrication

Two approaches are described here for gasket microfabrication: casting and laser cutting. The gasket material is a silicone rubber, PDMS.

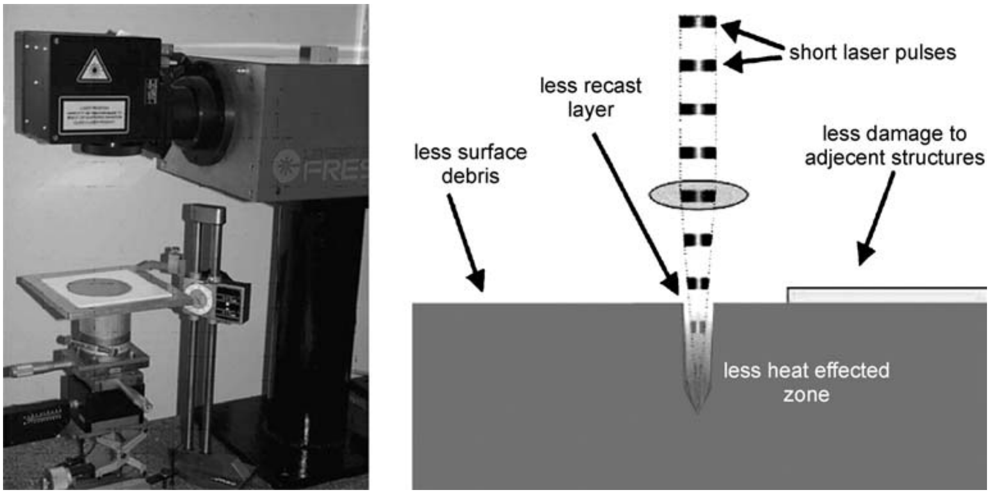
Casting of PDMS gaskets The PDMS is cast on DRIE silicon masters. The DRIE masters ensure very accurate lateral channel dimensions of the gaskets. For a better cutout and demolding, rims are recommended on the DRIE master around each individual gasket. The rims should have the same height as the microchannels on the master. The silicon masters are silane treated to facilitate demolding.

The DRIE masters are placed into a casting setup as shown in Fig. 2. The casting setup is a stack of the following components: aluminum holder with internal threads, 0.1 mm PE foil so that the masters are not glued to the aluminum, DRIE masters on which the PDMS monomer solution is cast after degassing, a 0.05 mm PE foil on which the PDMS sticks after curing allowing for an easy demolding, a 1 mm PMMA sheet, a 2 mm cured PDMS stress homogenizer and a PMMA clamp with screws. The setup is transparent and allows optical observation from above. The setup is clamped together using the screws. The DRIE master channel structures and the rims of the same height act as spacers ensuring the accurate thickness of the PDMS gaskets.

The PDMS is cured in the casting setup at 65 °C for 4 h. Since the PDMS shrinks during the curing in the mold but adheres to the DRIE master structures, the gaskets will have the defined height at the channel walls and the rims and will be somewhat lower in between. That is no disadvantage because the sealing is accomplished at the highest thickness, the channel wall. The effect can be avoided by an intelligent mold design. In a multi-channel gasket, channel separation walls have been demonstrated as thin as 200 μm for an eight channel system with 1 mm wide channels. After curing, the demolding of the gaskets and further handling should be done in alcohol, e. g., methanol,



Glass-Polymer Bonding, Figure 2 Setup for the casting of PDMS membrane gaskets. The PDMS monomer solution is applied and compressed between the DRIE silicon master and the 0.05 mm PE foil. Gaskets down to 50 μm thickness were fabricated using this method



Glass-Polymer Bonding, Figure 3 Nd.YAG 355 nm (frequency tripler) UV laser for cutting PDMS membrane gaskets and adhesive tape gaskets. The spot size is 20 μm. The laser burns less material in thermoplastics than IR lasers resulting in a cleaner cut and runs more stable than UV excimer lasers

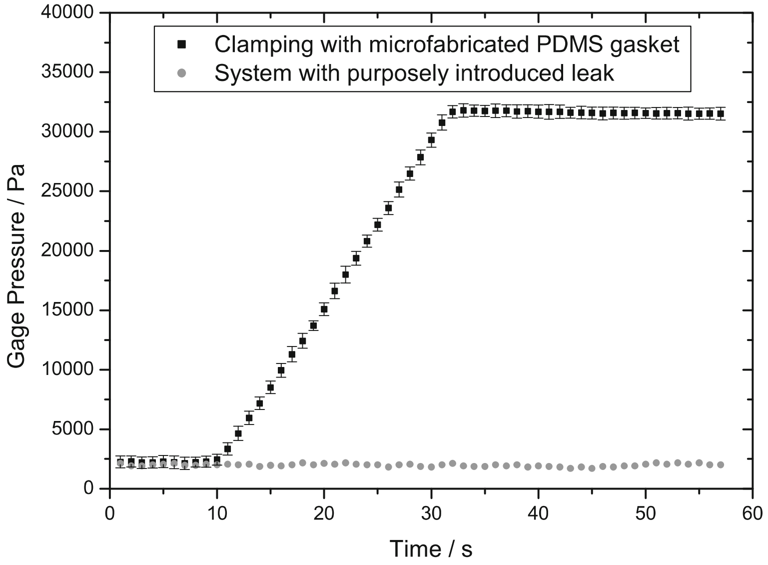
ethanol or isopropanol. This helps to avoid curling or damaging the delicate gaskets.

Laser cutting of PDMS gaskets Before laser cutting, the degassed PDMS monomer is spin-coated or knife-coated with the desired thickness on a substrate. Glass, for example, is a recommended substrate. The PDMS is cured at 65 °C for 4 h. For laser cutting, a Nd : YAG 355 nm laser was used (Fig. 3). The laser is a UV (ultraviolet light) laser. Compared to conventional IR (infrared light) lasers for material cutting, it causes less material damage in a polymer, i. e. it burns less material (smaller melt zone). That allows fabricating channel widths down to 20 – 40 μm as compared to typical IR laser channel widths of 250 μm [8]. In addition, the laser can be operated in short pulses. Therefore, the formation of the usual recast layer (bulges) at the cutting edges is reduced or even avoided [9]. Of particular interest is the beam diameter of 20 μm. This is the line width of the removed material. The Nd : YAG 355 nm laser is more stable in its operation than excimer UV lasers.

Laser cut gaskets possess a homogeneous thickness from the spin-coating or knife-coating process. Again, the peeling of the cut gaskets from the substrate and their handling should be done in alcohol, e. g., methanol, ethanol or isopropanol to avoid curling or damage.

Results: Clamping with Gaskets

The laser-cut or cast microchannel gaskets can be wetted with alcohol and placed and aligned on the glass chip or, alternatively, on the thermoplastic fluidic scaffold. For an optimal alignment, corresponding alignment marks should be provided. After the alcohol has dried, the glass chip and



Glass-Polymer Bonding, Figure 4 Gage pressure curve of a series of 15 leak tests performed with glass-PMMA systems clamped together using a PDMS membrane gasket. After full compression of the syringe pump (after about 32 s), a gage pressure of about 32,500 Pa is generated in the systems. This pressure is equal or higher than the maximum pressure generated by typical microfluidic pumps (see Table 1). No leaks were observed under the microscope and in the gage pressure curve. For comparison, a test curve of a system with a purposely introduced leak is shown. The pressure curves of the leak tests with systems bonded by adhesive tape bonding and gluing look similar

Glass-Polymer Bonding, Table 2 Surface roughness and waviness of glass chips and PMMA microfluidic scaffolds measured at the contact area of clamping

	R_a/nm	R_t/nm	R_z/nm	W_a/nm	W_t/nm
PMMA	29 ± 15	161 ± 86	230 ± 120	5 ± 4	117 ± 87
Glass	5.0 ± 2.8	28 ± 14	44 ± 29	0.48 ± 0.40	7.1 ± 2.7

the thermoplastic microfluidic scaffold with the gasket in between can be clamped together.

A series of leak tests was performed with glass chips clamped to PMMA microfluidic scaffolds using PDMS microfabricated gaskets. Both the optical observations under the inverted microscope and the quantitative pressure measurements with a gage pressure sensor indicated a perfect sealing in all tests. Figure 4 shows the gage pressure curve of a series of 15 leak tests. The pressure was generated with a 100 µl syringe pump. The gage pressure of about 32,500 Pa in the systems at the end of the leak test is as high or higher than typical maximum pump pressures generated by microfluidic pumps (see Table 1).

Another interesting result is that clamping with 50 µm thin PDMS gaskets did even seal systems where the glass chip had 300 nm thick electrodes on the surface. Planar electrodes microfabricated on glass chips are widely used in microfluidic systems, e. g., for electrochemical detection, ECL (electrochemoluminescence) detection, dielectrophoresis, AC electroosmotic flow and electrohydrodynamic pumping. As discussed earlier, glass-thermoplastic sealing with clamped PDMS gaskets are also suitable for multichannel systems.

Results: Clamping Without Gaskets

Another series of leak tests with clamped glass-thermoplastic systems was performed without the PDMS sealing gaskets. The microfluidic channels where micromilled into a PMMA fluidic scaffold. The surface roughness and the waviness values of glass and PMMA at the contact area are given in Table 2. Roughness is defined as the short range surface unevenness. R_a is the arithmetic average deviation of all roughness measurement points from the center line, R_t the difference between the highest and lowest roughness deviation from center line, and R_z the difference between the average of the five maximum positive and the average of the five maximum negative roughness deviations from the center line. Waviness is defined as the long range surface unevenness and

serves as the center line for the roughness. W_a is the average waviness and W_t the peak/valley waviness. The total surface unevenness comprises the sum of waviness and roughness.

The leaks between the relatively even PMMA surface and the glass chip were of capillary nature. The capillary leaks were filled immediately upon filling of the system and did not disturb the flow characteristics of the channel. They could only be observed under the microscope and were not detected by the gage pressure sensor in the measurement range up to about 33,000 Pa, which is above typical microfluidic pump pressures. The outside end of the PMMA-glass interface very likely marked the end of the leak, since the end of the interface acted as a capillary flow stop. No water was detected outside the system. This could perhaps be good enough for a disposable one-channel device, especially if the outside finish of PMMA-glass interface is additionally sealed with viscous glue or a rubber material after clamping. However, it would not be adequate for a multi-channel system because of possible cross-talk of substances/fluids through the capillary leaks between the different parallel channels.

Alternative to Gaskets: PDMS Polymerized on the Sealing Surface of Thermoplastic Fluidic Scaffolds

The PDMS can also be applied to the sealing surface of the thermoplastic fluidic scaffold by stamping or as the second step in a two-component injection molding process. In the stamping approach, there is a risk of blocking the microfluidic channels with excess PDMS. In the two-component injection molding approach, the fabrication of channels with dimensions smaller than 1 mm becomes difficult because of the mechanical machining restrictions for the injection molding tool. Both risks are eliminated when microfabricated PDMS gaskets are used for clamping, as described above. The bond between PDMS surface and glass sensor chip can be made, e. g., by clamping or plasma bond.

In another approach, a flat cured PDMS sheet is adhesively laminated to a polycarbonate (PC) substrate. The microfluidic channels are hot embossed into the composite, with all three resulting channel walls and the sealing interface consisting of PDMS [10]. This composite fluidic scaffold can be clamped or plasma-bonded to the glass sensor chip. Controlling the shape of the microfluidic channels seems to be a problem because PDMS as an elastomer, even if glued to a thermoplastic like PC, is not an optimal hot embossing material.

Bonding of pre-baked (more viscous PDMS) spin-coated on a substrate chip to a thermoplastic fluidic scaffold without blocking the channels is also an interesting approach [11]. But if the substrate is a glass chip with a sensor, the sensor surface will be blocked by the PDMS. Photostructurable polysiloxane could provide an interesting alternative here in the future.

Glass–Thermoplastic Bonding With Microstructured Adhesive Tape Gaskets

In this approach, the glass chip and the thermoplastic microfluidic scaffold are bonded together by a double-sided adhesive tape. The bonding is done at room temperature allowing deposition of bio-molecules on the sensor chip before sealing the system. The tape had to meet certain criteria to qualify as a sealing tape.

G

Tape Choice

Many commercially available office or packaging tapes and commercial blue tapes made double-sided sticky with adhesive transfer tape on the non-sticky side are not suitable. The adhesive on these tapes is usually not homogeneous, i. e. it forms islands resulting in leaks when the glass chip and the thermoplastic fluidic scaffold are bonded together. Further, these tapes tend to make poor contact with low-energy surfaces (thermoplastics).

An ideal tape is composed of a polyester substrate with polyester liners to protect the adhesive on both sides. Polyester is well-suited for laser cutting (see below). The adhesive film should cover the tape as a homogeneous layer (no islands). It should make good contact to low-energy thermoplastic surfaces. Finally, for microfluidic systems targeted at life sciences or diagnostic applications (protein assay, DNA chips, cell handling etc.) the adhesive should be biocompatible. Medical grade, pressure sensitive acrylic adhesives meet these stringent requirements.

For completeness it should be mentioned that there are adhesive transfer tapes. The adhesive layer is protected by two removable liners. This transfer adhesive may be a choice if very thin channels are required not allowing for accommodation of a double-sided adhesive tape with a stabilizing polymer substrate between the two adhesive layers. Transfer adhesive tapes can also be used for self-made double-sided adhesive tapes with a non-standard substrate material.

Structuring of Microfluidic Channels into the Tape

Bonding with adhesive tapes is an attractive low cost and low temperature method for polymer and glass-polymer bonding. First tests for microfluidic applications were reported with unstructured tapes [12]. If the glass chip carries a sensor or electrodes, it is necessary to cut microflu-

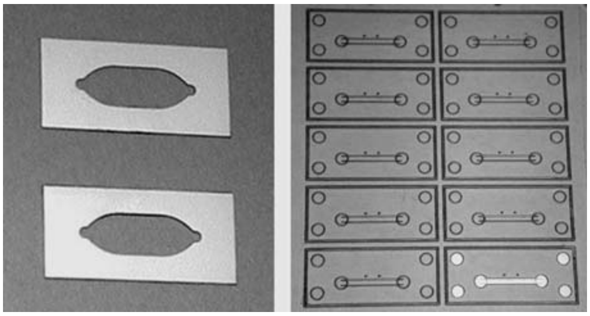
idic channels into the tape in order not to block the sensor or electrode surface. There are two methods to accomplish that.

Die cutting (punching) Die cutting of double-sided adhesive tapes becomes tricky for channel dimensions below 1 mm. The dimensional limitations are caused by the fabrication and wear of the cutting tools. There are, however, reports of punching tools made by wire electric discharge machining with lateral feature dimensions as small as 300 μm [13]. This lateral resolution is almost as good as for IR lasers. UV lasers are still better by one order of magnitude which makes laser cut tapes for microfluidic glass-polymer sealing very interesting.
During the punching, the tape should be protected and stabilized on both sides by supporting material, e. g., thermoplastic foils or sheets, to avoid tape deformation during die cutting.

Laser cutting The same UV laser system as for cutting the PDMS gaskets was used to structure the microfluidic channels into the double-sided adhesive tape. The use of IR lasers has been reported for cutting coarse structures into transfer adhesive tapes (one transfer adhesive layer with two liners for protection) for sealing gaskets of micropumps [14]. But for cutting of microchannels, a UV laser is recommended to achieve the required finer lateral resolution, particularly for cutting through a real double-sided adhesive tape (one substrate with two adhesive layers and two liners on each side).
Laser cutting allows for almost free design of the microfluidic channels in the tape gasket. The design limitations are the laser spot size (20 μm in our system) and the step size of the laser (3 μm in our system). For a multitude of microfluidic applications, this is good enough. Figure 5 shows laser-cut double sided adhesive tapes with microfluidic channels. The tape adhesive is still protected by its liners.

Results

The to-be-bonded surfaces should be clean (e. g., ultrasonic bath and/or rinsing with isopropanol, blow drying). The tape can be aligned with respect to the glass chip and thermoplastic fluidic scaffold using alignment marks. During tape application and bonding, air bubble trapping should be avoided, e. g., through a rolling application or a slow application of the tape and by applying a contact pressure.
The leak tests showed that the glass-thermoplastic sealing using the microstructured adhesive tapes was good. No leaks were observed both under the microscope and in the



Glass-Polymer Bonding, Figure 5 Laser-cut double sided adhesive tapes. The adhesive is still protected by the liners. Polyester is the preferred tape substrate and liner material for UV laser cutting

pressure measurements up to the gage pressure of about 32,500 Pa generated by the syringe pump. The sealing is therefore strong enough for typical microfluidic pump pressures (Table 1).

Glass–Thermoplastic Bonding by Gluing

Gluing is an irreversible bonding method. When a glass chip with a sensor is bonded to a thermoplastic microfluidic scaffold, the microchannels are often in the thermoplastic material. The main risk with this bonding strategy is that the glue may go into and thus block the channels. To avoid that and to achieve a good bond quality by gluing, the process parameters need to be controlled. On the other hand, voids can form between the bonded parts due to solvent out-gassing, inhomogeneous wetting or too little amount of glue.

Important Process Parameters

Glue deposition The glue can be deposited by different methods, such as dispensing or another kind of transfer, e. g., stamping with a spin-coated substrate or a dedicated intermediate stamp.

Glue viscosity For dispensing or transfer by stamping, glues with low viscosities of about 50 mPas are favorable. They wet the thermoplastic surface very well (homogeneous layer), can be deposited as an only a few microns thin layer or thinner and tend to have no trapped bubbles. The microfluidic channel itself can act as a capillary flow stop for the glue, i. e. the glue stops at the channel wall and does not go into the channel if the other parameters are chosen correctly (e. g., amount and position of glue, contact pressure, possible pre-curing etc.).

Amount of deposited glue Too much glue will result in blocking of the microfluidic channels. On the other hand,

if the amount of applied glue is not large enough, the glue may not advance to channel wall leaving some capillary leaks between the thermoplastic and the glass open.

Location of deposited glue and design of bonded parts Besides the amount of glue, the position of the glue, i. e. its distance form the microfluidic channels, is important. Another issue is the design of the bonded parts, e. g., providing overflow cavities to absorb excess glue. To reduce the risk of glue being pressed into the microfluidic channel during bonding, the channel walls should have sharp edges at the contact surface and an orientation perpendicular to the contact surface (not trapezoidal) [15]. With a sharp perpendicular edge, the channel walls form a capillary flow stop for the glue in the bonding process.

Glue pre-curing: An interesting approach to avoid blocking of the microfluidic channels with glue is a pre-curing step after glue application and before the actual bonding. The glue is applied while it still has its original low viscosity, thus wetting the thermoplastic surface well. Then a pre-curing is done, increasing the glue viscosity. As a result, the contact pressure during bonding is less likely to press the glue into the microfluidic channels.

Contact pressure during curing As mentioned above, the channel walls acts as a capillary flow stops for the glue. If the contact pressure is too high, the capillary flow stop is overcome, and glue flows into the channel. If on the other hand the contact pressure is too low, the glue may not advance to the channel wall (if it was deposited in some distance from it) leaving capillary leaks between the thermoplastic and the glass open.

Surface cleaning/pre-treatment In order to achieve a constant wettability for the glue, the to-be-bonded surfaces of the thermoplastic fluidic scaffold and the glass chip can be pre-treated in an isopropanol bath, rinsed and blow dried, or exposed to UV radiation or plasma. The latter can not be done with the sensor chip if bio-molecules are deposited on it before bonding.

Glue biocompatibility For life science or diagnostic applications, the biocompatibility of the glue is important. If probe molecules (capture molecules) are already deposited on the glass sensor chip prior to bonding, the curing regime of the glue is also an important parameter. UV curing and thermal glues should be avoided in that case.

There are no universal recommendations for glue choice and gluing process parameters. This set of parameters needs to be developed and optimized for a particular application. This development process may require considerable effort.

Results

A fast-curing (non-UV, non-thermal) acrylic low-viscosity medical glue was chosen for a series of bonding experiments. This allows for the presence of bio-molecules on the sensor chip when the microfluidic system is being sealed. With the right choice of process parameters, glass chips could be bonded to PMMA fluidic scaffolds without clogging the microfluidic channels. However, to achieve this for a certain chip geometry and glue, some process development was necessary. It also proved to be difficult to keep the process stable, probably because a critical parameter is the wettability of the bonded surfaces. This is a disadvantage compared to the clamping or adhesive tape approach. Once a good bonding was achieved, the sealing of the microfluidic channels was good. No leaks were observed both under the microscope and in the pressure measurements. The bond sealed up to the tested gage pressure of about 32,500 Pa which is high enough to seal against the pump pressures of typical microfluidic pumps (see Table 1).

Glass–Thermoplastic Bonding Based on Heating

For this bonding strategy, the thermoplastic material is heated up to around its glass transition temperature. The major disadvantage of this strategy is that no bio-molecules can be deposited on the sensor chip before the bonding process because typical glass transition temperatures of thermoplastics are well above 40 °C, the limit to which most bio-molecules can be heated without degradation or damage.

Bonding with Laminated Thermoplastic Films

Two glass or silicon chips or a combination of both are used for this approach. One glass or silicon chip has microfluidic channels. A thin film (thickness below one micrometer) of thermoplastic polymer, e. g., polypropylene, fluorocarbon polymer or parylene, is deposited on both to-be-bonded parts, e. g., by plasma polymerization. The microfluidic channels are not blocked because they are considerably deeper than the thickness of the thermoplastic coating. The lamination bonding is performed under heat close to the glass transition temperature of the thermoplastic and pressure. A problem of this approach is that no bio-molecules can be deposited on the sensor chip prior to sealing due to the high temperatures involved in the process. Also, sensor integration into the microfluidic channel

can be difficult if both chips have to be coated with a thermoplastic layer for a good lamination bond.

Another lamination approach is the bonding of a film of thermoplastic liquid crystal polymer (LCP) to glass. The LCP layer can be structured with microchannels dry etched in oxygen plasma using an aluminum mask. After removal of the aluminum mask, the LCP can be laminated onto glass, silicon or a metal under pressures at temperatures around 260 – 270 °C [16]. Again, the temperature is too high for bio-molecule pre-deposition.

Localized Heat Glass-Thermoplastic Bonding

For this approach, the microfluidic channel is micromachined into glass or silicon. On the bonding surface of the chip, close to the channel rim, metallic (aluminum) heater elements are patterned. The thermoplastic counterpart is a Mylar (polyethylene) foil laminated with a PVDC (polyvinylidene chloride) contact layer. The two parts are pressed together while maintaining a temperature of 150 – 200 °C at the aluminum-PVDC interface to locally melt the PVDC [17].

The advantage of this localized heating method compared to heating with thermal rollers for lamination, microwaves, ultrasound, laser or electromagnetic fields is the very local heat generation due to the microfabricated heaters. This interesting bonding method has two disadvantages. Firstly, it has been demonstrated only with thin Mylar-PVDC laminates. Therefore, the integration of a sensor on the glass or silicon substrate is problematic because it also contains the microfluidic channels. Secondly, the heating elements require an additional photolithographic step. Thirdly, if bio-molecules are present on the chip during the bonding process, the microfluidic channels have to be filled with water or a buffer during the bonding in order not to heat the bio-molecules above 40 °C.

Future Directions for Research

Several interesting research activities can be observed in the field of glass-polymer and particularly glass-thermoplastic bonding. One approach is direct bonding of glass and thermoplastic materials using plasma or UV radiation and special (e. g., softer) grades of thermoplastic materials or solvent-treated thermoplastic surfaces.

Another direction is the development of photostructurable polysiloxane grades (PDMS like materials structured by photolithography like photoresists). These materials could be used instead of gaskets with much better and easier alignment for clamping or perhaps for direct plasma bonding to glass chips.

The laser cutting process for silicone gasket membranes and double sided adhesive tape gaskets will be developed further. Die cutting (punching) tools might also improve due to advances in mechanical machining and microfabrication.

Clever designs and processes for glue dispensing or glue transfer could lead to advances in gluing glass chips to thermoplastic microfluidic scaffolds.

Another interesting approach in glass-polymer bonding technologies is the direct bonding of photolithographically structured *soft* SU-8 microchannels to glass or thermoplastic materials without another laminate SU-8 or PMMA layer.

Both for fluidic issues (e. g., hydrophilic/hydrophobic) and bonding issues (e. g., for glue deposition), it is desirable to have better control of the surface properties of thermoplastic materials. This can be achieved by progress in thermoplastic surface modeling and physical or chemical surface treatment, and by better control of material and process parameters in thermoplastics fabrication.

Gray-Scale Lithography

Synonyms

Gray-tone lithography

Definition

Gray-scale lithography is an inexpensive one-step lithography technology to create 3-D microstructures in a photoresist layer using an optical gray-scale mask. The ultraviolet (UV) light through the gray-scale mask during lithography process produces local intensity modulation and the 3-D profile on the surface of photoresist remains on the substrate once the exposed photoresist is stripped off by developing. This is due to various light energies absorbed by the photoactive compound as the light travels in the depth of the photoresist.

The gray-scale mask is a key component in this process. It can be generated by either using the sub-resolution, two-dimensional binary patterns (or cells) as the pixels on a conventional chrome-on-glass mask, or exposing special high energy beam sensitive (HEBS) glass with electron beam, which achieves high resolution at the gray-scale level.

The 3-D profile also can be transferred from the photoresist to a substrate such as silicon by plasma dry etching for MEMS and microfluidic applications.

Guard Flows

Definition

Small fluid flows used in the no-moving-part fluidic and microfluidic valves to ensure no cross-contamination takes place between various fluids leaving the valves into a common vent space. Guard flows are used especially in the valvesof a sampling unit. Since the guard flow enters the vent outlet of the valve and dictates the direction of the flow away from the valve into the vent, it prevents the indiscriminate mixture existing in the common downstream space to move upstream into the valve. The amount of fluid forming the guard flow is sacrificed, being subtracted from the fluid the flow of which is controlled in the valve. This requires the guard flows to be as small as possible.

HSV Color Space

Definition

The HSV (Hue, Saturation, Value) model, also known as HSB (Hue, Saturation, Brightness), defines a color space in terms of three constituent components:

- Hue, the color type (such as red, blue, or yellow) ranges from 0 – 360° (but normalized to 0 – 100%)
- Saturation, the "vibrancy"of the color ranges from 0 – 100%. The lower the saturation of a color, the more "grayness"is present and the more faded the color will appear
- Value, the brightness of the color ranges from 0 – 100%.

The HSV model was created in 1978 by Alvy Ray Smith. It is a nonlinear transformation of the RGB color space, and may be used in color progressions.

Hybrid Bonding

Definition

Bonding of different material classes, e. g., polymers and non-metallic inorganic materials like glass. The bonding partners have substantially different physical and chemical properties. For example, non-metallic inorganic materials like glass are rather hydrophilic (wetted well by water) because both the material and the water molecules have strong dipoles. Polymers are usually more or less hydrophobic (not very well wetted by water) depending on the number of physical (e. g., van der Waals bonds) and chemical (e. g., oxygen-containing acrylic or epoxy groups) dipoles in the polymer.

Synonyms

Band broadening; Convective dispersion; Fluid dispersion; Taylor dispersion; Taylor–Aris dispersion

Definition

Hydrodynamic dispersion refers to the stretching of a solute band in the flow direction during its transport by a convecting fluid. Variation in the fluid velocity across the channel cross-section leads to such band broadening which is often quantified in terms of the Taylor–Aris dispersion coefficient.

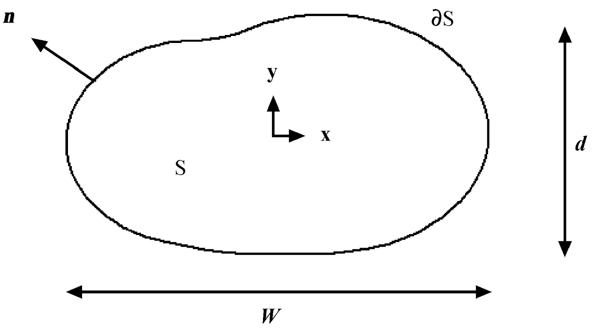
H

Overview

Dispersion of solute samples in a convective fluid (gas or liquid) is an area of significant interest to many branches in science and engineering. This phenomenon governs a wide range of processes from the spreading of contaminants in streams and rivers to the productivity of commercial scale reactors used in chemical industries. On miniaturized analytical devices, the broadening of analyte bands during their transport through the analysis channel also affects the speed and efficiency of assays performed on these systems [1]. While hydrodynamic dispersion in microchannels tends to reduce the resolution of pressure-driven separations, it diminishes the throughput of the device in other applications by decreasing the frequency with which samples can be analyzed.

Hydrodynamic dispersion of solute slugs in a straight conduit occurs due to non-uniformities in the fluid velocity across the channel cross-section. On microfluidic devices, such solutal spreading is commonly encountered during the pressure-driven transport of analyte samples. The slowing down of the fluid by the channel walls in this case introduces differences in the streamline velocity that stretches out a solute band as it travels through the duct. Although such dispersion is usually negligible under electroosmotic flow conditions due to a nearly uniform fluid velocity profile, unwanted pressure-driven flows in these devices can introduce significant band broadening [2]. Pressure gradients in electrokinetically-driven systems can arise due to differences in the hydrostatic head of end-channel reservoirs, gradients in channel wall surface charges (i. e., gradients in zeta potential at the channel wall) or gradients in fluid conductivity (as in sample stacking). Moreover, the Joule heating of the liquid in these devices can lead to a spatial variation in the fluid viscosity yielding a non-uniform flow profile. In the limit of small temperature differentials however, the resulting solutal spreading is quite similar to that in pressure-driven flows. In this entry, we present a review of the hydrodynamic dispersion phenomenon for unidirectional pressure-driven flow through microchannels. To quantify such solutal spreading the method of moment formulation that was proposed by Aris has been outlined here. We further discuss how changing the shape of the channel cross section affects this dispersion process and suggest ways for tailoring the channel geometry to control such band broadening.

The process of solutal spreading in pressure-driven flows was first analyzed by Sir Geoffrey Taylor in 1953. He showed that the variation in the fluid velocity over the channel cross-section in these systems spreads out an analyte band as convection proceeds in the flow direction. This convective spreading is ultimately limited by molecular



Hydrodynamic Dispersion, Figure 1 A conduit of arbitrary cross-section defined by the surface S and bounded by the closed curve ∂S. Here *d* and *W* are the characteristic depth and width of the channel respectively, while ***n*** is the vector normal to its boundary ∂S

diffusion across streamlines and may be described in terms of an effective dispersivity [3], often referred to as the Taylor–Aris dispersivity (K). The Taylor–Aris dispersivity determines the rate at which the spatial variance of the solute slug grows in the axial direction (σ^2) with time (t) i. e., $\mathrm{d}\sigma^2/\mathrm{d}t = 2\mathrm{K}$ and depends critically on the flow conditions in the channel. In pressure-driven flow between two parallel plates for example, the quantity K is given by

$$K = D\left[\underbrace{1}_{\text{axial diffusion component}} + \underbrace{\frac{1}{210}\left(\frac{Ud}{D}\right)^2}_{\text{conevtive disperson component}}\right] \qquad (1)$$

where U is the average fluid velocity, d is the separation distance between the plates and D is the molecular diffusion coefficient of the solute species. The dimensionless group in Eq. (1) denotes the characteristic Peclet number which quantifies the relative magnitude of convective to diffusive transport for the analyte molecules in the system. Eq. (1) shows that the overall dispersivity in simple pressure-driven flow between two parallel plates may be decomposed into two additive contributions. While the first term given by the molecular diffusion coefficient of the solute species, quantifies the effect of axial diffusion in the system, the second term determines the effect of fluid shear in the channel and scales with the square of the Peclet number (Ud/D) times the diffusivity of the solute molecules. The proportionality constant for the convective dispersion component in the expression, i. e., $1/210$, depends on the flow conditions and the exact geometry of the analysis channel. Note that in pressure-driven systems the axial diffusional limit of slug dispersion between two parallel plates is only realized for a Peclet number $\ll \sqrt{210}$. Such conditions are typically encountered during gas phase transport when analyte diffusion is often significant compared to solute convection due to fluid flow. In

liquid phase systems however, the convective dispersion component is usually more dominant and tends to determine the spreading of solute slugs in the microchannel.

While Eq. (1) quantifies the broadening of analyte bands between two parallel plates, this result can be significantly affected by the exact cross-section of the conduit. Mathematically, one can evaluate this effect by introducing a function f in Eq. (1) to yield

$$K = D\left[1 + \frac{1}{210}\left(\frac{Ud}{D}\right)^2 f\right] \quad (2)$$

where d here denotes the characteristic narrower transverse dimension of the channel (see Fig. 1). The constant $1/210$ in the above expression could, of course, be absorbed into f. However, its value is chosen such that this function is equal to unity for the parallel-plate device. In this situation, f essentially quantifies the dispersion due to the slowing down of the fluid by the channel sidewalls, and is, therefore, expected to assume values greater than 1 for most closed channel profiles. For example, the reduced velocity in the side-regions of a rectangular duct causes a substantial increase in the magnitude of f which grows with its aspect ratio (ratio of the channel width W to its depth d) approaching a value of about 7.95 in the limit $d/W \to 0$ [4, 5].

It is important to note that the Taylor–Aris dispersion limit for band broadening described above is reached only after solute molecules have a chance to diffuse across the wider channel dimension (W), i.e., $t \gg \left(1/4\pi^2\right)\left(W^2/D\right)$. The numerical prefactor $1/4\pi^2$ for this time scale arises from the decay of the corresponding eigenvalue problem determining the higher moments of the solute concentration in the system. While the exact magnitude of this prefactor depends on the precise geometry of the conduit, numerical simulations have shown [6] that the slug dispersivity approaches 95% of its Taylor–Aris dispersion limit for $t \sim W^2/(20D)$. Because we focus on this asymptotic limit for solutal spreading in this entry, the analysis presented here strictly holds for microchannels with lengths on the order of $UW^2/(20D)$ or greater. For a fluid velocity of 1 mm/s and a solute diffusivity of $10^{-6}\,\mathrm{cm^2/s}$, this corresponds to a length of 0.5 cm for a 100 μm wide channel. In shorter conduits, the broadening of the analyte bands is usually smaller than that predicted by the results based on the Taylor–Aris dispersion limit discussed here.

Basic Methodology

Method of Moments Formulation

The mathematical formulation that is commonly used to quantify the hydrodynamic dispersion of sample slugs is based on the work that was presented by Aris in 1956. In his article, Aris described a general procedure to frame and solve the equations governing the integral moments of the solute concentration in a flow stream [7]. We outline this mathematical formulation in this section for calculating the dispersivity of analyte bands in a pressure-driven flow though a straight conduit.

Using the method of moments formulation proposed by Aris, it is possible to show that the solutal spreading in a unidirectional pressure-driven flow can be calculated by solving two 2-dimensional problems. First, the velocity field $u(x, y)$ for the analyte molecules is determined under steady-state condition based on the fluid flow in the system. For a straight channel whose axis is aligned along the z-direction, this quantity is governed by the 2-dimensional Poisson equation

$$\begin{aligned} &\text{Dimensional form:} && \nabla^2 u = -\frac{\Delta P}{\eta L} \\ &\text{Boundary condition:} && u|_{\partial S} = 0 \\ &\text{Dimensionless form:} && \nabla^{*2} u^* = -1 \\ &\text{Boundary condition:} && u^*|_{\partial S} = 0 \end{aligned} \quad (3)$$

In the above expression, all length scales have been rendered dimensionless with respect to the narrower channel dimension d while u has been normalized by the characteristic velocity $U_c = \left(\Delta P d^2\right)/(\eta L)$. Here $\Delta P/L$ denotes the pressure drop per unit length in the flow direction and η denotes the viscosity of the fluid. Note that the operator ∇^2 is the two-dimensional Laplacian because there is no variability in the z-direction. Its dimensionless form $\left(\nabla^{*2}\right)$ in Eq. (3) has been obtained upon normalization with respect to d^2. Once we obtain u^* by solving Eq. (3), the average fluid velocity in the channel, $\overline{U}$, may be determined using the integral

$$\overline{U} = \frac{U_c}{A^*}\int_S u^*\,\mathrm{d}A^* \quad (4)$$

where $A^* = A/d^2$ is the dimensionless cross-sectional area of the conduit normalized with respect to d^2. This velocity may then be used to renormalize u as $\hat{u} = u/\overline{U}$.

The concentration profile $c(x, y, z, t)$ of a passive tracer under these flow conditions can be determined using the diffusion-convection equation given below

$$\begin{aligned} &\frac{\partial c}{\partial t} + u(x, y)\frac{\partial c}{\partial z} = D\left(\nabla^2 c + \frac{\partial^2 c}{\partial z^2}\right) \\ &\text{Boundary Condition:} \quad (D\nabla c)\,.\,\boldsymbol{n}|_{\partial S} = 0 \end{aligned} \quad (5)$$

Here D is the diffusion coefficient of the solute molecule and ∇ denotes the two-dimensional gradient operator. The quantity $\boldsymbol{n}$ appearing in the boundary condition here refers to the unit vector pointing outward normal to the channel surface (see Fig. 1). It is important to note that Eq. (5) assumes that the analyte molecules moves with the local fluid velocity u and diffuses uniformly throughout the channel. The description presented here therefore, is only valid for systems in which the size of the solute particles is negligible compared to the channel dimensions. While the effect of a finite particle size may be taken into account using a vectorial, position-dependent form for the parameter D and appropriate modifications to the velocity field u [8], this analysis focuses on the simpler situation.

For systems with solute molecules much smaller than the channel size, we proceed further by expressing Eq. (5) in a dimensionless form after normalizing t with respect to the diffusion time scale d^2/D,

$$\frac{\partial c}{\partial t^*} + \mathrm{Pe}\,\hat{u}\frac{\partial c}{\partial z^*} = \nabla^{*2}c + \frac{\partial^2 c}{\partial z^{*2}} \qquad \text{Boundary Condition:} \quad \nabla^* c\,.\,\boldsymbol{n}|_{\partial S} = 0 \tag{6}$$

where $\mathrm{Pe} = \overline{U}d/D$. Following the method of moments, Eq. (6) may be rewritten as

$$\begin{aligned} &\frac{\partial \phi_p}{\partial t^*} - p\,\mathrm{Pe}\,\hat{u}\phi_{p-1} = \nabla^{*2}\phi_p + p\,(p-1)\,\phi_{p-2} \\ &\quad\text{where} \quad \phi_p = \int_{-\infty}^{\infty} z^{*p} c\,\mathrm{d}z^* \\ &\frac{\mathrm{d}m_p}{\mathrm{d}t^*} = p\,\mathrm{Pe}\int_S \hat{u}\phi_{p-1}\,\mathrm{d}A^* + p\,(p-1)\int_S \phi_{p-2}\,\mathrm{d}A^* \\ &\quad\text{where} \quad m_p = \int_S \phi_p\,\mathrm{d}A^* \end{aligned} \tag{7}$$

If the total amount of solute in the channel is normalized to unity (i. e., $m_0 = 1$), it may be shown that the asymptotic solutions $\phi_0 = 1/A^*$ and $m_1 = \mathrm{Pe}\,t^*$ satisfy Eq. (7).

Under these steady-state conditions, the solute slug acquires a constant velocity in the channel and hence ϕ_1 grows linearly in time yielding the following expression for the Taylor–Aris dispersivity

$$\begin{aligned} &\phi_1 = \frac{\mathrm{Pe}\,t^*}{A^*} + \frac{\mathrm{Pe}}{A^*}g\,(x,y) \qquad \text{and} \\ &\frac{K}{D} = \frac{\mathrm{d}\left(m_2 - m_1^2\right)}{\mathrm{d}t^*} = 1 + \mathrm{Pe}^2\frac{1}{A^*}\int_S \hat{u}\,g\,\mathrm{d}A^* \end{aligned} \tag{8}$$

where g is the solution to the differential equation

$$\nabla^{*2}g = 1 - \hat{u} \qquad \text{satisfying the conditions}$$
$$\nabla^* g.\boldsymbol{n}\big|_{\partial S} = 0 \qquad \text{and} \qquad \int_S g\,\mathrm{d}A^* = 0 \tag{9}$$

In the absence of any spatial variation in u, as in electroosmotic flow, the function g is identically equal to zero. It is the interaction of g with the velocity field that results in dispersion of the solute slugs under pressure-driven flow conditions. The dispersivity function f defined in Eq. (2) in this situation can be simply obtained from the area integral

$$f = \frac{210}{A^*}\int_S \hat{u}\,g\,\mathrm{d}A^* \tag{10}$$

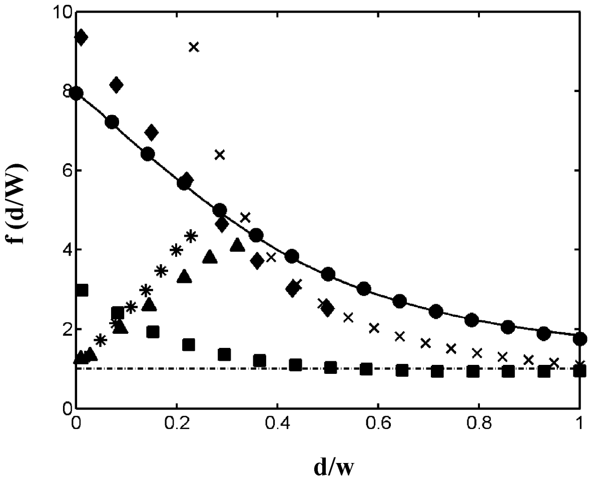
The above equations can be solved analytically to yield f for simple geometries such as a tube, an ellipse and a rectangular channel with no sidewalls. For more complicated geometries such as a trapezoidal channel or one arising from isotropic etching fabrication methods, one has to resort to numerical solutions. In these cases, commercially available solvers such as FEMLAB and PDE Toolbox in MATLAB may be used to rapidly determine the dispersivity function f via numerical techniques.

Key Research Findings

In this section, we analyze the hydrodynamic dispersion of solute slugs using the dispersivity function f defined above for unidirectional pressure-driven flow through microchannels. We also discuss how changing the shape of the cross section affects this band broadening as we move from one channel geometry to another. Based on this understanding, this section further suggests ways to control such solutal spreading by tailoring the cross-section of the analysis channel.

Rectangular Channels

Microchannels created using dry etching techniques on silicon-based substrates often have a cross section that is close to a rectangle. This geometry is also common in polymer based microchips e. g., created using PDMS (polydimethylsiloxane) material, which are popularly used in the research community due to their simpler fabrication procedure. The effect of the rectangular geometry on the hydrodynamic dispersion of solute slugs has been well investigated in the past by several researchers [4, 5]. These studies have shown that the function f for this profile increases monotonically with an increase in the



Hydrodynamic Dispersion, Figure 2 Effect of aspect ratio on solute dispersivity in pressure-driven flow systems for a fixed channel depth. aspect ratio of the conduit (see Fig. 2). While $f \approx 1.76$ for a square cross section ($d/W = 1$), this function approaches a value of 7.95 in the opposite limit when $d/W \to 0$. The greater dispersion in a rectangular channel over that in a parallel plate design occurs due to the slowing down of the fluid around its vertical sidewalls. This results in an increase in the average fluid shear and also produces velocity variations in the transverse direction which usually, on account of its greater length scale, is subject to greater diffusional limitation. It is important to note that these two effects dominate the dispersion process in a rectangular channel in two different scenarios. For small aspect ratio profiles ($d/W \approx 1$), the characteristic length scale for diffusion along the vertical and horizontal directions of the rectangle are similar. In this case, the larger dispersion in a rectangular conduit over that between two parallel plates occurs due to a greater fluid shear introduced by the channel side-walls. With a decrease in the value of d/W however, this contribution to band broadening diminishes. This occurs as the channel sidewalls in a rectangular conduit slow down the fluid only over a length scale of order d around them. In designs with $d/W \ll 1$, because these slow moving regions are widely separated the diffusional resistance across them has a larger effect on the overall band broadening. Although the Taylor–Aris dispersivity still scales with d^2 in the limit $d/W \to 0$, the coefficient multiplying Pe^2 is nearly 8 times greater than that resulting from diffusion in the narrower direction.

Hydrodynamic Dispersion, Figure 3 Cross-section of an isotropically etched channel

Isotropically Etched Channels

On glass substrates, microfluidic ducts are commonly fabricated using isotropic wet etching techniques originally developed in the semiconductor industry. Such techniques often yield channels that are not rectangular but rather have cross-sections close to the profile depicted in Fig 3. These conduits referred to as isotropically etched channels consist of a rectangular central section of depth d and width l, with quarter disk shaped side regions of radius d (see Fig. 3). In this situation their overall width is given by $W = l + 2d$ restricting their aspect ratio W/d to values greater than 2. The quarter circular sidewalls in the isotropically etched channel significantly modify the pressure-driven flow field and hence affect the dispersivity in the system. This is shown in Fig. 2 where we have quantified the effect of the aspect ratio on solute dispersion in this geometry. As may be seen, the function f for this profile assumes values somewhat greater than that for a rectangular design in the limit of small d/W. This occurs as the quarter circular sidewalls slow down the fluid to a greater extent than the vertical walls in the rectangular geometry. This yields an asymptotic value of 9.42 for f in the limit of $d/W \to 0$, about 18% greater than that in a rectangular channel. It is interesting to note that the isotropically etched profile causes lower band broadening in the opposite limit when d/W approaches its minimum value of 0.5. This is simply a consequence of a smaller average channel depth, which in turn reduces the diffusional resistance in the vertical direction. Overall, the two channel cross-sections exhibit a similar dispersivity for all values of d/W. This similarity in the behavior of rectangular and isotropically etched channels also suggests a similar performance of glass and polymer (e. g., PDMS) based microdevices. In this situation, polymer microchips can be a better commercial choice compared to their glass counterparts in view of the lesser fabrication effort required to produce them. The elasticity of polymers however, may significantly increase analyte dispersion in these devices under high pressure conditions due to bowing of microchannels as will be discussed later in this entry.

Hydrodynamic Dispersion, Figure 5 Effect of the second etch on solute dispersion in the double-etched isotropic profiles (i) $l_2/d = 0$ (ii) $l_2/d = 0.2$ (iii) $l_2/d = 0.4$

Trapezoidal Channels

A channel profile also commonly employed in microchip based analytical devices is the trapezoidal geometry. Such cross sections result from techniques in which the substrate material is etched away at different rates along different directions (e. g., anisotropic etching). Microchannels created on crystalline silicon wafers, for example, tend to have geometries close to the idealization depicted in Fig. 4. The trapezoidal profile essentially comprises of a rectangular central section of depth d and width l in between two triangular side-regions having a wedge angle θ. The key difference between the trapezoidal and isotropically etched designs is that the width of the side-regions in the former case can be much greater than the channel depth. Note that this width determines the length scale over which the fluid is slowed down by the side-walls and, therefore, the scaling for the additional dispersivity introduced as a result of this effect. In Fig. 4, we have presented the effect of the dimensionless geometric parameters l/d and θ on the dispersivity function f for a trapezoidal channel. As may be seen, the band broadening in this profile diverges in the limit of large wedge angles as $\theta \to \pi/2$, for all values of l/d. This occurs due to an unbounded increase in the width of its triangular side-regions, which grow as $d \tan\theta$. In this situation, the dispersion in these sections dominate the overall solutal spreading in the channel yielding a function f that scales as $\tan^2\theta$ and has a weak dependence on the parameter l/d (see Fig. 4). The ratio l/d, however, becomes more significant for designs with smaller wedge angles in which $\tan\theta$ assumes a value on the order of 1 or less. Figure 4 shows that while the dispersivity in a trapezoidal conduit increases monotonically with θ for moderate and large values of l/d, it actually goes through a minimum for geometries with $l/d \ll 1$. In a triangular channel, this occurs for a value $\theta \approx 22°$ when the width of the upper wall is about 80% of the channel depth. Moreover, for this optimum wedge angle the convective dispersion component in this geometry is reduced by about a factor of 4 over its value at $\theta = 0$.

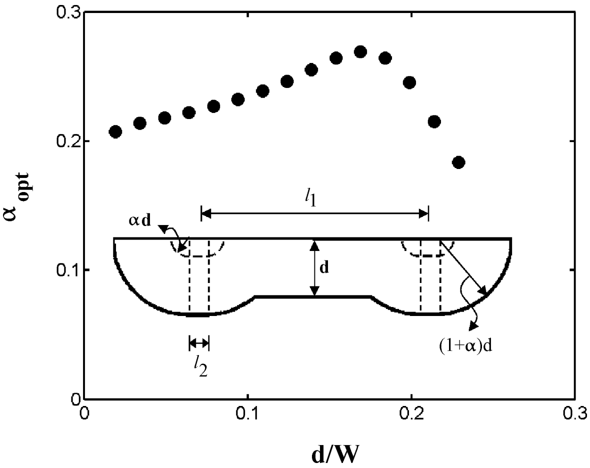
It is important to note that while the dispersivity function f in a triangular profile assumes a value of about 4 for $\theta = 0$, this quantity decays off as $(l/d)^2$ for trapezoidal channels with $l/d \ll 1$. In this situation, f rises sharply with θ for small wedge angles ($\theta \ll l/d$) as the contribution to dispersion from its side-regions starts dominating the overall solutal spreading. The combination of this effect with the behavior discussed in the previous paragraph means that the dispersivity function shows an inflection point (a maxima followed by a minima) for small but non zero l/d (see Fig. 4). The maxima in the curve occurs for these designs when $\theta \approx l/d$ while the minima is observed when $\theta \approx 22°$. In this situation, the inflection point in f is observed only for trapezoidal designs with $l/d \ll \tan 22°$. For profiles with the central rectangular section having an aspect ratio greater than this value, a monotonic increase in the dispersivity is observed with θ. The dispersivity for the case $\theta = 0$ in these designs is equal to that in a rectangular channel of identical depth and width.

Double-Etched Isotropic Profiles

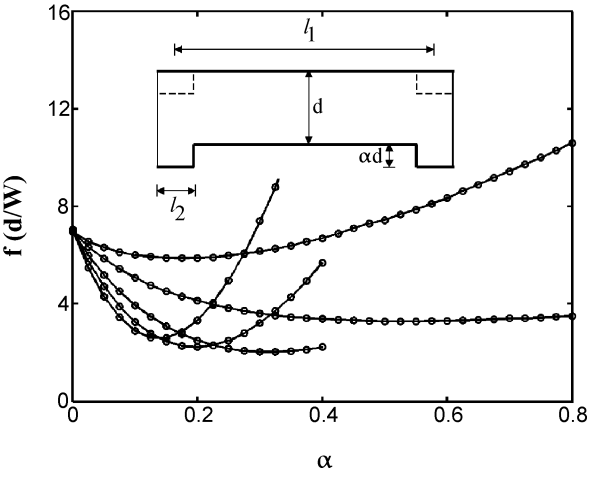
The analyses presented in the previous sections show that the overall dispersion in large aspect ratio channel geome-

tries is often dominated by the contribution arising due to their slow moving side-regions. It may, therefore, be possible to reduce such band broadening by simply speeding up the fluid in the vicinity of the sidewalls. One way to realize this effect is to modify the cross section of the microchannel, which in turn alters the pressure-driven flow field in it. In particular, a greater depth in the side-regions of the conduit can lead to a local increase in the solute average velocity around these corners, yielding a lower dispersion in the system [9]. Such channel geometries created using standard isotropic etching techniques have been proposed recently [6, 10]. In this design, the side-regions are first etched out (shallow etch) to a depth $\Delta d = \alpha d$, followed by subjecting the whole channel to a second etch (deep etch) process excavating an additional distance d (see Fig. 5b). The resulting cross section can be completely specified using three dimensionless parameters l_1/d, l_2/d and α. Note that the value of l_2 in this geometry is determined by the line thickness that is photolithographically patterned onto the substrate for the shallow etching process. In Fig. 5a, we have presented the effect of the extra depth in the double etched profiles on the hydrodynamic dispersion of solute slugs. As may be seen, the function f for these geometries is minimized for an optimum choice of α when the average fluid velocity in the side-regions equals that in the center. The performance of these optimum designs, however, deteriorates with an increase in the value of l_2/d for a given aspect ratio due to an increase in the average depth of the channel. Increasing l_2/d also shifts the optimum value of α downward for these designs. Note that these effects are more prominent for larger values of d/W when the solute fraction in the side-regions of the microfluidic channel is significant.

In Fig. 2, we have compared the performance of the optimized profiles to that of the single-etched geometries, which shows a dramatically different effect of the aspect ratio on the function f. Instead of increasing for small values of d/W as in the case of the single-etched designs, it actually approaches an asymptotic value of unity as $d/W \to 0$ in the double-etched channels. This occurs as the variation in the average solute velocity across the wider direction of this modified cross section is almost completely eliminated. Although the greater depth in their side-regions introduces some additional dispersion, this contribution diminishes in the limit of large aspect ratios. The choice of α_{opt} for these designs is not a strong function of d/W and only varies between 0.1 and 0.3 for the case $l_2/d = 0$ (see Fig. 5b). The optimum double etched profiles yield a dispersion that increases with a reduction in their widths, eventually offering no benefits over the single-etched geometries for designs with $d/W > 0.25$. However, for a value of $d/W = 0.1$ the dispersivity in this cross section is the same as the minimum possible for a single-etched isotropic profile ($d/W = 0.5$), even though its area is more than five times greater. This results in a significant benefit for applications requiring some fixed solute throughput in the system.



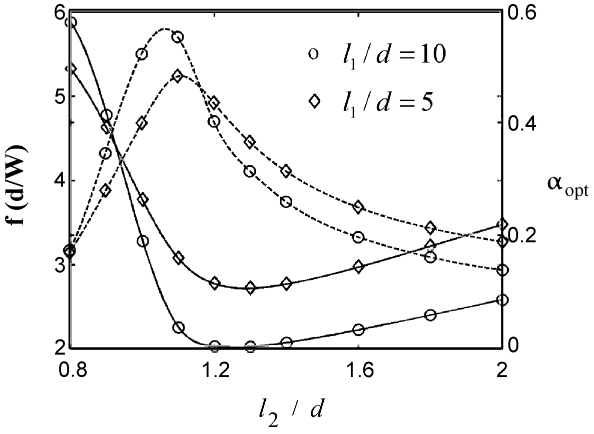
Hydrodynamic Dispersion, Figure 6 Optimum choice of α that minimizes hydrodynamic dispersion for the design $l_2/d = 0$



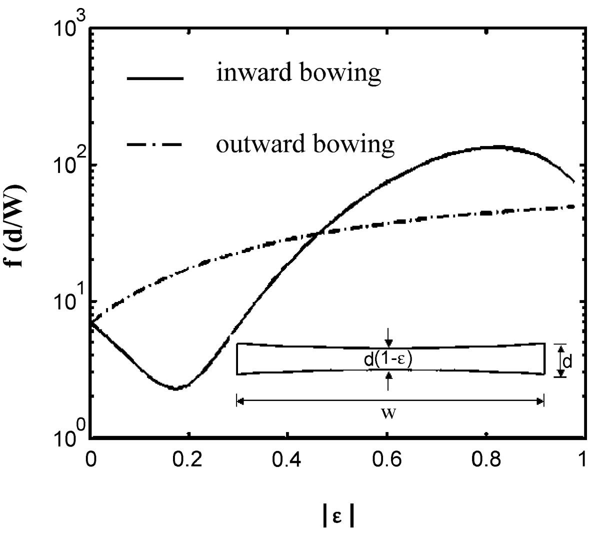
Hydrodynamic Dispersion, Figure 7 Effect of the second etch on solute dispersion in the double-etched rectangular channels

Double-Etched Rectangular Channels

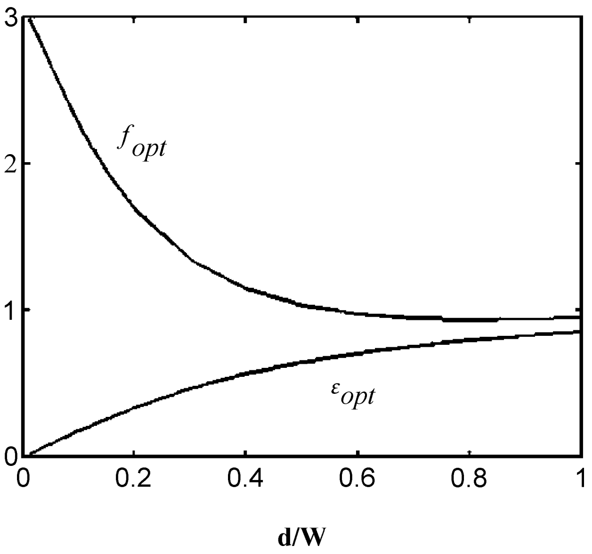
While the fabrication of the optimum profiles described above requires the use of isotropic wet etching techniques, dry etching methods may also be used to produce geometries that minimize band broadening in pressure-driven flow systems. In this case, a shallow etch in the side-regions by an amount $\Delta d = \alpha d$ followed by a deep etch of the entire channel by a distance d yields a cross sec-



Hydrodynamic Dispersion, Figure 8 The solid lines depict the effect of the feature width in the double-etched side-regions on the performance of the optimized designs and the dashed lines here denote the optimum choice for α in these profiles



Hydrodynamic Dispersion, Figure 9 Effect of bowing on the dispersion of solute slugs in rectangular channels



Hydrodynamic Dispersion, Figure 10 Optimum choice of ε that minimizes band broadening in positively bowed rectangular profiles

tion close to the idealization depicted in Fig. 6a. Note that the lack of any undercutting beneath the photo-patterned mask provides a better control over the geometry around the sidewalls in the dry etched designs. In Fig. 6a, we have presented the effect of α on the dispersion of solute slugs in the double-etched rectangular channels. As expected, the extra etch around the sidewalls of this profile again leads to a minima in the function f for a given value of l_2/d and l_1/d. Moreover, the width of these deeper regions may be further optimized with respect to the parameter l_2/d in the system (see Fig. 6b). The optimum choice of α and l_2/d, however, depends weakly on the aspect ratio of the channel (see Fig. 6b). As in the case of the double-etched isotropic profiles, the performance of the optimum dry etched designs improves with an increase in their widths, approaching the parallel plate limit as $d/W \to 0$. For a given value of d/W, the optimum double-etched rectangular channels also yield a slightly lower dispersion compared to their wet etched counterparts, again due to a greater control over the feature width in their side-regions.

Channels with Bowing

The analyses presented above describe hydrodynamic dispersion in idealized geometries that closely approximate the actual channel cross sections commonly used in microfluidic devices. However, fabrication constraints and flow conditions can lead to significant deviations from these idealized forms, particularly for large aspect ratio designs. For example, during the anodic bonding of a silicon substrate to a glass plate, the strong electrical force exerted on the device can lead to inward bending and even collapse of the surfaces. A similar inward bowing near the channel center is also observed during the thermal annealing of conduits milled out on a plastic footprint. Moreover, the elasticity of the polymers often used for creating microchannels (e. g., PDMS) renders them susceptible to outward bulging under sufficiently high flow pressures. In this section, we consider the effect of such bowing of microchannels on the Taylor–Aris dispersion of solute slugs during their pressure-driven transport.

Consider the bowed microchannel cross-section depicted in Fig. 7a with a depth d and width W. The easiest way of

capturing the effect of bowing for this geometry is to introduce a quadratic variation in the channel depth across the width of the conduit i. e., $h = W\left[1 - \varepsilon + 4\varepsilon\,(x/W)^2\right]$. In this design, the dimensionless parameter ε represents the degree of bowing into the channel whose effect on the dispersivity function $f\,(d/W, \varepsilon)$ has been shown in Fig. 7a for an channel aspect ratio of $d/W = 0.1$. As may be seen from the figure, for rectangular channels with an outward bowing $(\varepsilon < 0)$, f increases monotonically with an increase in the magnitude of ε. This occurs as the greater depth around the channel center in these geometries further speeds-up the faster moving streamlines increasing the disparity in the depth-averaged fluid velocity across the channel width. In the case of inward bowing however, an increase in the parameter ε actually slows down the fluid near the channel center. This results in a decrease in the value of f which reaches a minimum when the average flow speed in the side-regions equals that in the channel center. If ε is increased beyond this optimum value of 0.17, the fluid around the channel side-walls now starts traveling faster than the average flow velocity in the system leading to an increase in the function f. Note that beyond a critical bowing of $\varepsilon = 0.3$, the dispersion coefficient is actually greater than that for a plain rectangular channel with the same aspect ratio. For even larger values of ε, the dispersion coefficient shows a maximum and then decreases. This final decrease is due to a reduction in the area of the slow moving central region as the channel pinches off at $\varepsilon = 1$. Finally in Fig. 7b we have depicted the variation in the optimum bowing and the minimum dispersion in the positively bowed rectangular conduits as a function of the channel aspect ratio. These results show that for moderate aspect ratios, the optimally bowed channels yield a lower dispersion than the optimized double-etch profiles discussed earlier. But unlike the double-etch optimization strategy where the increase in channel depth is provided exactly where it is required, i. e., near the channel sidewalls, bowing alters the channel depth throughout the width of the conduit. This limits the performance of the bowing strategy compared to the double-etch strategy at large aspect ratios.

Future Directions for Research

In large aspect ratio channels as typically used in microfluidic devices, diffusion limitations across the slow moving side-regions tend to dominate slug dispersion under pressure-driven flow conditions. The theoretical analysis presented here show that this contribution however, can be substantially reduced by increasing the channel depth around these corners. Such a modification in the channel geometry leads to a higher fluid velocity near the sidewalls yielding lower dispersion in the system. Although the low-dispersion designs proposed in this work can be realized using standard photolithographic techniques, experimental data supporting their better performance is lacking in the literature. In the future, experimental work in this area needs to be performed and the results need to be compared with the theoretical predictions presented here.

Hydrogen Bond

Definition

A *hydrogen bond* is a special type of attractive interaction that exists between certain chemical groups of oppo-

site polarity. Although stronger than Van der Waals forces, the typical hydrogen bond is much weaker than both the ionic bond and the covalent bond. Within macromolecules such as proteins and nucleic acids, it can exist between two parts of the same molecule, and figures as an important constraint on such molecules' overall shape. As the name "hydrogen bond"implies, one part of the bond involves a hydrogen atom. The hydrogen atom must be attached to a relatively electronegative element.

Hydrophilic/Hydrophobic Patterning

TETSU TATSUMA
Institute of Industrial Science, University of Tokyo, Tokyo, Japan
tatsuma@iis.u-tokyo.ac.jp

Synonyms

Hydrophobic/hydrophilic patterning; Wettability patterning

Definition

Hydrophilic/hydrophobic patterning is to prepare two-dimensional patterns consisting of hydrophilic and hydrophobic regions on a solid surface.

Overview

Hydrophobic/hydrophilic patterning is a useful technique for preparing microfluidic channels. The technique is also used for the preparation of sensor arrays, biochips and electronic circuits because a solution of a functional molecule or a suspension of conducting nanoparticles can be trapped in the hydrophilic regions. There are several different ways for the pattering.

A hydrophilic surface is modified with an organic hydrophobic layer. The layer may be a self-assembled monolayer of a hydrophobic silane coupling agent such as a fluoroalkylsilane or an alkylsilane in the case of glass substrates or other surfaces with hydroxyl groups. In the case of a gold surface, the hydrophobic layer may be formed by treatment with a fluoroalkylthiol or an alkylthiol. The organic hydrophorbic layer is partially removed by irradiation with deep-UV light through a photomask [1, 2], near UV-light through a photomask coated with a TiO_2 photocatalyst (photocatalytic lithography) [3, 4] or scanned electron or ion beam [5, 6].

An elastomeric stamp [7, 8] and a normal photolithographic technique with a lift-off process can also be used for preparing hydrophobic patterns on a hydrophilic surface.

Introduction of nano- or micro-roughness onto the substrate surface enhances both hydrophilicity and hydrophobicity so that super-hydrophobic/super-hydrophilic patterns could be obtained.

Hysteresis

Synonyms

Memory; Memory-effect

Definition

Hysteresis is a property of systems (usually physical systems) that do not instantly follow the forces applied to them, but react slowly, or do not return completely to their original state: that is, systems whose states depend on their immediate history. For instance, if you push on a piece of putty it will assume a new shape, and when you remove your hand it will not return to its original shape, or at least not immediately and not entirely. The term derives from an ancient Greek word υστέρησις, meaning *deficiency*. The term was coined by Sir James Alfred Ewing.

Synonyms

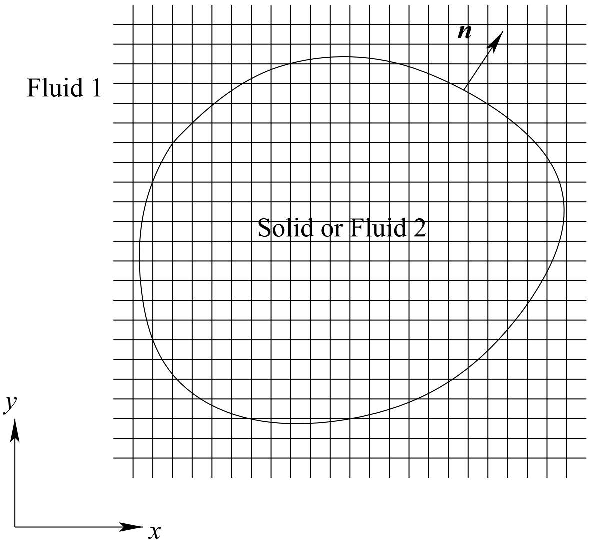
Immersed interface method

Definition

The immersed boundary method is a numerical method in computational fluid dynamics where the flow boundary is immersed in the grid that does not conform with the boundary. In the immersed boundary method, special treatment has to be taken at the boundary to incorporate the boundary conditions.

Overview

The immersed boundary method was first introduced by Peskin [5] to simulate the blood flow in the heart. Since then a few variants have emerged and the method has been used to compute many flows with complex and/or moving geometries (Mittal and Iaccarino [4]). The distinguishing feature of this method is that the computations are done on either a Cartesian grid or a curvilinear grid which do not necessarily conform to the flow boundary.
When simulating flow in an irregular domain, the conventional method is to employ a structured or unstructured grid that conforms to the domain boundary. In either case, the grid usually has to be generated numerically, which may significantly increase the computational cost. Especially, if the flow boundary is moving, the grid has to be



Immersed Boundary Method, Figure 1 Schematic the fluid–fluid or fluid–solid interface and the Cartesian grid used for the immersed boundary method

re-computed correspondingly, and the associated calculations may become very expensive. In contrast, the grid generation in the immersed boundary method is easy, and once generated, the grid may remain fixed even if the flow boundary moves. Furthermore, in the immersed boundary method, the calculations can be done efficiently on the structured grid. This is particularly attractive when compared to an unstructured grid based method.

The downside of the immersed boundary method is that implementation of the boundary conditions is not straightforward since the boundary does not coincide with any grid line. In addition, the immersed boundary method has less flexibility of distributing the grid in the vicinity of the boundary compared to the boundary-conforming methods. Figure 1 shows an example where a Cartesian grid is used to discretize the domain including both sides of the boundary. The fluid–fluid boundary or fluid–solid boundary intersects with the grid lines. The governing equations are discretized on the grid using a finite-difference method. Near the boundary, special treatment has to be taken in order to incorporate the boundary conditions. Different boundary treatments lead to different variants of the immersed boundary method.

In this article, we consider incompressible Newtonian flows and briefly describe the underlying numerical methodology of the immersed boundary method. We will use the Cartesian grids for the purpose of illustration. The same methodology can be applied to the compressible flows (e. g., Ghias et al. [2]) and on the curvilinear grids (e. g., Luo et al. [3]).

Basic Methodology

Fluid–Fluid Interface

Consider a two-fluid flow governed by the incompressible Navier–Stokes equations:

$$\rho\left(\frac{\partial \boldsymbol{u}}{\partial t}+\boldsymbol{u}\cdot\nabla\boldsymbol{u}\right)=-\nabla p+\mu\nabla^2\boldsymbol{u} \tag{1}$$

$$\nabla\boldsymbol{u}=0\,, \tag{2}$$

where $\boldsymbol{u}$, t, p are velocity, time, and pressure respectively, and $\mu=\mu_j$, $\rho=\rho_j$, $j=1$ or 2, are the viscosities and densities of the two fluids. The flow is subject to the kinematic condition requiring continuity of the velocity at the interface, and a dynamic condition expressing a balance between the hydrodynamic traction exerted on either side of the interface,

$$\Delta\mathbf{f}\equiv\left(\boldsymbol{\sigma}^{(1)}-\boldsymbol{\sigma}^{(2)}\right)\cdot\boldsymbol{n}=\gamma 2\kappa_m\boldsymbol{n}\,, \tag{3}$$

where $\boldsymbol{\sigma}^{(j)}$ is the Newtonian stress tensor in the jth fluid, $\boldsymbol{n}$ is the unit normal vector, and $\kappa_m=(1/2)\nabla\cdot\boldsymbol{n}$ is the mean curvature of the interface, as illustrated in Fig. 1. The interface is assumed to be clean. When a surfactant is present, Marangoni traction has to be added to the right-hand side of Eq. (3).

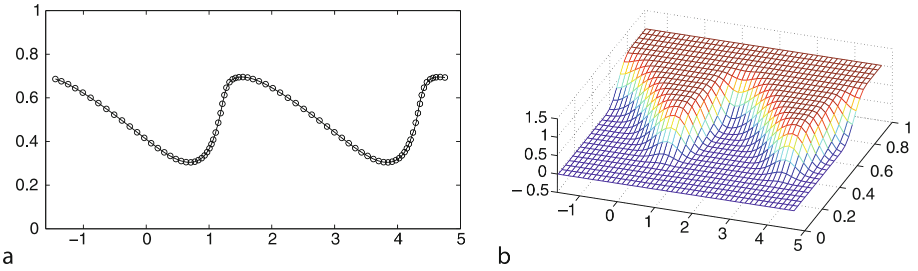
The momentum equation for both fluids can be combined into a generalized equation incorporating viscosity and density differences as well as the jump in the traction across the singular interface,

$$\rho\left(\frac{\partial \boldsymbol{u}}{\partial t}+\boldsymbol{u}\cdot\nabla\boldsymbol{u}\right)=-\nabla p+2\nabla\cdot(\mu\mathbf{E}) - \int_{\mathrm{I}} D_2(\boldsymbol{x}-\boldsymbol{x}')\Delta\mathbf{f}(\boldsymbol{x}')\,\mathrm{d}s(\boldsymbol{x}')\,, \tag{4}$$

where $\mathbf{E}=1/2\left(\nabla\boldsymbol{u}+\nabla\boldsymbol{u}^T\right)$ is the rate-of-deformation tensor, D_2 is Dirac's delta function, the jump in the interfacial traction, $\Delta\mathbf{f}$, is defined in Eq. (3), and $\boldsymbol{x}'$ is a point on the interface denoted by I. The surface integral in the equation is defined on the interface. It is reckoned that the physical properties of the fluid undergo a step discontinuity across the interface.

The basic idea of Peskin's immersed boundary method is to choose an approximate delta function to smear the interface, and therefore, the physical properties of the fluid and the interfacial traction undergo a smooth transition across the interface. One example of such approximation in the two-dimensional space is

$$D_2(\boldsymbol{x}-\boldsymbol{x}_{\mathrm{I}})\simeq\frac{1}{16\Delta x\Delta y}(1+\cos\hat{x})(1+\cos\hat{y})\,, \tag{5}$$



Immersed Boundary Method, Figure 2 (**a**) A snapshot of an evolving interface between two fluids, computed using the immersed boundary method, and (**b**) the corresponding mollifying function, $c(\boldsymbol{x})$ (simulation done by the author)

for $|x - x_\mathrm{I}| < 2\Delta x$ and $|y - y_\mathrm{I}| < 2\Delta y$, where $\boldsymbol{x}_\mathrm{I} = (x_\mathrm{I}, y_\mathrm{I})$ is a point on the interface, Δx and Δy are spatial discretization intervals associated with the finite difference method, and

$$\hat{x} \equiv \frac{\pi(x - x_\mathrm{I})}{2\Delta x}\,, \qquad \hat{y} \equiv \frac{\pi(y - y_\mathrm{I})}{2\Delta y}\,. \tag{6}$$

Next, a mollifying function, $c(\boldsymbol{x})$, can be defined such that its gradient is aligned with the surface normal $\boldsymbol{n}$,

$$\nabla c(\boldsymbol{x}) = -\int_\mathrm{I} D_2(\boldsymbol{x} - \boldsymbol{x}')\,\boldsymbol{n}(\boldsymbol{x}')\,\mathrm{d}l(\boldsymbol{x}')\,, \tag{7}$$

where l is the arc length along the interface. The mollified fluid properties are then described as $\mu(\boldsymbol{x}) = \mu_1 + (\mu_2 - \mu_1)c(\boldsymbol{x})$, and $\rho(\boldsymbol{x}) = \rho_1 + (\rho_2 - \rho_1)c(\boldsymbol{x})$. The mollifying function can be obtained by taking the divergence of Eq. (7) and solving the result-in Poisson equation for c. An example of the mollifying function for a two-layer flow is illustrated in Fig. 2, where the function takes the value of of zero in Fluid 1 and unity in Fluid 2, and undergoes a quick but smooth transition across the curved interface.

Using the approximate delta function, the integral term on the right-hand side of Eq. (4) can be evaluated for any collocation points, $\boldsymbol{x}$, on the Cartesian grid using a surface integration scheme. As a result, the surface force, $\Delta\mathbf{f}$, is smeared and distributed into the flow near the interface, acting as a body force. When marching the flow field in time, the interface is updated at each step using a Lagrangian method

$$\frac{\mathrm{d}\boldsymbol{x}_\mathrm{I}}{\mathrm{d}t} = \boldsymbol{u}(\boldsymbol{x}_\mathrm{I}, t)\,, \tag{8}$$

where the velocity at the interface, $\boldsymbol{u}(\boldsymbol{x}_\mathrm{I}, t)$, is interpolated from the flow field. The mollified fluid properties and distributed interfacial force are computed for the updated interface, and the generalized Navies–Stokes equations can be solved using a standard finite-difference method as if there were no interface. For further details, readers are referred to Blyth et al. [1].

When the fluid–fluid interface has a massless elastic membrane, the jump in the traction across the membrane, $\Delta\mathbf{f}$ in Eq. (4), is computed using the physical law that describes the constitutive relationship between the stress in the membrane and the membrane deformation. The generalized Navies–Stokes equations can be solved in the same way as for the pure fluid–fluid interface (e. g., Peskin [5]).

Fluid–Solid Interface

In some variants of the immersed boundary method dealing with the boundary between a fluid and a solid body, the fictitious fluid is introduced inside the solid body, and a boundary force, $\boldsymbol{F}$, in place of $\Delta\mathbf{f}$ in Eq. (4), is distributed into the augmented flow field in the same way as described for the fluid–fluid interface (e. g., Goldstein et al. [6]). To impose the no-slip and no-penetration boundary conditions at the interface, $\boldsymbol{F}$ is modeled as

$$\boldsymbol{F} = \alpha \int_0^t \boldsymbol{u}(\boldsymbol{x}_\mathrm{I}, \tau)\,\mathrm{d}\tau + \beta\boldsymbol{u}(\boldsymbol{x}_\mathrm{I}, t)\,. \tag{9}$$

where $\boldsymbol{u}(\boldsymbol{x}_\mathrm{I}, \tau)$ is the velocity at the boundary and α, β are the coefficients. The force has to be computed iteratively such that the boundary velocity is brought to the specified condition.

In some other immersed boundary methods for a fluid–solid interface, the no-slip/no-penetration conditions are enforced via an interpolation scheme (e. g., Mittal [4]). To carry out the interpolation, the variables on the grid points near the interface are used, and the interpolation may involve the "ghost nodes" defined outside the flow domain. In these methods, the boundary conditions are satisfied at the exact location of the interface. There is no need to compute the boundary force, and the interface may remain sharp.

Immunoassay

Definition

An immunoassay is an analytical procedure that takes advantage of the very specific binding between antibodies and antigens to evaluate the characteristics of a system. Immunoassays can be classified as competitive or non-competitive. Competitive assays introduce a known amount of antibody-antigen complex to the sample and the amount of antigen displaced from the complex is used to infer the amount of antigen present (i. e., by *competing* with the antigen already bound) in the sample. Non-competitive assays measure the amount of antigen present in a sample by quantifying the amount of antibody-antigen complex formed when the sample is exposed to an antibody.

Immunoassays can also be classified as homogeneous or heterogeneous. In a homogeneous immunoassay, antigen, antibody, and sample are mixed in the solution phase, while in a heterogeneous assay, one constituent (typically the antibody) is immobilized on a solid surface while the other constituents are delivered via the solution phase.

ts5@ecs.soton.ac.uk

Synonyms

Dielectric spectroscopy; Single cell impedance spectroscopy

Definition

Impedance measurements are performed by applying an AC excitation voltage to an unknown system whilst measuring the current. The ratio of the excitation voltage to the current gives the complex impedance of the system. Impedance measurements of cells provide data on the intrinsic dielectric properties of the cells.

Overview

A biological cell is the basic structural and functional unit of all living organisms; often called the *building block of life*. Working at the cellular level is of fundamental importance for biomedical and clinical applications.

Cellular analysis requires a combination of biophysical and technological approaches, including counting, manipulation (trapping/focusing/sorting/rotating) and identification (staining/labeling) of cells. Traditional analysis is performed with bulk techniques, which are well established. However, measurements on large populations of cells only provide population averaged information. Individual cells, which may look identical, have different characteristics and behaviour. High throughput single cell analysis platforms offer the unique ability to characterize large numbers of individual cells at high speed. Microscale devices can be used for single cell analysis. Standard laboratory processes, including sample preparation, chemical reaction and synthesis can all be integrated on a single Lab-on-a-Chip (LOC).

Fluorescence spectroscopy is performed by binding antibody conjugated fluorescent probes to the cells and then performing analysis in a flow cytometer. Electrical measurement of cells are performed using high speed dielectric/impedance spectroscopy, a technique which is non-invasive and label-free.

The dielectric properties of biological cells and tissues have been of interest for nearly a hundred years. The early work of Maxwell [1] and Wagner [2], Fricke [3], Cole [4] and Schwan [5], amongst others laid the foundations for this field of research; see [6] for a review. In dielectric/impedance spectroscopy, the dielectric properties of a system are determined by applying a frequency-dependent excitation signal and measuring the response. Conventionally, a small AC voltage, $\tilde{U}(j\omega)$, over a range of frequencies is used as the excitation signal. The electrical current response, $\tilde{I}(j\omega)$, is measured and the complex impedance of the system, $\tilde{Z}(j\omega)$, is given by:

$$\tilde{Z}(j\omega) = \frac{\tilde{U}(j\omega)}{\tilde{I}(j\omega)} = \tilde{Z}_{\mathrm{re}}(\omega) + j\tilde{Z}_{\mathrm{im}}(\omega)\,,$$

where $\tilde{Z}_{\mathrm{re}}(\omega)$ and $\tilde{Z}_{\mathrm{im}}(\omega)$ are the real and imaginary parts of the complex impedance, respectively. The real part is called resistance while the imaginary part is called reactance.

The magnitude and phase angle of the complex impedance are:

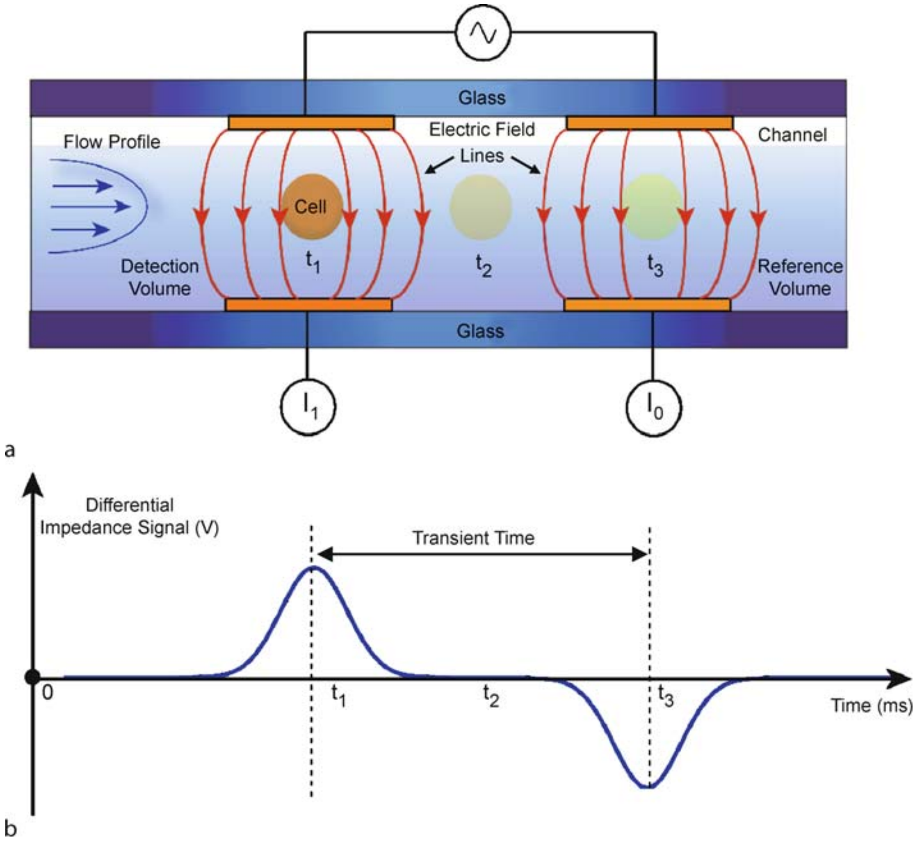
$$\left|\tilde{Z}(j\omega)\right| = \sqrt{\left[\tilde{Z}_{\mathrm{re}}(\omega)\right]^2 + \left[\tilde{Z}_{\mathrm{im}}(\omega)\right]^2}$$

and

$$\angle\tilde{Z}(j\omega) = \arctan\left(\frac{\tilde{Z}_{\mathrm{im}}(\omega)}{\tilde{Z}_{\mathrm{re}}(\omega)}\right)\,.$$

In impedance-based microfluidic cytometers, microelectrodes are fabricated inside a microchannel and the impedance signals of large numbers of cells are measured at high speed, one cell at a time (Fig. 1). The first cytometer capable of measuring the electrical properties of single cells, was developed by Coulter [7]. The device measures the DC resistance between two electrically isolated fluid-filled chambers as cells pass through a small connecting orifice. For a fixed sized orifice, the change in electrical current can be used to count and size the cells. Recent micro-chip designs now use AC signals at high frequencies to give information on cell dielectric properties as well as cell volume [8–10].

A typical example of on-chip single cell impedance measurement is shown in Fig. 1. Two pairs of microelectrodes are fabricated in a microchannel which is typically 20 to 40 μm high and wide. The two electrodes allow a differential impedance measurement to be made. One pair is used for sensing the electrical signal fluctu-



Impedance Measurements of Cells, Figure 1 (**a**) Diagram showing the impedance analysis chip and a single cell flowing through the microfluidic channel. In the differential measurement scheme, the difference between the currents passing through the detection and reference volume is measured. The electrodes are typically 20 to 40 μm wide and long. (**b**) Diagram showing the variation of the differential signal as the particle passes through the channel

ation induced by the cell, the other measures the electrical signal passing through the unperturbed medium as an electrical reference. As the cell passes through the AC electric field in the channel (under pressure-driven flow), there is a change in the impedance which is indicative of the size, shape and dielectric properties of the cell. This impedance signal is sensed as a changing current signal by the bottom microelectrodes. A positive and negative peak is observed, as the cell passes though the channel (Fig. 1b).

For small cells (low volume fraction), the complex permittivity of a cell in suspension is determined by Maxwell's mixture theory [1]. This approach works well for volume fractions less than 10%; the analysis was extended for higher volume fraction by Bruggeman [11] and Hanai [12]. The characteristics of the impedance spectrum of the suspending system can vary over different frequency ranges. A cell has a thin insulating membrane, and the measured permittivity of a suspension of cells has a high value at low frequencies due to charging of this membrane. As the frequency increases, the value of the permittivity decreases, approaching that of the suspending medium. Using a differential measurement scheme, and for a cell suspended in physiological medium, the cell size is determined at low frequencies (< 1 MHz). The cell membrane capacitance can be measured in a frequency window between 1 – 10 MHz and at even higher frequencies, the properties of the cell cytoplasm are probed. The technique can be used to discriminate between different cell types (e. g. sub-populations of leukocytes), measure the effects of chemical agents on cells, or probe changes in cell structure.

In summary, impedance measurements of single cells gives information on cell size, membrane capacitance and cytoplasm conductivity. It allows the identification and differentiation of cells sub-populations at high speed. It is non-invasive and label-free, and has a wide range of biotechnological and biomedical applications.

Definition

► Biosensors are bioanalytical systems defined by the integration of four key components: sample presentation, biotransduction, instrumentation, and data output. Central to the biosensor system is the ► biotransducer that converts the activity (concentration) of the targeted analyte into a proportional signal via an intimate combination of a biological recognition membrane layer and a physicochemical transducer. The biological recognition membrane provides its specificity by the use of biomolecules such as DNA, RNA, PNA, enzymes, antibodies, enzyme-linked antibodies, and receptors, and may use subcellular fragments such as mitochondria and cell membrane components (receptors), whole cells (bacteria or mammalian cells), and/or tissue slices (liver, brain, etc.). An impedimetric biosensor is constructed by immobilizing biological recognition elements onto an electrode surface. It reports, through measurement and/or monitoring, the targeted analyte through the output of an ► electrical impedance signal made proportional to analyte activity.

Overview

Biosensors have gained in popularity over the last two decades because of the growing need to offer an analytical footprint considerably smaller than laboratory-based instruments. This growing need is nowhere more pressing than in clinical molecular diagnostics, home health care, "theranostics" (the molecular linkage of diagnostics with therapeutics, particularly with regard to personalized patient dosing), and global security from chemical and biological threats and potential terror attacks. In the areas of most promising growth it is the need for rapid, point-of-concern decision making that motivates attention to biosensors. In these cases, the biosensor system may serve as a screening test for further confirmatory tests performed at a remote site or molecular diagnostics laboratory, thereby eliminating the cost burden associated with running large numbers of costly confirmatory tests when they are not warranted, or it may itself be a confirmatory test intended to elicit actionable decisions at the point of concern.

The advent of micro- and nanofluidics has led to a resurgence of interest in biosensors; in part because the purposeful manipulation of small volumes of liquids within a single device platform allows the streamlined integration

of many sample preparation operations with the biosensor detection and monitoring system. Two major criticisms of biosensor systems, reflecting their poor commercial success to date, have been their continued reliance on traditional, operator–intensive sample preparation and manipulation prior to bioanalytical measurement and the need for relatively large amounts of sample. By successfully integrating micro- and nanofluidics with biosensors, many of the unit operations associated with sample preparation and presentation, such as separation (cell or biomolecule), mixing, incubation, and concentration, may be performed directly in a Lab-on-a-Chip format. Also, the use of microliter and nanoliter volumes implies the use of smaller sample volumes, smaller quantities of usually costly reagents, and greater analytical sensitivity.

Impedance, as a transduction principle, has been applied to biosensor systems and so-called impedimetric biosensors. It has been regarded as an effective way for sensing the formation of antigen–antibody, biotin–avidin complex, oligonucleotide–DNA interactions, etc., on electrode surfaces by probing the features of the interfacial properties (capacitance, electrode transfer resistance, etc.) of the electrode. The advances in microfabrication technologies have launched the use of microfabricated ▶ interdigitated microelectrodes (IMEs) in impedimetric biosensors. An IME consists of a pair of microband arrays of digit electrodes that mesh with each other. The width of digit electrodes and the interdigit space is in the micrometer to nanometer range. The dimensional compatibility of the IME with biological entities makes it an obvious choice for its ability to detect sensitively the biological reactions on the electrode surface without any amplification step, achieving label-free biosensing. Besides, microelectrodes in general have great advantages over conventional electrodes for analytical measurements, such as low ohmic drop of potential, applied high potential scanning, high signal-to-noise ratio, rapid attainment of steady state, and the use of small volumes of solutions. Attractively, the integration of IMEs with micro- and nanofluidics would allow the biosensor to perform in a Lab-on-a-Chip format. The basic methodology for impedance measurements, the use of IMEs, and the immobilization of biological elements onto microelectrodes are illustrated below.

Basic Methodology

Electrical and Electrochemical Impedance

Generally, there are two categories in impedance measurement: electrical and electrochemical impedance. Electrical impedance (EI) is a two-electrode measurement performed using a lock-in amplifier and function generator or frequency response analyzer (FRA) with a pair of electrodes, the working electrode (WE) and counter electrode (CE), which may be of equal or different areas. Electrochemical impedance (ECI) is a three-electrode measurement performed using similar instruments along with a front-end potentiostat. The electrode arrangement includes an additional electrode, the reference electrode (RE), which contributes a half-cell potential, to which the potentiostat references its interrogating voltage. Figure 1 shows the schematic setup for the measurement of EI and ECI. In both cases the instrumentation delivers a sinusoidally varying and interrogating potential of specified frequency to the CE and the ensuing AC current is measured at the WE. The transfer function, the ratio of V/I in the complex plane, allows a measure of the impedance of the device under test (DUT). The applied excitation voltage is sinusoidal and given by

$$V = V_{\mathrm{m}} \sin \omega t \tag{1}$$

in which ω is the radial frequency, V_{m} is the maximum voltage at the peak, and V is the voltage at any given instant. The AC response (i) is characterized by both its amplitude (i_{m}) and its phase shift (θ) with respect to the applied AC voltage, as follows:

$$i = i_{\mathrm{m}} \sin(\omega t + \theta) \tag{2}$$

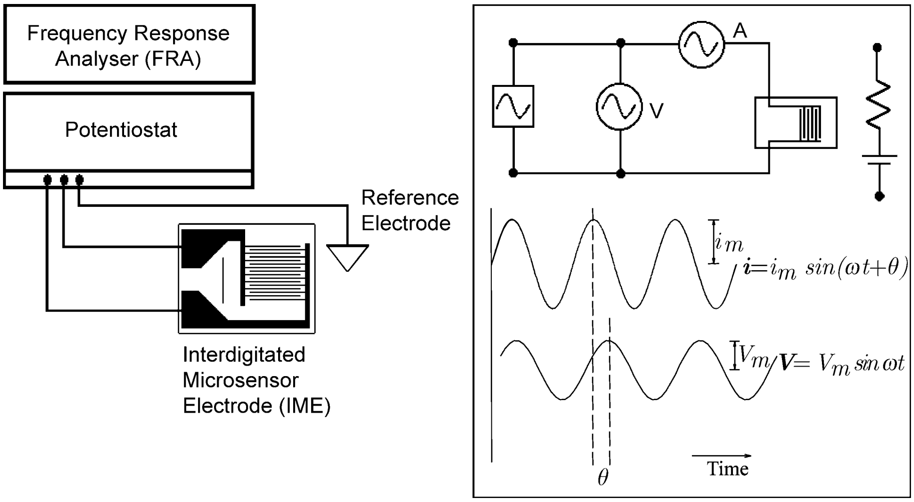
The ratio of the amplitudes of the applied and the response signal ($V_{\mathrm{m}}/i_{\mathrm{m}}$) and the phase shift between these signals (θ) is used to determine the impedance of the DUT, which can be represented as a complex number. The real component of impedance is known as the resistance, R, and the imaginary component, X, is known as the reactance:

$$Z = R + jX \tag{3}$$

The reactance, X, describes that part of the DUT that behaves as a capacitor or inductor while the resistance term, R, describes that part of the DUT that behaves as a resistor; reactance indicates charge storage aspects of the DUT and resistance indicates dissipative aspects. The magnitude of the impedance, determined by the square root of the sum of the squares of the resistance and reactance [1], and the phase angle are determined by

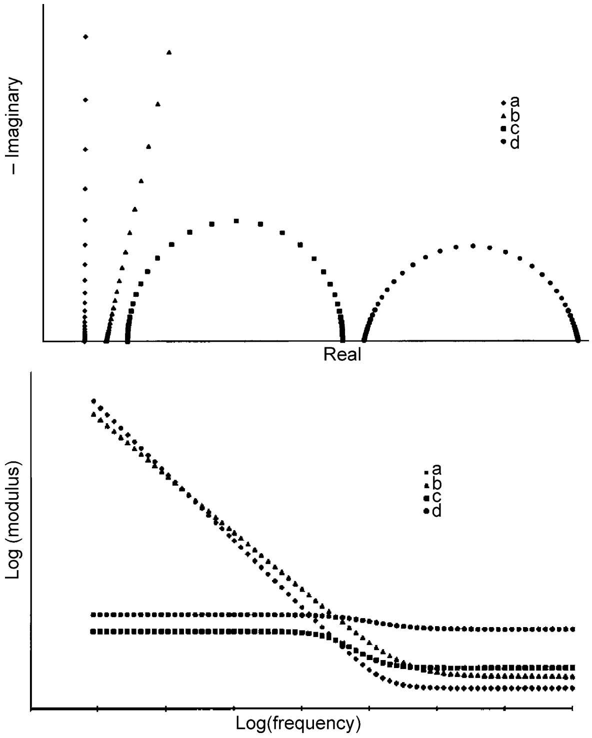
$$|Z| = \sqrt{R^2 + X^2} \qquad \text{and } \theta = \arctan X/R \tag{4}$$

When a range of frequencies is applied to the DUT, both EI and ECI techniques are called spectroscopies, i. e., electrical impedance spectroscopy and electrochemical impedance spectroscopy. Electrochemical impedance spectroscopy (EIS) profiles, measured as a function of the



Impedimetric Biosensors for Nano- and Microfluidics, Figure 1 The basic instrumental setup for the measurement of electrical impedance and/or electrochemical impedance spectroscopies and impedimetry

interrogating frequency, can be presented by two popular plots: Complex plane impedance diagrams, sometimes called Nyquist or Cole–Cole plots, and Bode ($|Z|$ and θ) plots (Fig. 2). As the impedance, Z, is composed of a real and an imaginary part, the Nyquist plot shows the relationship of the imaginary component of impedance, Z'' (on the Y-axis), to the real component of the impedance, Z' (on the X-axis), at each frequency. A diagonal line with a slope of 45° on a Nyquist plot represents the Warburg impedance which would be equivalent to a phase shift of 45° on a Bode plot. The semicircle is characteristic of a single *time constant*. Electrochemical impedance plots often contain several time constants, but often only a portion of one or more of the semicircles can be seen. However, the major shortcoming of a Nyquist plot is that the plot does not explicitly show the frequency data. The two-component Bode plot is a comprehensive and detailed representation of the frequency dependence of the impedance and presents the magnitude of the impedance, $|Z|$, and the phase shift, θ, in relation to the interrogating frequency. Specific regions of the spectrum can be linked to characteristic frequency ranges [1].



Impedimetric Biosensors for Nano- and Microfluidics, Figure 2 Representative (**a**) Complex plane diagrams (Nyquist or Cole–Cole plots) and (**b**) Bode plots from electrochemical impedance spectroscopy measurements

EIS data are generally interpreted based on defining an appropriate equivalent circuit model that best fits the acquired frequency-dependent real and imaginary data. An equivalent electrical circuit usually consists of a specific arrangement of resistors, capacitors, and inductors in series or parallel (or both) combinations. Table 1 lists the common circuit elements and their impedances and phase shifts. The impedance of a resistor is independent of frequency and has only a real component. The current through a resistor is always in phase with the voltage. The impedance of a capacitor decreases as frequency increases and has only an imaginary impedance component. The current through a capacitor is phase shifted by −90° with

Impedimetric Biosensors for Nano- and Microfluidics, Table 1 Impedance properties of common electrical elements

Element	Impedance	Phase shifted*
Resistor	$Z = R$	0
Capacitor	$Z = 1/j\omega C$	−90
Inductor	$Z = j\omega L$	90

Z, R, C, and L stand for impedance, resistance, capacitance, and inductance; $\omega = 2\pi f$, where f is frequency (Hz); $j = \sqrt{-1}$.
* Indicates phase shift with respect to voltage.

respect to the voltage. An inductor's impedance increases as frequency increases and has only an imaginary component. The current through an inductor is phase shifted by 90° with respect to the voltage. However, the inductance is usually negligible in electrochemical measurements.

To be useful, the elements in an equivalent circuit should always have physicochemical significance in the physical electrochemistry of the tested system. For example, in most equivalent circuits, a resistor is used to represent the solution resistance, and the double-layer capacitance is represented by a capacitor since it closely resembles a pure capacitance. Considering a system that is treated as a series combination of a resistor and a capacitor, the impedance of the system (Z) is a function of its resistance (R), capacitance (C), and applied frequency (f):

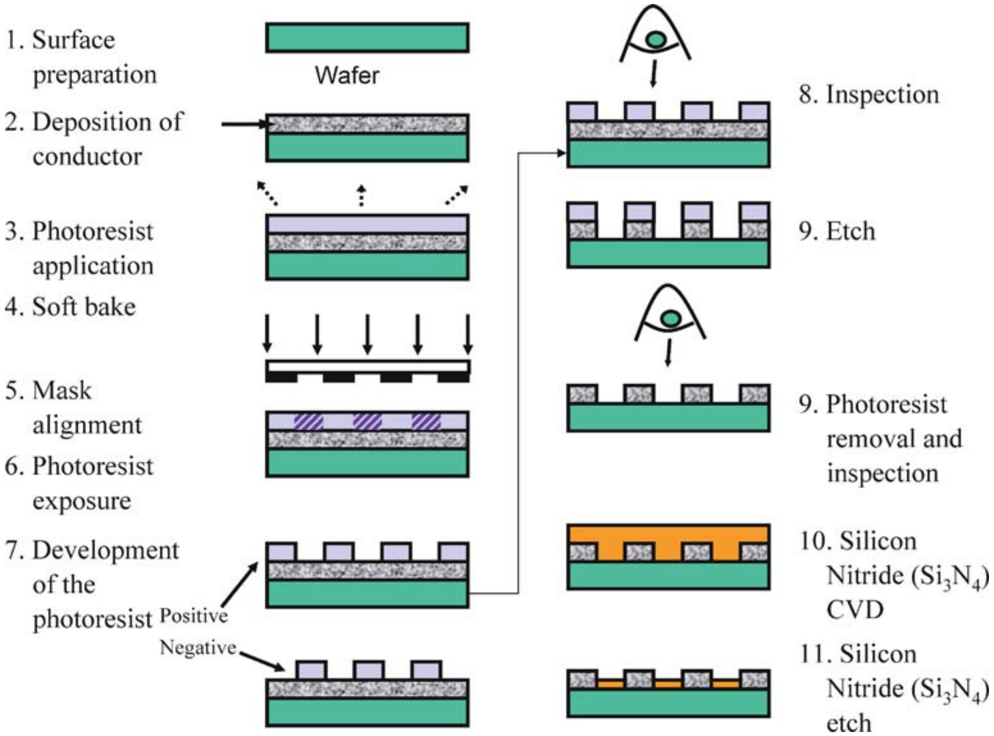
$$Z = R_s + \frac{1}{j2\pi fC} \tag{5}$$

Microfabricated IME Devices for Impedimetry

For integration with micro- and nanofluidics, a suitable format for the two- and three-electrode arrangements used in impedimetry is that based on the microlithographically fabricated, co-planer, interdigitated microsensor electrode array (IME or IDA). Each sensor element of the array consists of a pair of opposing platinum, gold, or indium tin oxide (ITO) electrodes of 1 – 5 mm digit length and of digit width and separation that may be equal or unequal in the range 100 nm to 10 µm. These dimensions serve to define the serpentine length (width of the channel), the interdigit space (length of the channel), and the overall area of interdigitation. The metallization is typically 10 nm of magnetron sputter-deposited titanium/tungsten (Ti/W), which serves as an adhesion-promoting layer for the metals (chromium is entirely inappropriate for the electrolytic environment), followed by 100 nm of electron-gun-deposited platinum, magnetron sputter-deposited gold, or is entirely of ITO (ITO has good adhesion to most substrates). The substrate may be oxidized silicon with a minimum 100 nm of thermally grown oxide or may be a highly polished, electronics-grade borosilicate glass such as Schott D262. These independently addressable interdigitated elements are sufficient for two-electrode impedimetry or electrical impedance spectroscopy. However, they may be accompanied by a large-area counter electrode of area 100 to 1000 times that of the area of each region of interdigitation. Such a counter electrode would serve to support the electrochemical oxidation or reduction of electroconductive layers (e. g., conductive, electroactive polymers) that may be deposited or grown on each region of interdigitation. Finally, a reference electrode of silver/silver chloride may also be included to allow for electrochemical impedance spectroscopy. This reference electrode provides the reference potential for the electrochemical impedance determination of each multiplexed element of the array. This reference electrode, one on each chip or associated with each sensing element of the chip, may be fabricated of platinum and subsequently electroplated with silver. This process of silverization introduces an additive step that essentially creates a new metal surface on the device. Similar electroless and electroplating options may be explored in creating arrays of different metals, e. g., gold and palladium. The subtractive steps in the microlithography that serve to define the conductor pattern may be via ion bean milling or lift-off techniques. Figure 3 summarizes the several steps in the microlithographic preparation of IME devices.

EIS of Microfabricated IME Devices

In the case of the impedimetric IME sensor, the two sets of electrodes of the IME can be two poles in a two-electrode configuration for electrical impedance measurements. Figure 4 shows 4a a picture, 4b a schematic, 4c the equivalent circuit model for the IME device, and 4d the Bode plot of the electrochemical impedance spectrum obtained in aqueous 0.01 M phosphate-buffered saline containing 10 mM ferricyanide at room temperature. The equivalent circuit for the IME device in Fig. 4c consists of an ohmic resistance (R_s) of the electrolyte between two sets of electrodes and the double-layer capacitance (C_{dl}), an electron transfer resistance (R_{et}), and Warburg impedance (Z_W) around each set of electrodes [2]. R_s and the two branch circuits are connected in series, since all the current must pass through the uncompensated resistance of the electrolyte and each set of the array electrodes. Each of the two identical branch circuits represents the behavior of each set of electrodes. Considering the total current through the electrode surface is the sum of faradic current (i_f) and double-layer charging current (i_c), the Warburg impedance is considered to be in series with the electron transfer resistance and both of them



Impedimetric Biosensors for Nano- and Microfluidics, Figure 3 Schematic illustration of the several steps involved in the preparation of microlithographically fabricated interdigitated microsensor electrode (IME) arrays

are connected in parallel with the double-layer capacitance. Among these electrical elements, R_s and Z_W represent the properties of the bulk solution and the diffusion of the redox probe, respectively, whereas C_{dl} and R_{et} depend on the dielectric and insulating features at the electrode/electrolyte interface, respectively. The electrochemical impedance spectrum in Fig. 4d shows a typical Bode plot for the IME system with mixed kinetic and charge transfer control. The agreement between the measured data (solid line) and the fitting spectrum (broken line) indicates that this equivalent circuit provides a feasible, if not unique, model to describe the performance of the IME electrode system.

Conferring Biospecificity to IME Devices

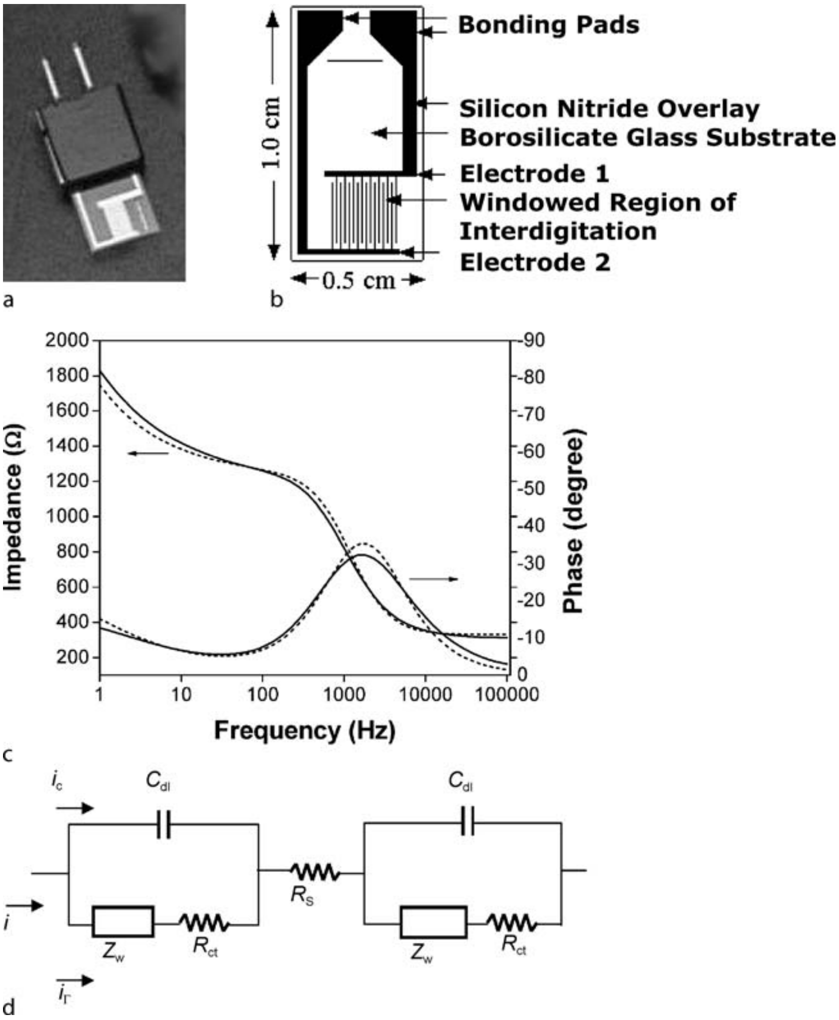
Biospecificity is the property of the ►biorecognition membrane of the biotransducer that is conferred by the purposeful use of a bioactive receptor. There exists a wide range of possible approaches to the conferment of biospecificity to impedimetric array biosensors. These methods vary somewhat depending upon the bioactive receptor to be immobilized (molecule, subcellular fragment, cell, or tissue). However, these methods have one major purpose: to confer the molecular recognition and specificity inherent to the bioactive receptor to the biotransducer in a manner that maximizes the sensitivity of the physicochemical transducer that lies beneath. Amongst the various ►bioimmobilization approaches are:

- adsorption (physical, chemical, and electrostatic),
- adsorption followed by covalent cross-linking,
- covalent tethering, and
- entrapment (physical or covalent) within host matrices (e. g., polymers, polymeric hydrogels, and sol–gels).

Regardless of the specific linking chemistry and substrate employed, the key goals in all biomolecule immobilization strategies are:

- reproducible, high-density coverage of the biomolecule on the substrate,
- the orientation of the biomolecule for efficient kinetics of the biological reaction,
- minimal background and nonspecific adsorption to the support or substrate,
- improved sensitivity, and
- long-term stability (retained bioactivity) of the immobilized biomolecule.

These, of course, also apply to the biomolecule immobilization in impedimetric IME devices.



Impedimetric Biosensors for Nano- and Microfluidics, Figure 4 (**a**) A picture of a microfabricated interdigitated microsensor electrode, (**b**) a schematic illustration of the IME, (**c**) the Bode plot of $|Z|$ and θ obtained from the frequency dependent interrogation of an IME 1525.3 ITO device in 0.01 M PBS containing 10 mM $[Fe(CN)_6]^{3-/4-}$ (solid line, 10 mV p-t-p, offset = 0) and the corresponding fitting data (dotted line), and (**d**) the equivalent circuit model derived from the NLLS fitting of the impedance data

The most common immobilization of biomolecules onto an IME device for impedimetric detection is the covalent linkage by the use of organosilane chemistries on the exposed glass of the interdigit space and alkanethiol chemistries on the gold digits. However, immobilization of the biological elements to the interdigit space between the electrodes or to the digit electrode surface affects the final signal in impedance detection through different response mechanisms. The impedimetric response of an IME device with biological molecules immobilized on the digit electrodes arises principally from the change in dielectric constant at the interface as water and ions become excluded following biological binding reactions. Such responses are manifest largely in the capacitative term of the complex impedance and are generally not very sensitive to the biological reactions because the alkanethiol layer has already contributed appreciably to the capacitative character of the electrified interface. The impedimetric response of an IME device with biomolecules immobilized within the interdigit space arises principally from the change in ion density within the electric field formed between the electrodes. Such responses are manifest in the solution resistance term of the complex impedance and are generally sensitive to biological reactions occurring on the device.

Here we describe examples of the immobilization of DNA, enzymes, and antibodies to IME devices at the interdigit space for impedimetic biosensing. In general this proceeds by the cleaning (activation) and subse-

quent surface modification of the IME device using organosilane chemistry on the exposed glass. A commonly used covalent coupling protocol uses 1-(3-dimethylamino-propyl)-3-ethylcarbodiamide hydrochloride (EDC) and *N*-hydroxysulfosuccinimide (sulfo-NHS) to activate carboxylic acid groups followed by coupling to primary amines of the biomolecules. An additional requirement is that the silanol that is condensed on the gold digits must be removed to expose the interrogating metallic electrodes. This may be achieved by repeatedly electrochemically scanning the IME device in 0.1 M H_2SO_4 until a stable gold oxidation/reduction cyclic voltammogram is obtained.

Impedimetric Genosensors Using Immobilization of Oligomeric DNA

Figure 5 illustrates 5a the immobilization chemistry and 5b the hybridization scheme for DNA at the IME device using organosilane chemistry. Synthetic 5′-amine-terminated single-stranded oligonucleotides (ssDNA) were immobilized on the glass surface between the metallic digits of microlithographically fabricated microsensor electrodes (IMEs) using 3-glycidoxypropyltrimethoxysilane. Nonspecifically adsorbed probes onto the metallic digits were removed by a cathodic cleaning step [3]. Such a sensor provides a useful means to directly detect the hybridization of DNA strands using electrical impedance measurements. The ensemble of single-stranded DNA chains immobilized between the opposing electrodes is associated with counter cations that support ionic conductivity. The hybridization reaction occurs on the IME genosensor when the complementary strand DNA molecule present in the sample solution makes sufficient use of hydrogen bonding between the nucleic acid bases to expel water from between the double helix. Therefore, the density of water molecules, and thus solvated ions, associated with the double helix is correspondingly reduced when compared with the single strand. Consequently, an increase in the overall impedance of the IME is anticipated upon the DNA hybridization reaction.

In DNA immobilization, several factors, such as the line and space dimensions of the IME (cell constant), immobilization strategy, the nature of the immobilized DNA molecules, and the length of the DNA probe, may affect the final signal in impedimetric detection. For example, oligonucleotide probes that are oriented parallel to the electrode result in decreased conductance compared to oligonucleotides that are oriented perpendicular to the electrode. The increase in conductance is associated with increased current and hence lowered detection limits. In general, upon immobilization the Brownian motion and translational degrees of freedom of the immobilized DNA are reduced, which affects the final performance of the IME biosensor through the hybridization kinetics. However, immobilized DNA can result in a rate of reaction that is comparable to the reaction rate of complementary strands free in solution. The length of the immobilized DNA strand has also been shown to have a much greater effect than the effect of immobilization on a two- or three-dimensional surface for DNA strands with lengths greater than 100 bases. The hybridization rate was shown to decrease with linker lengths greater than 712 bases.

(**b**) A schematic illustration of the cross-sectional representation of DNA hybridization reaction occurring between a pair of electrode digits (Dimensions are not to scale)

Impedimetric Enzyme Biosensor using Immobilization of Enzyme

Immobilization of urease onto an IME device can produce an impedimetric enzyme biosensor for determination of urea [4]. The enzyme urease can be immobilized by a similar covalent tethering strategy to the interdigit surface via 3-aminopropyltrimethoxysilane monolayer and sulfo-NHS and EDC as crosslinkers. This creates an enzyme

layer which is very thin relative to the electrode dimensions. The immobilized urease catalyzes the hydrolysis of neutral urea, leading to the formation of ammonium, bicarbonate, and hydroxide ions:

$$\text{Urea} + 3H_2O \xrightarrow{\text{urease}} 2NH_4^+ + HCO_3^- + OH^-$$

The charged products of the above reaction increase the solution conductivity in the vicinity of the IME surface, which results in a change in impedance signal detected by the IME. The conductivity change, measured in a low-conductance environment such as tris buffer or deionized water, may be made directly proportional to the urea concentration.

Impedimetric Immunosensors using Immobilization of Antibody

An impedimetric immunobiosensor may be fabricated by the covalent immobilization of primary or secondary IgG (immunoglobulin G) to the IME device on the exposed glass or on the exposed gold. To immobilize IgG to the gold digits, a self-assembled monolayer (SAM) of 11-mercaptoundecanoic acid (MUDA) or 11-amino-1-undecanethiol hydrochloride (AUT) is first formed on the gold surface. Following SAM formation, the surface–COOH groups of MUDA-modified electrodes are activated by EDC/sulfo-NHS, and then incubated in primary or secondary IgG solutions. To immobilize the IgG to the interdigit glass space, similar protocols are used, except an organosilane, such as 3-aminopropyltrimethoxysilane, replaces the alkanethiol in the surface modification step. The silanol that is condensed on the gold digits is removed by repeatedly electrochemically scanning the device in 0.1 M H_2SO_4.

The two foregoing modification approaches produce devices in response to impedance in two different ways: capacitive and resistive, as described above. Both are label-free approaches with the potential directly to detect antigens and haptens in sandwich or competitive immunoassay formats. However, they are both somewhat limiting in their overall sensitivity. Non-label-free impedimetric approaches that offer enhancements in sensitivity are the use of electroactive polymer layers and the use of redox-active and/or nanoparticle labels.

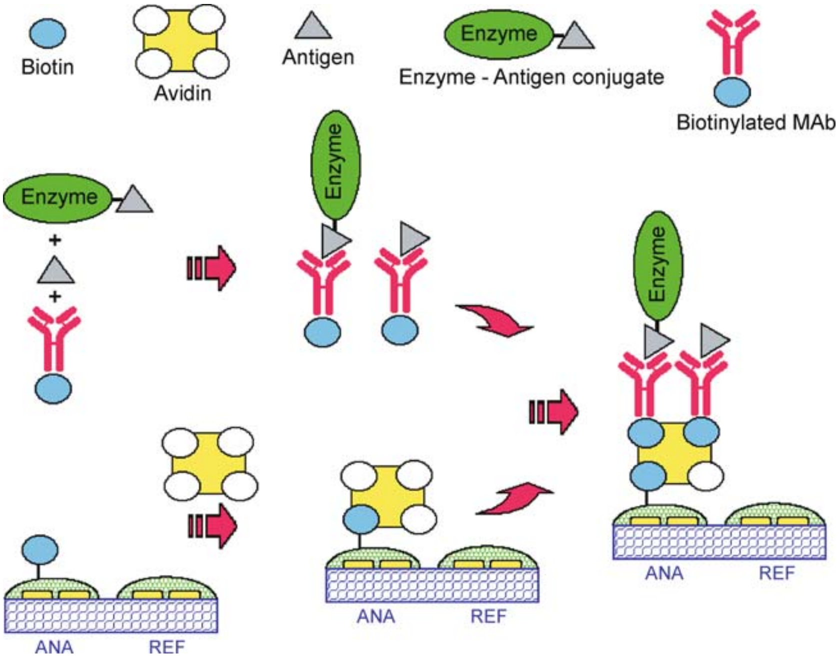
Electropolymerizable monomers that give rise to conductive electroactive polymers (CEPs) provide a convenient approach for the immobilization of antibodies and other biomolecules for the creation of biosensors [5]. Polypyrrole has been explored for the immobilization of antibodies in immunosensors. Pyrrole monomer may be electrochemically oxidized (aqueous solution; +0.75 V vs. Ag/AgCl) to produce a highly conjugated and electronically conductive polymer film in which dopant anions can be incorporated to maintain charge neutrality. The thickness of the film and its morphology may be controlled by the amount of charge passed and by the conditions of the electropolymerization. Because of the overall negative charge on IgG molecules, direct incorporation within electroactive polymer films is achievable in which the IgG acts as a single macromolecular counter anion dopant. Retained immunoactivity may, however, be compromised. A companion approach is to form copolymers using pyrrole and pyrrolebutyric acid. The copolymer presents available carboxylic acid groups at the surface that may serve to covalently immobilize the IgG. Figure 6 illustrates the covalent tethering of amine-functionalized biotin following EDC/sulfo-NHS activation of the pendant carboxylic acid groups of poly(pyrrole-*co*-pyrrolylbutyric acid). Subsequent incubation in streptavidin or neutravidin followed by incubation in biotinylated IgG immobilizes the primary antibody to the device surface. This format has been used to build sandwich immunoassays for antigens that are detected by the indirect action of the oxidoreductase enzyme-linked antibodies on the conductivity of the polymer film.

A further alternative is to implement these approaches with the use of redox and/or nanoparticle labels. The redox and nanoparticle labels replace the familiar enzyme labels in enzyme-linked immunosorbent assays (ELISAs) and offer the advantages of simplified protocol, wider linear dynamic range, higher stability compared to enzymes, and higher separation efficiency. Redox labels such as ferrocene, viologen, and (η^5-cyclopentadienyl)tricarbonyl manganese (cymantrenyl) may be directly conjugated to primary or secondary antibodies to serve as amperometric, voltammetric, and impedimetric reporters of immunobound conjugates. Since they invoke the faradic component of the impedance, they may be made quite sensitive.

Colloidal gold nanoparticles and carbon nanotubes may be used as reporting labels in immunobinding reactions on IME chips [6, 7]. These highly conductive particles make a contribution to a conductive network upon the immunobonding reaction. More appropriate when implemented in a threshold sensitivity switch in a YES/NO vs. a quantitative bioassay, these conductive labels once assembled on the surface provide a very sensitive electrical means for reporting the equilibrium binding condition.

Impedimetric Biosensors for Whole Cells

An impedance biosensor for whole cell detection is constructed by immobilizing antibodies or receptors that are specific to the target cells on an electrode surface. The sen-



Impedimetric Biosensors for Nano- and Microfluidics, Figure 6 Illustration of the immobilization biotinylated IgG to the IME device surface, through the covalent tethering of amine–functionalized biotin following EDC/sulfo-NHS activation of the pendant carboxylic acid groups of poly(pyrrole-co-pyrrolylbutyric acid), with subsequent incubation in streptavidin or neutravidin following by incubation in biotinylated IgG

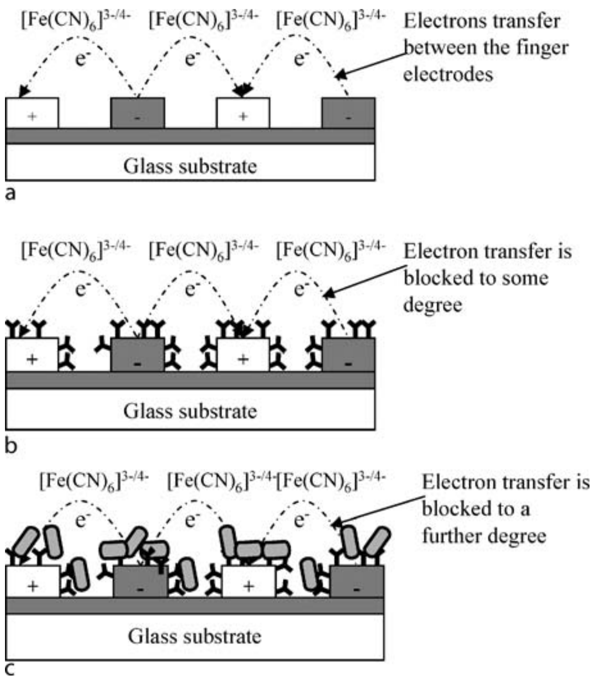
sor probes the attachment of cells by measuring the change in electrical properties of the sensor due to the insulating property of the cell membrane. The presence of intact cell membranes on the electrodes determines the current flow and thus the sensor signal. The overall impedance of a biological cell includes the resistance and the capacitance of the cell membrane. Natural cell membranes (thickness 5 – 10 nm) show a membrane capacitance of $0.5 – 1.3\ \mu F/cm^2$ and a membrane resistance of $10 \times 10^2 – 10 \times 10^5\ \Omega\, cm^2$. The structure and size of an IME have made it the best choice to realize a label-free biosensor for cell detection that is amenable to impedance measurement. Compared with the size of a bacterial cell, 1 – 2 μm long and ~ 0.5 μm in diameter, or a mammalian cell of 5 – 10 μm in diameter, the dimensional compatibility of the IME makes it an obvious choice for its ability sensitively to detect cells on the electrode surface without any amplification step.

Impedimetric Biosensors for Bacteria Detection

Figure 7 shows the detection principle of an impedimetric IME biosensor for bacterial detection [8]. It is based on measurements of electrochemical faradic impedance in the presence of $[Fe(CN)_6]^{3-/4-}$ as a redox probe. When a bare interdigitated microelectrode is immersed into an electrolyte solution containing the redox couple and a small-amplitude AC potential (5 mV) is applied to the electrode, the faradic process of oxidation and reduction of the redox couple occurs, and then electrons are transferred between the two sets of array electrodes through the redox couple (Fig. 7a). When antibodies are immobilized onto the electrode surface (Fig. 7b) they form a layer that can inhibit the electron transfer between the electrodes, and thus an increase in the electron transfer resistance can be expected. If bacterial cells attach to the antibody-modified electrode surface (Fig. 7c), the intact cells can create a further barrier for the electrochemical process, thereby hindering the access of the redox probe to the electrode surface, resulting in a further increase in the electron transfer resistance.

Capture of Bacteria Cells in Microfluidic Devices

Taking advantage of the IME, the capture of bacterial cells in a micro-/nanofluidic device could be realized using ▶dielectrophoresis (DEP). DEP is the electrokinetic motion of dielectrically polarized particles in non-uniform electric fields [9]. Combining the advantages of DEP concentration and antibody capture, target cells may be captured from a flow field achieved in a microfluidic biochip [8]. With the assistance of DEP to capture cells within the microfluidic device, IME impedi-



Impedimetric Biosensors for Nano- and Microfluidics, Figure 7 The detection principle of impedimetric IME biosensor for bacterial detection

metric biosensors have shown great potential in bacterial detection. Suehiro et al. [10] reported a detection technique called dielectrophoretic impedance measurement (DEPIM), which utilizes positive DEP to trap suspended biological cells onto an interdigitated microelectrode array to form pearl-chains. Cell population can be quantitatively evaluated by monitoring the change in the electrode impedance or admittance. Later, this DEPIM method was combined with antigen–antibody reaction to realize selective detection of *E. coli*. To further increase the sensitivity of this technique, the same group reported an improved DEPIM method for detection of *E. coli* by combining this technique with electropermeabilization, in which a high AC electric field was applied to the trapped bacterial cells, leading to intracellular ion release through damaged cell membranes, which causes an effective conductance increase.

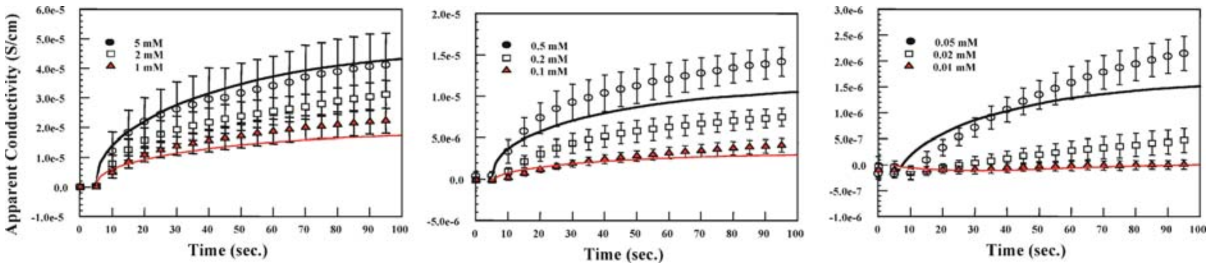
Immobilization of Mammalian Cells for Toxicity Biosensors

Mammalian cell immobilization to electrode surfaces is vitally important for the construction of cell-based biosensors which hold out the promise for the development of practical methods for the screening of drugs for possible toxic side effects and for the monitoring of the effects of biochemical warfare agents. Surface modification of the substrate could effectively enhance the attachment of mammalian cells on the substrate. For example, pheochromocytoma cells (PC-12) are inherently poorly adherent cells that proliferate on substrates. Covalent immobilization of the extracellular matrix (ECM) protein laminin to the surface of gold electrodes can yield conditions that allow for tighter neuron-to-electrode contract [11]. The gold electrode is first modified with SAMs of ω-amine alkanethiols, cysteamine (CA), or 11-amino-1-undecanethiol (11-AUT). These amine-terminated SAMs then serve to irreversibly couple laminin to the electrode surface and give rise to a strong covalent linkage between the electrode and laminin. Laminin is able to establish the strong attachment of PC-12 cells to a gold IME, because the immobilized laminin induces secretion of neuron adherence molecules that act as receptors in the neuron cell membrane and offer a wide range of potential adhesive interactions. An excellent area of application is that of microfluidic cell-based sensors with well-positioned recording sites for cell adhesion.

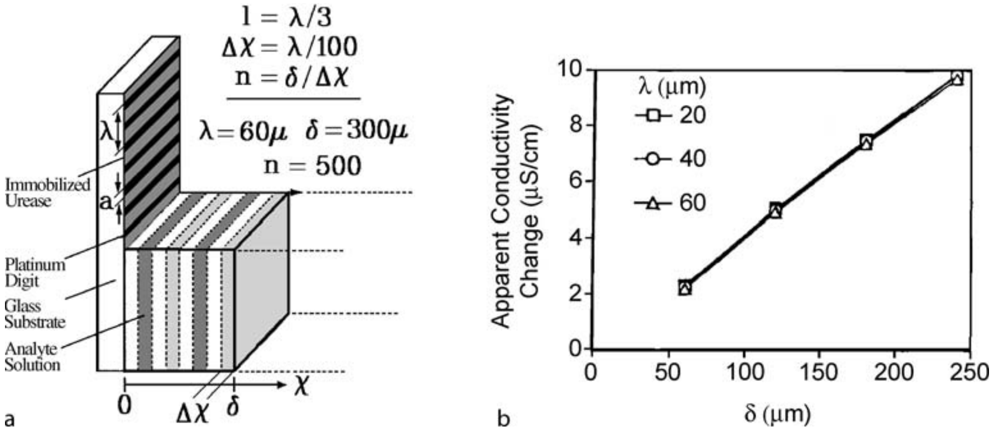
Key Research Findings

In impedimetric biosensor systems, biological reactions such as DNA hybridizations, enzymatic reactions, and immunoreactions usually involve the production or consumption of ions, which results in electrical impedance changes at the interface of the IME electrodes. We present here some representative results from an impedimetric biosensor for urea. The impedance response of this urease biosensor is contributed by charged products of the enzymatic reaction, which increases the solution conductivity in the vicinity of the IME surface and is detected by the change in IME impedance. Figure 8 shows typical experimental plots (points) and numerical simulations (solid lines) of the apparent solution conductivity with time when the immobilized urease biosensor is immersed in urea samples at concentrations ranging from 0.01 to 5.0 mM. At any given concentration, the conductivity increases most rapidly upon first immersion in the urea solution and increases less rapidly as time evolves establishing a kinetic assay. The final conductivity is also directly proportional to the urea concentration, as it increases most rapidly and to the highest level at the highest urea concentration.

It was found that the geometry of the IME used to construct the biosensor influences the magnitude of the response, but not the kinetics, which is solely determined by the reaction rate and mass transport. In the urease biosensor, a change only in the lateral extent of the array, affected by modifying the length of the digits or the number of digits, will not affect the response. A more interesting case to consider is miniaturization of the sensor, by reducing the digit width and/or interdigit spacing. If



Impedimetric Biosensors for Nano- and Microfluidics, Figure 8 Typical experimental plots (points) and simulations (lines) of the apparent solution conductivity with the time when the immobilized urease biosensor is immersed in urea samples at concentrations ranging from 0.01 to 5.0 mM



Impedimetric Biosensors for Nano- and Microfluidics, Figure 9 The effect of decreasing the spatial wavelength, λ, of the interdigitated microsensor electrode array. (**a**) Schematic illustration of λ and δ. (**b**) A plot of the steady-state, apparent conductivity change versus boundary layer thickness for devices having λ's of 20, 40 and 60 μ immersed in a 1 mM urea solution

these are reduced proportionately, while maintaining the original length of the digits, then the cell constant will remain unchanged [4]. Figure 9 illustrates the definition of the spatial wavelength, λ and the effect of decreasing the spatial wavelength of the interdigitated electrode array on the response. The figure is a plot of the steady-state, apparent conductivity change vs. boundary layer thickness for devices having values of λ of 20, 40, and 60 (used in the experiments) μ, and immersed in a 1 mM urea solution. Decreasing λ increases the magnitude of the response; the progressively smaller volume of electrolyte sampled by the miniaturized sensor has a higher average conductivity, since the conductivity decreases with distance away from the sensor surface. However, for the boundary layer thicknesses of 100 μm or more expected in practice, Fig. 9 demonstrates that the steady-state conductivity changes differ by less than 5% for the three different devices. It is believed that this geometry influence also occurs in impedimetric DNA sensors, immunosensors, and cell-based biosensors. Therefore, optimization of geometry/dimension of the IME is very important in construction of the biosensor.

Impedimetric biosensors for whole cells have demonstrated two mechanisms in response. Considering the overall impedance of a biological cell as including the resistance and the capacitance of the cell membrane, the presence of intact cell membranes on the electrodes would contribute to the sensor's capacitance and/or resistance, and would determine the current flow and thus the sensor signal. However, when cells are attached to the electrode surface, they are usually separated by a gap of 10–20 nm (up to several hundred nanometers). This aqueous gap between the cell membrane and the electrode surface prevents a direct influence of the cell membrane capacitance on the impedance of the electrode. Therefore, the cell membrane resistances of these attached cells act as resistors on the IME surface and affect the interfacial resistance. The interfacial resistance is best represented as electron transfer resistance in the presence of a redox probe (e. g., $[Fe(CN)_6]^{3-/4-}$) and can be sensitively monitored. Figure 10a presents a representative group of Nyquist plots of the impedance spectroscopic responses of an IME-based biosensor to different cell numbers of *E. coli* O157 : H7 at 10a antibodies, 10b 4.36×10^5 CFU/ml,

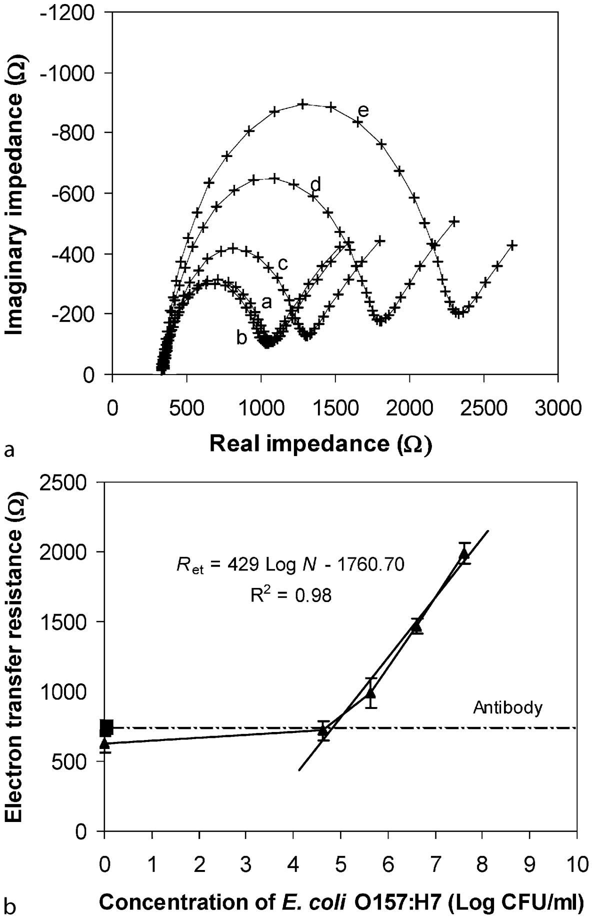
10c 4.36 × 10^6 CFU/ml, 10d 4.36 × 10^7 CFU/ml, and 10e 4.36 × 10^8 CFU/ml. Each of the impedance spectra includes a semicircle portion and a linear portion, which correspond to the electron transfer process and diffusion process, respectively. The electron transfer resistances (the diameters of the semicircles at the x-axis) of the sensor increase with increasing cell concentration. The analyzes of cell concentration can be realized on the basis of the linear relationship between the electron transfer resistance and logarithmic value of *E. coli* concentrations (Fig. 10b). As shown in Fig. 10, when the electron transfer resistance of the antibody immobilized IDA microelectrode was taken as the threshold of the signal, the detection limit of this immunosensor was 10 × 10^6 CFU/ml, which is comparable with other label-free immunosensors for detection of pathogenic bacteria using different transducer techniques.

Mammalian cells present the same impedance biophysics as bacterial cells at electrodes. Fig. 11a shows the normalized temporal impedance change (average and standard deviation) of PC-12 cells cultured on laminin-modified gold electrodes. Figure 11b shows similar PC-12 cells cultured on laminin-modified gold electrodes and dosed with 5 mM nifedipine. There is a clear immediate reduction in network impedance upon dosing with nifedipine.

Nifedipine (3,5-pyridinedicarboxylic acid-1,4-dihydro-2,6-dimethyl-4-(2-nitrophenyl)-dimethyl ester, $C_{17}H_{18}N_2O_6$; $MW = 346.3$ g/mol) is a calcium channel antagonist L-type Ca^{2+} channel blocker that inhibits depolarization-induced Ca^{2+} uptake into the cells. Statistically significant differences in the temporal response to different dosing levels of the same drug and differences arising from different drug classes are the bases for the development of a neurotoxicitiy biosensor. The PC-12 cells are progenitor cells capable of chemically induced differentiation. The impedance responses of chromafin-like PC-12 cells vs. neuronal-like PC-12 cells establish the basis for a neurotoxicitiy biosensor that informs on likely tissue-specific responses to candidate drugs. In vitro temporal impedance output from the whole cell neurotoxicity biosensor will allow determination of toxicity of chemical agents on cellular health and serve as an alternative to the use of whole animals in toxicity screening.

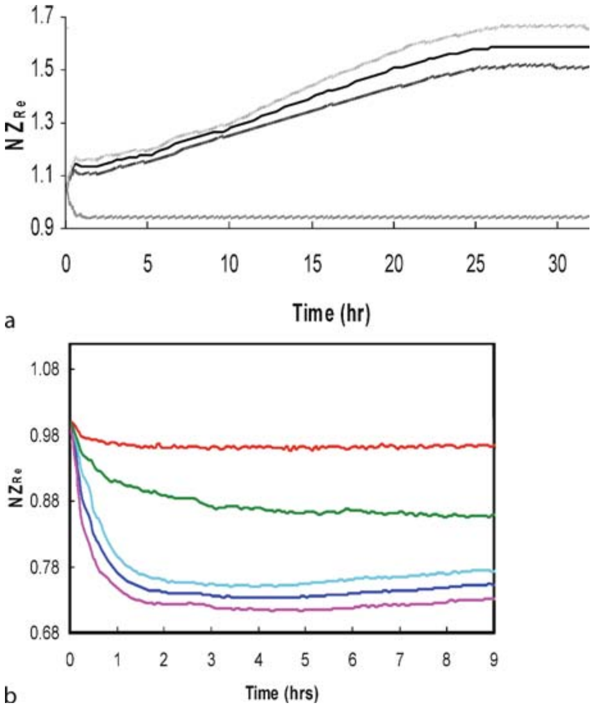
Future Directions for Research

Microfabricated IME-based impedimetric biosensors are ready to be integrated with micro- and nanofluidic systems. Many of the operations (surface modification, derivatization, bioimmobilization, incubation, washing, etc.) needed to achieve reproducible, high-density covalent immobilization of biomolecules or whole cells



Impedimetric Biosensors for Nano- and Microfluidics, Figure 10 The principle of IME impedimetric detection of the antibody immobilization and the bacterial attachment. (**a**) Nyquist impedance spectra of the IME-based biosensor upon antibody immobilization and bacterial attachment with different number of *E. coli* O157:H7 cells on their surface. a = antibodies only, $b = 4.36 \times 10^5$ CFU/ml, $c = 4.36 \times 10^6$ CFU/ml, $d = 4.36 \times 10^7$ CFU/ml, and $e = 4.36 \times 10^8$ CFU/ml. Data points from left to right correspond to decreasing frequency. Amplitude voltage: 5 mV; Electrolyte: 10 mM $[Fe(CN)_6]^{3-/4-}$ (1 : 1) in 0.01 M PBS, pH 7.4. (**b**) The linear relationship between the electron transfer resistance and logarithmic value of *E. coli* concentrations derived from Fig. 10a

on the IME device may be performed directly within the microfluidic environment of a fully integrated Lab-on-a-Chip. However, within a micro-/nanofluidic device, biological reactions often occur in a dynamic fluid which is quite different from the usual static environment. Because of the flow within a micro-/nanofluidic device, biological molecules would have much less opportunity to come into contact with the biosensor surface that is embedded in a microfluidic channel and to interact with the immobilized biomolecules, which would lead to a low probability of biological reaction. Therefore, integration of other techniques to manipulate biological entities in microflu-



Impedimetric Biosensors for Nano- and Microfluidics, Figure 11 The time-dependent profile (mean and standard deviation) of the normalized impedance response of the self-assembled monolayers (SAMs) of ω-amine alkanethiols, cysteamine (CA)-laminin modified IME chip (**a**) cultured with PC-12 cells ($n = 6$) and (**b**) PC-12 cells exposed to 5 mM nifedipine

idic environments is needed. Thus, dielectrophoresis to contain cells and nanoparticles, electrophoresis to drive biomolecular targets to the reactive surfaces, and pre-concentration techniques that enhance driving fluxes are expected to improve the efficiency and kinetics of biological reactions within microfluidic systems. This integration is highly desirable in order to drive micro-/nanofluidic detection systems towards the practical applications in point-of-concern molecular diagnostics. Efficient and reliable sample preparation, including cell sorting, lysis, DNA isolation, and protein separation, and methods to reduce the large volume of samples to microliters are necessary as the volumes required to perform analyzes in microfluidic devices usually range from a few to hundreds of microliters. Successful integration of impedimetric biosensors with micro-/nanofluidic systems presents one opportunity to approach the desirable result of the *tissue in–information out* paradigm of modern molecular diagnostics.

Synonyms

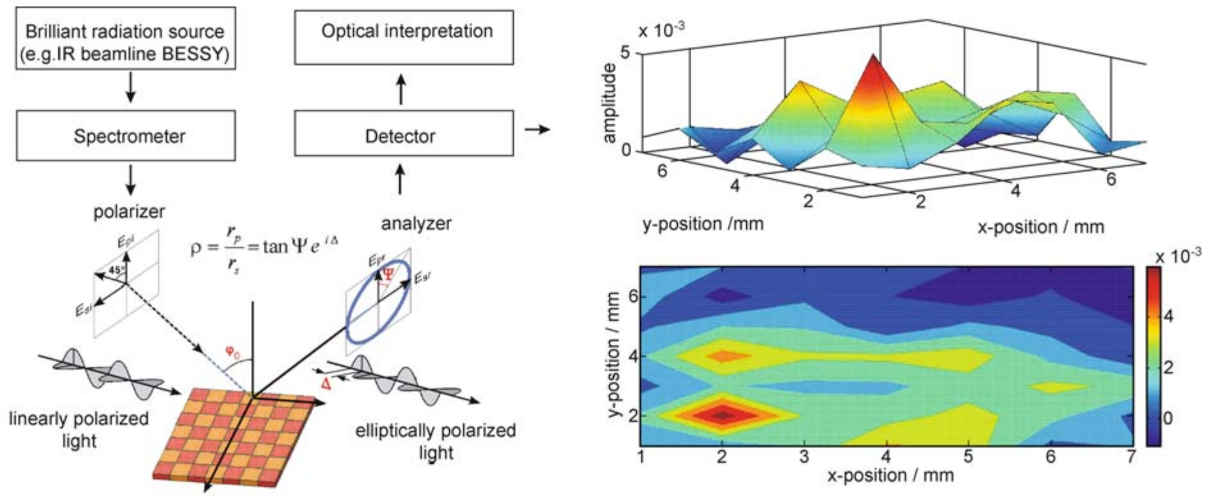
Infrared (IR) mapping; Imaging for biosensors/biochips/microchips; Biosensors Using Infrared Imaging

Definition

Infrared imaging or mapping techniques are meant here as those that potentially can be used for biosensors and their characterization. The mid-infrared (MIR) spectral range is defined from 2.5 to 16 μm (IR in [1]). For the production of laterally resolved images typically a two-dimensional sample movement stage is employed for defined lateral movements of the sample, whereby for every position a measurement with a single detector is performed or alternatively the image is obtained in one shot involving a detector array (e. g. focal plane array in [2]). Typical spectrometers used for the MIR range are Fourier transform infrared (FTIR) spectrometers; however, for specific purposes also infrared grating spectrometers are used.

Overview

Many optical techniques could potentially be used for biosensors and their characterization [1]. Among the label-free optical vibrational spectroscopies are Raman spectroscopy (RS) and infrared spectroscopy, which are frequently used as fingerprinting methods for characterization of thin films of biological compounds and biosensors. In comparison to the visible, for the IR spectral range absorption bands of molecular vibrations deliver often a higher spectral contrast. The interpretation of absorption bands can deliver, for example, thickness, molecular identification, molecular orientation, and composition. For the IR spectral range standard methods are transmission spectroscopy, IR microscopy [2], external reflection spectroscopy (e. g. reflection absorption IR spectroscopy (RAIRS) and IR spectroscopic ellipsometry (IRSE) [3]), and IR internal reflection spectroscopy (e. g. attenuated total reflection (ATR) [1, 4]). All of them are typically noninvasive, contactless, and could potentially be used for biosensors. Additionally they offer the possibility to be coupled with imaging techniques. Even though there



a principle of synchrotron mapping ellipsometry

b map of band amplitudes: peptide adsorption on biosensor

Infrared Imaging and Mapping for Biosensors, Figure 1 (**a**) Principle of ellipsometric mapping measurement. Due to reflection at the sample, the polarization of the radiation is changed. For example, the incident linearly polarized radiation becomes elliptically polarized. The sample is moved by a two-dimensional mapping table and a spectrum is taken for every probed spot. The ellipsometric parameters defined by the quantity ρ, which is the ratio of the complex reflection coefficients r_p and r_s, are measured for every spot. Δ is the phase shift and tan Ψ the amplitude ratio of p- and s-polarized reflection coefficients. (**b**) Three-dimensional presentation and contour plots of 7 mm $\times$ 7 mm map of ellipsometric (tan Ψ) band amplitudes of a peptide band at 1547 cm^{-1} (adapted from [5]). The peptide Cys-GCN4 was immobilized on a linker-covered silicon wafer. In principle electronic recognition of the specific adsorption site could serve for fast analysis of the samples under investigation [5]

is an emerging potential for IR spectroscopy for studying biosensors [5, 6] and IR imaging of biomedical samples [7–9], only a few studies with respect to the IR imaging of biosensors have been published up to now [5]. Figure 1b shows an experimental example of biosensor characterization by IR synchrotron mapping ellipsometry (Fig. 1a). Important key properties of the imaging techniques in the MIR range are:

- *Lateral resolution.* When brilliant light sources like lasers or synchrotron radiation are used the lateral resolution typically is diffraction limited in the range of a few micrometers for IR microscopy [2, 10]. This can be improved by orders of magnitude with scanning near-field IR microscopy (SNIM) [11], which enables resolution down to a few tens of nanometers. However, for broad-band sources such SNIM studies have not been performed so far. IRSE biochip characterization with lateral resolution down to approximately 200 µm $\times$ 400 µm is possible.
- *Sensitivity.* For SNIM, RAIRS, ATR, and IRSE the high sensitivity allows detection of nanometer thick biomolecular films.
- *Quantification of experimental results.* Reliable quantification of optical spectra and signals can be performed by involvement of optical modeling of RAIRS, ATR, and IRSE spectra. Here, IRSE has some advantages because it delivers up to three method-independent parameters (phase shift and amplitude ratio of s- and p-polarized reflection coefficients and the polarization degree). For SNIM quantitative evaluation is more difficult than for the other methods and is dependent on the geometry of SNIM.

Infrared Radiation

► Infrared Thermography

Infrared Thermography

Definition

Since all bodies with a temperature above 0 Kelvin emits heat radiation it is possible to determine the body temperature by analyzing the emitted radiation. While the spectra of the visible light are between 380 to 750 nm, infrared (IR) radiation lies between 0.7 and 1000 microns. Usual IR cameras have a sensitivity range between 3.5 and 14 microns because the atmosphere is transparent in this range. IR Thermography means displaying the infrared light intensity in images which are visible for the human eye. IR Thermography is a contact less technique; thus very fast processes like explosions can be visualized in sequence of frames.

Injection Molding

► Micromolding

Injection Slit

Definition

This etched structure is used to optimize and automate the injection procedure for shear-driven systems. Instead of injecting the sample by introducing it in front of the channel, an etched structure (injection slit) stands perpendicular towards the flow direction and the injection becomes more repeatable and an automated can be performed.

Inkjet

Definition

Inkjet printing certainly is the biggest industrial market using single droplets. Nearly all existing home and office inkjet printers are based either on the ►bubble jet or the piezo principle. High quality color image, low machine cost and low printing noise are basically the main advantages of such *inkjet* printers producing droplets in the 1 – 100 pl range. The two competing technologies in this field are the thermally actuated *bubble jet* commercially available from Hewlett Packard, Canon, Olivetti I-Jet and others and the piezoelectric driven printheads commercially available from Epson, Xaar, Spectra and others. Both methods made remarkable progress in the last two decades.

Inkjet print

Definition

Inkjet printing is a microfabrication technology to print the designed polymer patterns on a substrate by using an inkjet printing system (similar to the desktop printer) for MEMS and microelectronics applications. It is a bottom-up fabrication method. 3-D microstructures are sprayed directly on the substrate by the repeatable generations of small fluid droplets. The 3-D profile is precisely controlled by layer-by-layer printing associated with the computer program.
The printing fluids are often UV-curable, heat-sensitive or conductive polymers for various applications. The resolution of 3-D structure is limited by the size of droplet or nozzle, usually with diameters of $25 \sim 125\,\mu$m. The quality of the printing system determines the speed and precision of the spray and stage control. This technology is adapted in various applications of optical interconnect, electrical devices, microfluidic structures and assembly.

Integrated Actuators

Definition

A micropump or active microvalve is said to use integrated actuators when the component responsible for opening or closing the valve, or moving the fluid, is fabricated as an integral part of the device. An example would be an integrated movable flap or membrane that is electrostatically attracted to an integrated electrode when a voltage is applied.

Definition

Integrated microdevices for biological applications seek to create autonomous microfluidic devices capable of processing biological material from whole cell sample introduction to component extraction, biological sample manipulation and analysis. Although, there has been considerable research in creating devices for cell handling and analysis and proteomics, the major research thrust in creating integrated microdevices for biological applications has been towards genomic research and DNA analysis. Here, integrated devices for DNA purification, and DNA analysis for both plasmid and genomic DNA and a wide variety of biochips performing many different laboratory functions have been produced with varying levels of integrated functionality. Specific modules which have been demonstrated are fluidic cell concentration chambers, a DNA extraction chamber for DNA preparation, molecular biology reaction chambers for PCR amplification, and capillary electrophoresis separation arrays. These techniques are fundamental components of highly integrated biological analysis systems by allowing efficient DNA purification and analysis.

Overview

In biological studies, biological organisms can be studied on many levels. The whole organism can be directly investigated to study its behavior. In order to study a single cell, tissues or organs can be further broken down by either mechanical lysis or chemical (enzymatic) digestions. In order to study subcellular components of cells, cells are further broken down (disrupted) to extract subcelluar components of interest. After obtaining either subcellular or molecular components, a sample is further processed with techniques that may include sample purification, DNA amplification, and analysis. There are several essential techniques that are commonly used in subcellular levels studies. In this section, cell lysis, polymerase chain reaction (PCR), and electrophoresis (EP), are briefly reviewed as foundations of integrated microdevices for biological applications, although there are many other techniques commonly used in cellular or molecular biology studies as found in [1].

Integrated microfluidic devices have many advantages over conventional methods such as fast analysis time, small reagent and sample consumption, and less waste generation. In addition, they have the capability of integration, coupling sample preparation and analysis processes such as cell lysis, capillary electrophoresis (CE) and PCR. Therefore, integrated microfluidic devices enable hundreds of assays to be performed in parallel and in an automated manner.

Basic Methodology

Cell Lysis

Individual cells may be studied either by examining the cell morphology using a wide variety of specific cell stain-

ing procedures and microscopy or by isolating individual cells and culturing them for further molecular studies. In order to examine cells on a subcellular or molecular level, it is necessary to extract and purify subcellular components such as DNA, RNA, proteins and individual organelles from the cells of interest. However, it is well known that all cells contain a plasma membrane, which acts as a barrier between the extracellular and intracellular environment. Thus, in order to purify subcellular components the plasma membrane must be disrupted (lysed). Cell lysis may be achieved by either mechanical, chemical methods or a combination of both. Mechanical cell lysis may be accomplished by mechanical grinding of the sample by a mortar and pestle or rotating blade (blender) to process a large amount of biological samples. However, this method may also induce damage of the subcellular component of interest. A second method is through the use of sonication. Ultrasonic vibration produced by sonication can break the plasma membrane. However, heating produced by sonication may vesiculate the membrane and subcellular components. The most widely used method for cell lysis is to use detergents and simple agitation. Detergents can disrupt the lipid bilayer of the membrane causing the release of subcellular components [1]. However, many detergents can also denature proteins and are difficult to remove, once cell lysis process is finished. Therefore, the method used strongly depends on the cell type and the ultimate application of the research because the cell lysis may destroy the targeted sample of interest.

Polymerase Chain Reaction (PCR)

Since PCR was invented by Kary Mullis in 1983, it is widely used in molecular biology. PCR can selectively amplify DNA segments in a test tube by multiple cycles of DNA denaturation, specific primer hybridization and DNA polymerization [2]. The targeted DNA segments amplified by PCR may represent a small part of a large and complex mixture of DNAs such as from a genomic DNA lysate. In PCR, reactants are mixed together with an initial DNA sample. This mixture contains the DNA which is to be amplified, the enzyme DNA Taq polymerase, small primer sequences of DNA specific to and flanking the DNA sequence to be amplified and a large supply of the four nucleotide bases A, T, C, and G. Since the primers are specific to a single DNA sequence the primers gives PCR its specificity. The reaction mixture is heated to 90 – 95 °C for about thirty seconds. At this temperature the DNA strands separate as the hydrogen bonds holding them together break down. The mixture is cooled down to 55 – 60 °C. At this temperature the primers bind (or anneal) to the single DNA strands. The primers are short sequences of nucleotide bases which must join to the beginning of the separated DNA strands for the full copying process to begin. In the final step the mixture is heated up again to ∼ 72 °C for at least a minute. This is the optimum temperature for the DNA polymerase enzyme. The polymerase attaches nucleotide bases to the ends of the primers using the original DNA sequence as a template to build up complementary strands of DNA identical to the original molecule. The PCR cycle may be repeated up to thirty times to produce around 1 billion copies (2^{30}) of the original DNA. The whole process takes about 3 – 5 hours in a standard PCR reactor. The reasons for such a long processing time for PCR is mainly due to the large thermal mass of typical PCR systems, leading to slower heating and cooling rates.

Electrophoresis (EP)

Electrophoresis describes the migration of a charged molecule in a separation medium under the influence of an electric field. An accelerating force (F) acing on the molecule with charge q by an electric field E can be expressed by the Newton's law ($F = qE$). A terminal speed (u_E) of the molecule under the electric field can be achieved when the acceleration force equals to the frictional force (fu_E) generated by the separation medium [3],

$$u_E = \frac{qE}{f} \tag{1}$$

where f is a friction coefficient and u_E is the electrophoretic terminal speed. Also, the friction coefficient for a spherical particle of radius r moving through a fluid of viscosity η is given by $6\pi\eta r$. Thus, the terminal speed of a spherical molecule under influence of an electric field E can be written as,

$$u_E = \frac{qE}{6\pi\eta r} \tag{2}$$

where μ_E ($= q/6\pi\eta r$) is the molecule's mobility. Therefore, the difference in mobility (through either number of charges or size) produces a separation of molecules. Typically, electrophoresis is carried out in a sieving media made from either agar or polyacrylamide gels. Double-strand DNA is most commonly separated by gel electrophoresis. The sieving matrix slows down the migration rate of large molecules so that for a molecule of constant charge to mass ratio (such as DNA) there is a logarithmic dependence on the migration distance in the sieving matrix with respect to molecular weight. Electrophoretic separation is also used on other biological entities such as proteins, which are usually separated by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE)

where the SDS binds to the protein to create a constant charge to mass ratio on the protein surfaces.

Key Research Findings

In order to develop a fully integrated microfluidic device for biological applications, it is desirable to integrate essential biological processing functions such as cell lysis, sample purification, and genetic analysis. In addition, since integrated microfluidic devices are often made by connecting individual processing components which have to be individually controlled, the connection and control of a microfluidic network must also be developed. In this section, several examples demonstrating not only integrated microfluidic devices for biological applications but also unique control mechanisms of the network are discussed.

Belgrader et al. [4] reported the development of a personal PCR instrument by Cepheid Corporation. They demonstrated a battery-powered notebook thermal cycler for rapid multiplex real-time PCR analysis of nucleic acids in an inexpensive, portable format (Fig. 1). The instrument consists of a notebook computer, a reaction module, and integrated optics for four-color fluorescence detection. In the reaction module, several subcomponents such as heater elements and reaction chambers for PCR are included. In the optical module, an excitation block of 4 LEDs (470, 510, 540, and 574 nm) and a detection block of 4 photodiodes (520, 550, 585, and 628 nm) flanked the two bottom edges of the reaction tube. These edges served as optical windows for a series of focusing objectives, mirrors, and band-pass filters. They designed modules which could be operated together or independently. Using this system, they successfully demonstrated the detection and identification of that *Bacillus subtilis* and *Bacillus thuringensis* spores which have been used as safe biowarfare (anthrax) simulants. In addition, they characterized a single nucleotide polymorphism (SNP) for the hereditary hemochromatosis gene which is implicated in the hereditary disease hemochromatosis where a patient loses the ability to properly regulate the uptake of iron in the body. This system demonstrated how merging microelectronics with microbiology and genomics applications may result in smaller, less expensive bioinstrumentation with more flexibility, portability and functionality.

Woolley et al. [5] have successfully integrated silicon PCR reactors with glass capillary electrophoresis (CE) chips (Fig. 2). They directly connected the PCR chamber and the CE chip through a micropatterned channel filled with a hydroxyethylcelluose sieving matrix. They have shown that the PCR amplification of a β-globin target cloned in M13 took only a 15 min as well as the CE separation was completed within 120 sec, providing a total PCR-CE analysis time under 20 min. In addition, they also demonstrated that a rapid assay for genomic *Salmonella* DNA was able to be completed within 45 min, implying that challenging amplifications of diagnostically interesting targets can also be performed.

Easley et al. [6] reported a microfluidic genetic analysis system capable of accepting whole blood as a crude biological sample with the endpoint generation of a genetic profile (Fig. 3). Upon loading the sample, the glass microfluidic genetic analysis system device carries out on-chip DNA purification, PCR-based amplification, separation and detection in a sequential manner with a total process time of less than 30 min. The performance (genetic profiling) of the system was demonstrated using *Bacillus anthracis* (anthrax) presented in 750 nl of whole blood from living asymptomatic infected mice and *Bordetella pertussis* presented in 1 μl of nasal aspirate from a patient suspected of having whooping cough.

Blazej et al. [7] also reported a microfabricated bioprocessor for integrated nanoliter-scale Sanger DNA sequencing (Fig. 4). The bioprocessor is able to conduct all three Sanger sequencing steps, thermal cycling, sample purification, and capillary electrophoresis. They were able to

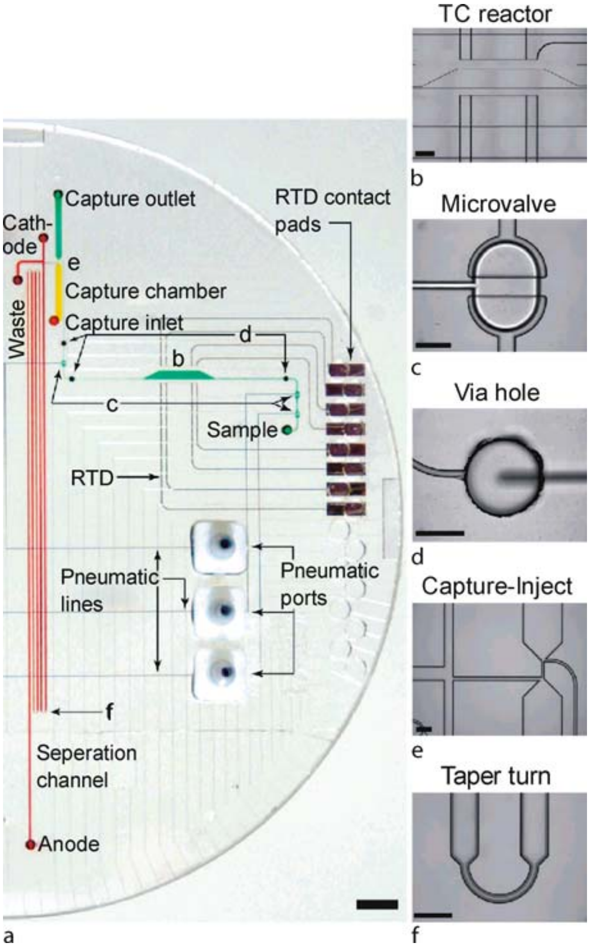
conduct complete Sanger sequencing from only 1 fmol of DNA template. In addition, they demonstrated that 556 continuous bases could be sequenced with 99% accuracy.

Lee et al. [8] reported a fully integrated microfluidic system for the DNA amplification and processing. This system integrated all essential cell processing functions from cell lysis, solution mixing, microfluidic transport (micropumping), and DNA amplification in a single system. In order to actively control each function, they integrated an electroosmotic pump, an active micromixer and an on-chip temperature control system (Fig. 5). In order to amplify the DNA of interest, the cell lysis is initially performed in a micro cell lysis reactor. The DNA samples are extracted from the cell lysis reactor, and the DNA samples, primers and reagents are driven by an electroosmotic pump into an active mixing chamber. Once a completely homogenized mixture is achieved, thermal cycling in a micro-PCR chamber to amplify the DNA fragments of interest is conducted. They demonstrated the functionality of the device using a 273 bp fragment obtained from *Streptococcus pneumoniae*, the most common cause of bacterial meningitis in adults.

Lagally et al. [9] also reported a fully integrated PCR-capillary electrophoresis microsystem for DNA analysis. The system consists of microfabricated heaters, resistance temperature detectors (RTDs), 8 parallel polymerase chain reaction (PCR) chambers, and a capillary electrophoretic (CE) DNA separation channel (Fig. 6).

In order to provide controlled and sensorless sample positioning and immobilization of the sample into the PCR chambers, valves and hydrophobic vents were used. In addition, by using microfabricated heaters and tempera-



Integrated Microdevices for Biological Applications, Figure 4 Photograph of bioprocessor components including sequencing reagents, capture gel, separation gel, and pneumatic channels. Blazej et al. Microfabricated bioprocessor for integrated nanoliter-scale Sanger DNA sequencing. Reprinted with permission from [7]

ture sensing systems, they were able to achieve a rapid heating and cooling rate ($20\,^{\circ}\mathrm{C\,s^{-1}}$) in the PCR chamber. Once the amplified PCR product was obtained, the sample was labeled with a fluorescent dye. Finally, the sample was injected into the gel-filled capillary to conduct capillary electrophoretic analysis. Throughout their demonstration, they have used human genomic DNAs as a template for multiplex PCR amplification and obtained successful multiplex amplification of sex markers from human genomic DNA in less than 15 min. This device is promising because it demonstrated an integrated analysis microprocessor for use not only in point-of-care diagnostics and sample analysis but also in forensics, where only an extremely low sample volume may be available.

One issue which affects the integration of many biologically functional components on a single chip is to control

many fluidic components in an autonomous fashion. For instance, media or sample solutions often have to be transported into a designated area to allow appropriate reactions to occur. Thus, many research groups have attempted to develop methods for microfluidic network control.

Thorsen et al. [10] reported a novel method to control a complex microfluidic network. Their microfluidic network is analogous to large-scale integration (LSI) of electronic circuits on a semiconductor wafer. The microflu-

(**d**) A fluorescence image showing cells (arrows) at comparator regions. Due to the enzyme reaction between CCP-expressing E. Coli in reagent and Amplex Red, cells produce fluorescence (resorufin), while other chambers remain low fluorescence due to the absence of CCP-expressing E. Coli. Thorsen et al. Microfluidic large-scale integration. Reprinted with permission from [10]

idic network consists of microfluidic channels with thousands of pneumatically actuated microvalves and hundreds of individually addressable sample processing chambers. An essential component of this fluidic network is the microfluidic multiplexor. The microfluidic multiplexors are combinatorial arrays of binary valve patterns that increase the processing power of the network by allowing complex fluid manipulations with a minimal number of controlled inputs. Figure 7a shows an operating principle of the multiplexor. Fluidic valves were placed at the intersection of the wide part of a control channel with a flow channel. By precisely controlling actuation pressure of control lines, the wide membranes placed at the intersection of control channels and fluid channels can be fully deflected and act as valves. Thus, the processing power of the fluidic network can be exponentially increased by placing hundreds of binary valve patterns. For instance, n fluidic channels can be individually addressed with only $2 \log_2 n$ control channels. In order to demonstrate this algorithm, they designed a device containing 2056 microvalves. This device can perform distinct assays in 256 subnanoliter reaction chambers and then recover the sample of interest with only 18 required external connections. In order to demonstrate complex fluid manipulation, they filled the fluid input lines with two dyes to demonstrate the process of loading, compartmentalization, mixing, and purging of the reagents of single chamber within a column of interest (Fig. 7c). Also, they have used this device as a microfluidic comparator to test for the expression of a particular enzyme. In their test, *Escherichia coli* expressing recombinant cytochrome c peroxidase (CCP), was used as a signal. In the presence of CCP, a fluorogenic substrate can be converted into a fluorescent product. In order to compare the signal generated by the enzymatic

reaction, the nonfluorescent resorufin derivative Amplex Red was used as a fluorogenic substrate. When an input signal chamber contains cells expressing the enzyme CCP, the nonfluorescent resorufin Amplex Red is converted to the fluorescent product, resorufin. Thus, the output fluorescent signal remains low in the absence of CCP. Figure 7d shows a fluorescence image of the comparator region of the chip after opening the mixing barrier located between the cell input and fluorogenic substrate input channels. Due to the enzyme reaction between the CCP-expressing *E. Coli* and Amplex Red, cells produce a fluorescence (resorufin) signal, while other chambers remain at a low fluorescence state due to the absence of CCP-expressing *E. Coli*. This result is very promising in many respects because it demonstrates how many different assays could be conducted in parallel on a single chip without contamination between samples.

Future Directions for Research

Although a variety of technologies related with microfluidic devices for biological applications are introduced here, there are still many challenges in producing these microdevices. For instance, many of these devices are still in the research phase of development and require significant personnel training for proper operation. Thus, there are significant challenges in improving the user input and operation for less stringent training requirements to make the systems available to a wide variety of researchers. They also have to be proven to be superior over conventional biological laboratory technology before they will be adopted in a wide number of biology laboratories.

Integrated biochips; i-STAT; Blood analysis; Drug delivery; Biomedical microdevices

Definition

Integrated microdevices for medical diagnostics seek to create autonomous microfluidic devices capable of performing laboratory grade analyses in a rapid, portable fashion where rapid results may mean the difference between life or death such as in an ambulatory or emergency room situation, or in harsh environments where there are no proper refrigeration or storage facilities such as in the third world or developing nations without access to these facilities. Another application of such technology is in personalized medicine allowing continuous patient monitoring during surgery or continuous feedback controlled drug delivery such as insulin, analgesics for chronic pain management or chemotherapy for cancer treatment. In these examples, integrated devices for blood analyses, blood typing, vaccine, antibiotic, or insulin delivery are presented, although a wide variety of biochips performing many different laboratory functions have been produced with varying levels of integrated functionality. These techniques are fundamental components of highly integrated

Integrated Microdevices for Medical Diagnostics, Figure 1 The i-STAT Portable Clinical Analyzer [1]

medical devices allowing personalized medicine or efficient point of care medical diagnostic systems.

Overview

The development of integrated microdevices for medical diagnostics allows rapid, reproducible laboratory grade tests for applications in point of care diagnostics, continuous patient monitoring and feedback controlled drug delivery and technologies to provide medical diagnostics and treatment especially to the developing world. Since these devices are very sophisticated, they must be designed for easy operation without technical training, improve patient compliance, provide advantages in time to analysis over conventional laboratory procedures. Furthermore, these integrated diagnostic modules must be inexpensive to produce and operate and be able to withstand harsh environments without the need for refrigeration, especially when used in the developing world. Most integrated microdevices for medical diagnostics fall into one of three categories described in this article; Specimen (blood, urine, saliva, etc.) analysis devices, continuous patient monitor, or controlled drug delivery devices although some integrated devices fall into more than one of these categories.

Basic Methodology

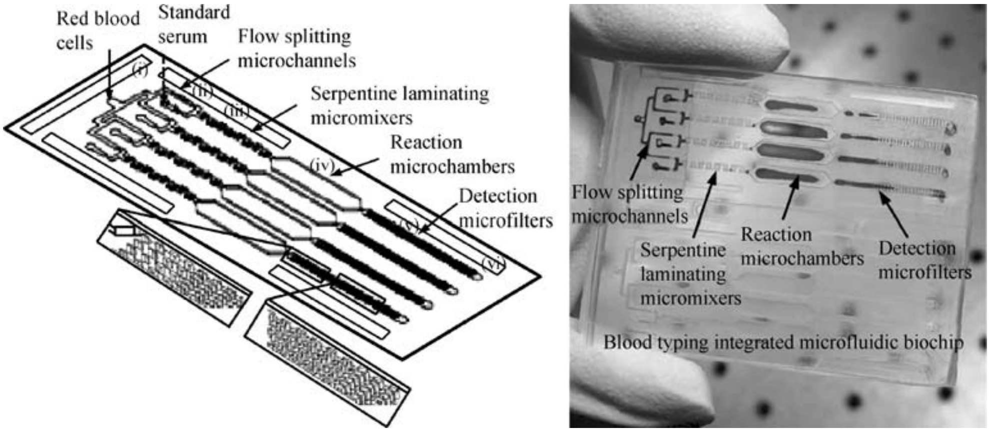
Most medical diagnostics are performed in a centralized laboratory within a hospital. A patient's specimen is collected and sent to this facility for analysis. Blood is usually collected via venipuncture with the blood drawn into color coded tubes. Urine is collected by patient excretion. Finally some specimens are collected on a cotton swab (cheek swab, cervical swab, etc.). After the specimen is collected it is analyzed in the lab facility. Blood is usually analyzed for a complete blood count (CBC) which determines the concentration of red blood cells, all types of white blood cells and platelets. A plasma chemistry panel may also be used to determine the relative amounts of different medically relevant components in the blood (i. e., sodium, potassium, chloride, magnesium, calcium, cholesterol, creatinine, urea, total protein, glucose, etc.). Urine is usually analyzed for glucose, protein, ketones and any blood within the urine, nitrite and leukocyte esterase. Urinalysis may provide clues to kidney disorders or infection. Cheek swabs are usually used for DNA genotyping of patients, while swabs from other areas such as vaginal or cervical swabs may be used to look for infection or sexually transmitted diseases.

Key Research Findings

Current Research on Integrated Microdevices for Medical Diagnostics

One of the first point of care devices developed was the i-STAT Portable Clinical Analyzer [1, 2]. This device is designed to perform laboratory grade blood analysis in an ambulatory or emergency department setting with a faster turnaround than drawing blood and waiting for laboratory results which may take up to several hours. The i-STAT uses a disposable cartridge which is inserted into an analysis unit that performs simultaneous assays of whole blood for sodium, potassium, chloride, glucose, urea nitrogen and hematocrit concentrations in less than 2 min (Fig. 1). The disposable cartridge is loaded with $\sim 65\,\mu$l of blood obtained from the patient which is transported to a parallel sensor array which performs the required tests. Sodium, Potassium, and Chloride are determined by direct ion-selective electrode potentiometry. Urea is hydrolyzed to ammonium by the enzyme urease and subsequently measured on another ion-selective electrode. Glucose is measured using standard enzyme based amperometry. The glucose is oxidized to gluconic acid and hydrogen peroxide by the enzyme glucose oxidase and the hydrogen peroxide is oxidized at a working electrode where the current generated is measured by amperometry. Finally, the blood hematocrit is determined by the blood conductivity. In correlating the results from the i-STAT device taken by non-laboratory personnel at a patient's bedside with the results from a standard centralized hospital blood analysis laboratory, the coefficient of variance between the i-STAT and central laboratory facility was less than 6.2% for all tests [1].

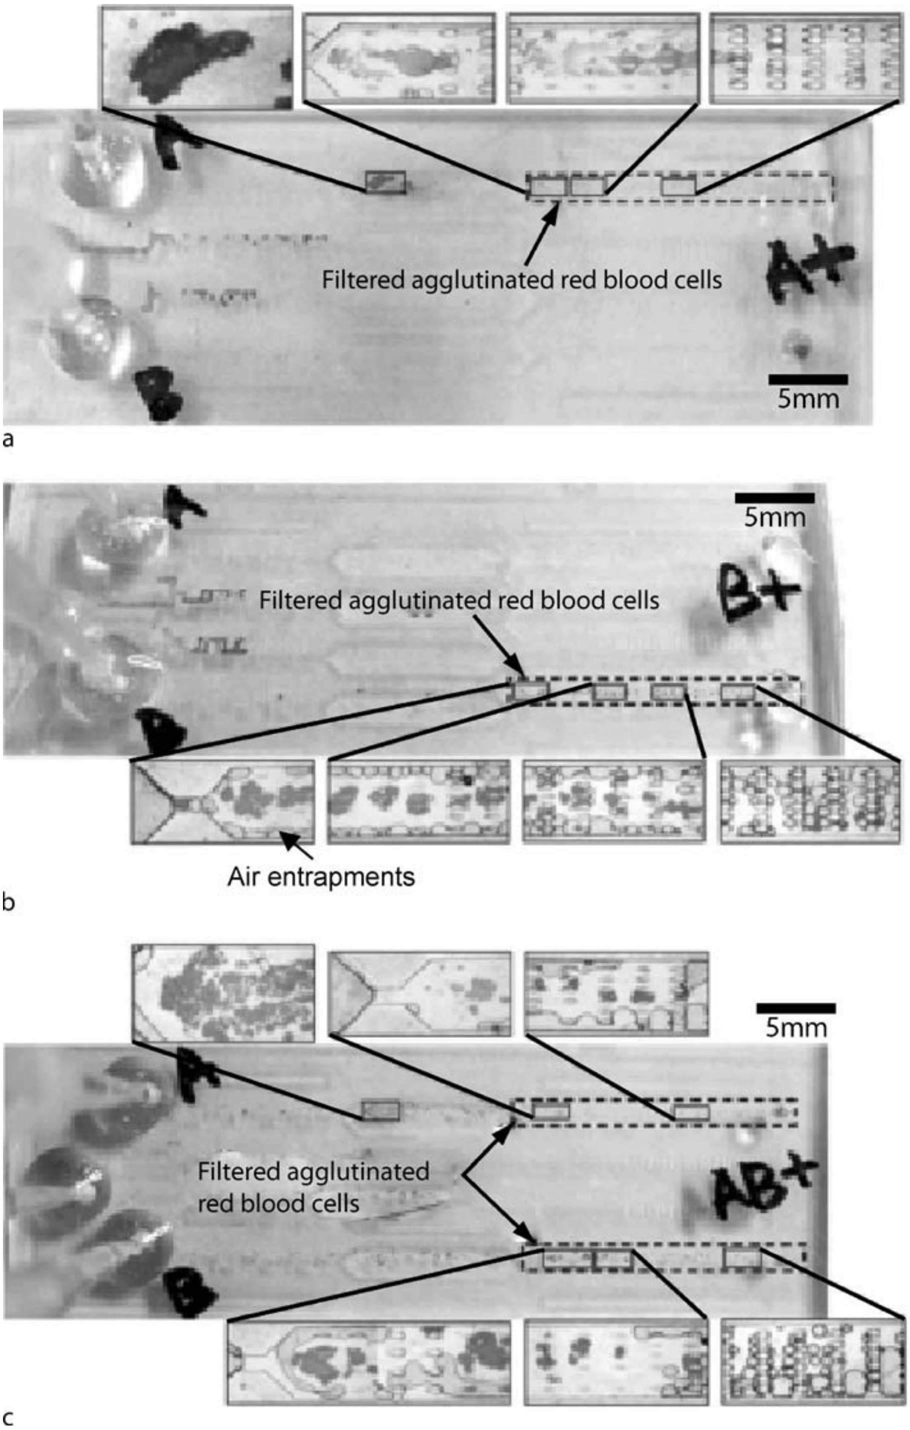
Another blood analysis device has recently been described by Ahn and colleagues [3]. Since blood typing is a critical procedure required for blood transfusions, the researchers fabricated an inexpensive disposable microdevice to rapidly determine blood type. This system is com-



Integrated Microdevices for Medical Diagnostics, Figure 2 (Left) Schematic diagram of a blood typing biochip. The device contains flow splitting microchannels, a serpentine micromixer, reaction microchambers and detection microfilters. The reaction chamber holds $\sim 3\,\mu$l of blood. The agglutinated RBCs formed by antibody-antigen reaction between the blood cells and test solution are observed in the microfilter region. (Right) A photograph of the blood typing biochip [3]

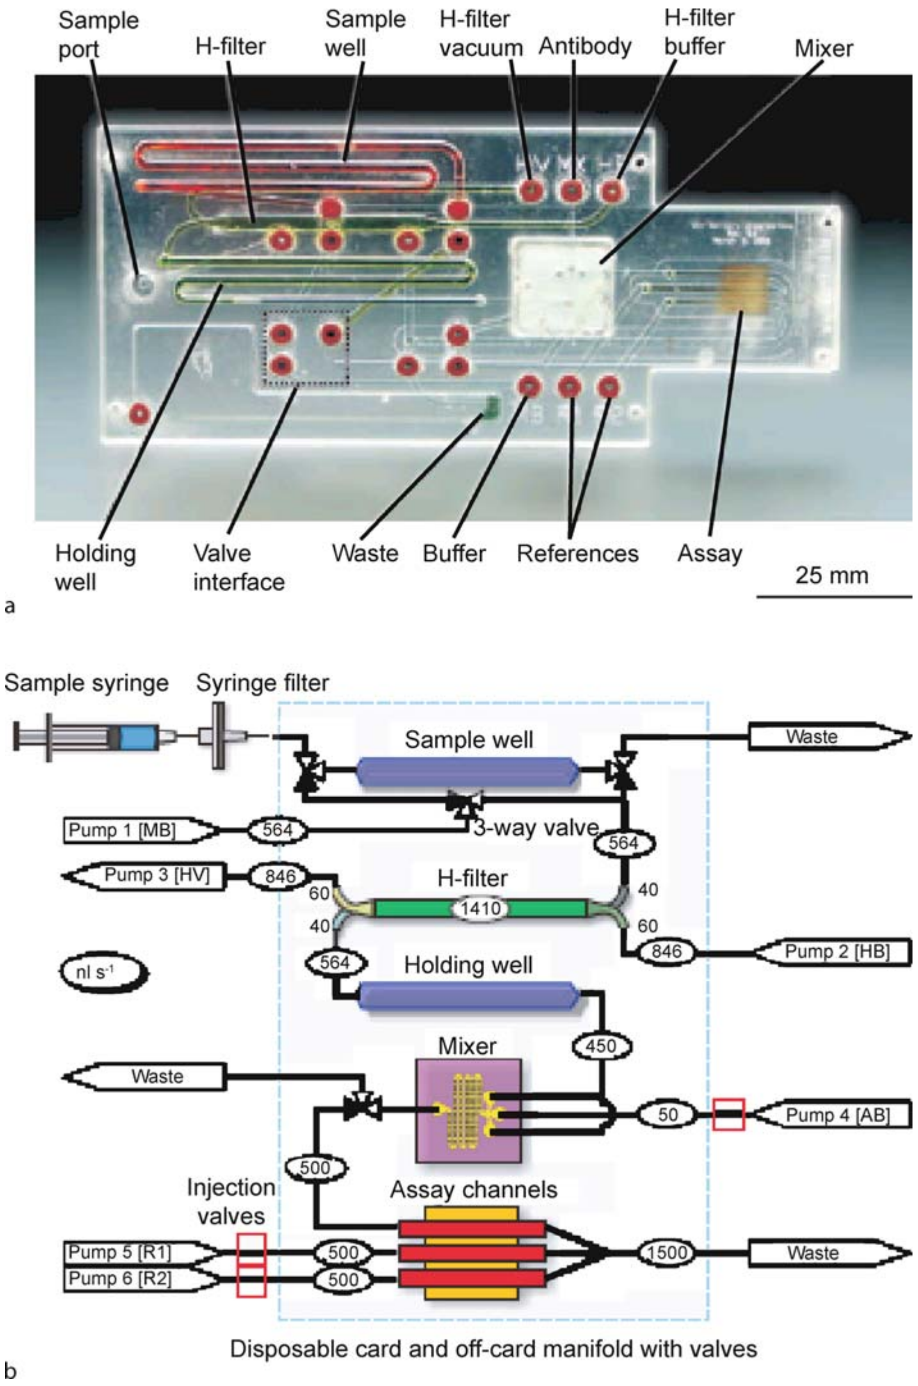
posed of integrated sample entry channels, micromixers for mixing the blood with the reaction sera, reaction microchambers and detection microfilters (Fig. 2). The blood sample is introduced and mixed with the reaction blood typing serum which contains either anti-A, anti-B or anti-AB antibodies. If the red blood cells (RBCs) express either the A or B surface antigen they will agglutinate (clump together) in the appropriate serum containing either the anti-A or anti-B antibodies. Each of these antibody/RBC reactions is performed in parallel in different microchannels/microreactors to detect whether the RBCs agglutinate to determine if they express the A, B, neither or both surface antigens. The researchers demonstrated the functionality of the device by typing blood samples which were A+, B+ and AB+ blood types by detecting RBC agglutination in two parallel microreactors with one containing an anti-A serum and the other containing the anti-B serum (Fig. 3).

There are also major research efforts to create microfluidic devices to affect global healthcare in the developing world [4]. These devices must be able to function in a wide variety of environments considering the fact that many healthcare facilities in the developing world do not have access to refrigerated storage of perishables, calibration standards and reagents, trained personnel and in some cases even stable electrical power or sterile medical supplies. Thus, the challenges for using point of care microfluidic devices for delivering healthcare to the developing world are considerable. As highlighted in [4] immunochromatographic strip tests for diphtheria toxin, or sexually transmitted diseases like HIV, gonorrhea or syphilis among others are one of the few diagnostic technologies which have been successfully used in the developing world and should be the format which microfluidic platforms should aspire to supplant. These tests are formatted for the detection of a wide variety of antigens or antibodies, are stable at ambient temperature and can be shipped and stored without refrigeration. It would also be preferable to used body fluids other than blood (which requires a sterile syringe to obtain) such as urine or saliva. An example of an integrated microfluidic diagnostic card for analyzing saliva is shown in Fig. 4. The authors highlight the use of an H-filter for sample preconditioning to separate small molecules from other contaminating components followed by a micromixer for combining the saliva with an antibody solution. An H-Filter is comprised of two converging microchannels into a single daughter channel at the inlet and a diverging channel at the filter outlet. When two fluid streams are brought together with different solution composition, material will transfer from one stream into the other by diffusion. Since small molecules (e. g., ions) have higher diffusivity than larger molecules or particles (e. g., proteins or cells) these differences in diffusivity can be used to separate molecules or particles by tailoring the residence time of the fluid streams within the H-filter. Therefore, the H-filter is seen as a way of continuously extracting molecules from one fluid stream without the need for membrane filtration. After preconditioning, the solution is then transported to a gold surface for analysis by surface plasmon resonance (SPR) based detection. SPR is an optical method which measures the refractive index of a solution within ~ 300 nm of a gold film surface. The surface plasmon is an optical wave which propagates along the metal/solution boundary. When used for biosens-



Integrated Microdevices for Medical Diagnostics, Figure 3 ABO typing results of (**a**) blood group A sample (**b**) blood group B sample and (**c**) blood group AB sample. The insets show the agglutinated RBCs [3]

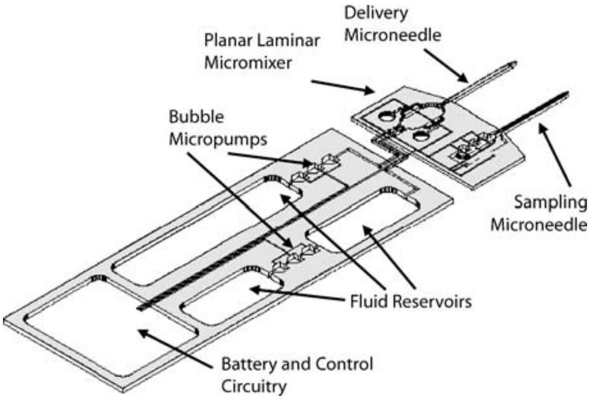
ing, SPR is sensitive to molecular adsorption to the metal surface determined by the change in refractive index at the surface. This change in refractive index can be correlated to the analyte of interest in a concentration dependant manner since the higher the analyte concentration in solution, the larger the surface adsorption and therefore the larger



Integrated Microdevices for Medical Diagnostics, Figure 4 (**a**) Image of a POC diagnostic card for saliva analysis. (**b**) Schematic of a card showing an H-filter for sample preconditioning, micromixer for introducing antibodies to the sample and gold coated surfaces for SPR immunoassay based detection [4]

the change in refractive index. Selectivity to a single analyte can be improved by preadsorbing antibodies or ligands which bind the analyte of interest.

Another approach for creating integrated microfluidic devices for medical diagnostics is to create a device for the reconstitution (hydration) of a lyophilized (freeze dried) drug solution, followed by dilution, and delivery into a patient at a constant rate. Such a system could utilize freeze dried antibiotics, analgesics, or insulin for treating a diabetic patient as described in [5]. This system,



Integrated Microdevices for Medical Diagnostics, Figure 5 Schematic of a drug reconstitution and delivery system [5]

shown schematically in Fig. 5, consists of several fluid reservoirs, micropumps for moving fluid within the device, a micromixer for sample dilution and microneedles for drug delivery. Since, diabetes accounts for a large percentage of healthcare expenses in the United States and around the world and is growing in prevalence, many of these integrated technologies are being developed to treat this disease. The individual components in development for a feedback controlled insulin delivery system for diabetes treatment is also described in [6]. This system describes the use of miniaturized microdialysis systems and insulin delivery through microneedles which are particularly well suited to allow feedback controlled insulin delivery. In particular, the use of microneedles for insulin delivery has been demonstrated [7] as well as the development of microdialysis systems for continuous glucose sensing [8]. The real advantage of using such miniaturized systems lies in the ability to obtain greater patient compliance by having miniaturized sensing systems with faster response times and greater patient sampling frequencies along with less invasive (and less painful) drug delivery. These systems will allow truly personalized medicine for closed loop patient monitoring with feedback controlled drug delivery. These devices, first designed for diabetes treatment, are expected to impact the treatment of many diseases by allowing truly continuous patient monitoring for continuous personalized medical treatment.

Another example of an integrated microfluidic device for medical diagnostics is a device under development for the continuous monitoring of a patient undergoing heart surgery, especially when cardiopulmonary bypass (CPB) is used. The systemic inflammatory response in patients undergoing CPB is significantly affected by the artificial cardiopulmonary bypass pump and associated equipment (tubing, blood oxygenator, arterial filter, etc.). This inflammation may lead to significant postoperative complications including vital organ dysfunction while the symptoms may not present until several hours or days post surgery. Currently, there is no effective medical intervention for preventing or even studying this inflammatory response in real time. Real time monitoring of inflammation markers will help surgeons understand how CPB and surgical procedures may be modified to prevent the inflammatory response. Furthermore, it would allow surgeons and clinicians to take appropriate clinical action to the inflammatory responses earlier to avoid some of the severe postoperative complications. The system described in [9] presents a integrated microdevice designed to effectively separate blood cells from plasma and to analyze the inflammation markers (cytokines, complements, etc.) in the blood plasma in real time, while the surgery is proceeding, so that medical intervention can be taken to severe inflammation. The system described combines a continuous flow plasma separation module with an immunoassay module. The plasma separation module is driven by the pressure generated by CPB pumphead which drives the circulation during the surgery, while the device is connected to an arterial port off of the membrane oxygenator. The device is able to continuously skim plasma off from the blood sample by having a well defined flow structure which does not allow cells to enter the plasma channels. Next, the immunosensing function is accomplished by creating a well defined flow structure which uses a fluorescent activated cell sorting (FACS) mechanism for processing cytometric immunosensing beads. The microdevice is designed to allow individual serial bead processing steps to occur. In the case demonstrated in [9], a strepavidin coated bead is introduced into the device, and transported into a biotin-FITC fluorescent solution. The strepavidin on the bead binds the biotin in solution. The flow structure is designed in such a way to allow the bead to cross over from the bead carrier solution into the biotin solution without mixing and dilution of the biotin concentration. Next, the bead is ejected from the biotin solution into a washing solution where the background florescence is removed. The bead then moves into a detection window where the fluorescence intensity of the bead is detected. Since the fluorescence intensity on the bead is proportional to the biotin concentration in solution and the beads are continuously injected into the solution, this system is able to track changes in the biotin concentration over time. Further research is being conducted to allow real time immunosensing using a similar mechanism.

A final concern in the creation of integrated devices for medical diagnostics is the ability to integrate light sources for fluorescence based detection techniques. One popular area of research to miniaturize detection methods for

point of care devices is through the integration of organic light emitting diodes (OLEDs) with microfluidics. This is an attractive approach to integrated detection due to the small footprint of OLEDs, ability to multiplex and parallelize detectors, lower cost compared to solid state LEDs and ease of integration with microfluidic channels. Yao et al. [10] describe the integration of a green OLED as a fluorescence excitation source with microfluidic channels and the ability to detect 35 fmol (50 μM) of Rhodamine 6G and 1.4 fmol (2 μM) of Alexa 532 dyes in a volume of 0.7 nl. The OLED was fabricated as a p-n diode from layers of 40 nm thick α-napthylphenylbiphenyl (NPB) and 60 nm thick tris(8-hydroxyquinoline) aluminum (Alq_3) sandwiched between anode and cathode conductive layers. On top of the OLED an interference filter pinhole layer and microfluidic channel were layered. The pinhole layer was used to aligning the green light with the microfluidic structure. The emission light was collected by a fiberoptic detector coupled to a photomultiplier tube. This device was also used to detect bovine serum albumin conjugates labeled with the Alexa 532 dye during a capillary electrophoresis experiment.

Future Directions for Research

Although a variety of technologies related with microfluidic devices for medical diagnostics are introduced here, there are still many challenges to producing microdevices for medical diagnostics. For instance, with the exception of the i-STAT system many of these devices are still in the research phase of development and will require significant clinical trials and Food and Drug Administration approval before they can be used in a clinical environment. In addition, there are still many challenges in integrating fluorescence detectors into point of care diagnostics. They also have to be proven to be superior over conventional laboratory diagnostics. These challenges implies that there still needs to be substantial improvement in the further development of these medical diagnostic microsystems for truly realizing the promise of personalized medical platforms for patient point of care diagnostics.

Inter-Atomic Potential

Definition

Chemical energy associated with the interaction between any two atoms. The potential gives rise to a force that can be repulsive or attractive and is usually dependent on the distance between the two atoms.

Interdigitated Microelectrode

Definition

Interdigitated microelectrodes (IME) or Interdigitated microelectrode array (IDA) are microelectrodes that each sensor element consists of a pair of opposing metal electrodes of digit width and separation that may be equal or unequal in the range 100 nm to 10 μ. These electrodes are usually microlithographically fabricated on silicon or glass substrates. They may be accompanied by a large area counter electrode of area 100 to 1000 times that of the area of each region of interdigitation. A reference electrode of silver/silver chloride may also be included to provide the reference potential for the electrochemical measurement. Such microelectrodes are well suited for electrical/electrochemical impedance spectroscopy, and have been widely used in impedimetric biosensing for DNA, enzymes, proteins, and cells.

Interface Capturing Schemes for Free-Surface Flows

ALI NADIM
School of Mathematical Sciences, Claremont Graduate University, Claremont, CA, USA
ali.nadim@cgu.edu

Synonyms

Volume of fluid (VOF) method; Level set method; Phase field method; Diffuse interface model; Interfacial flow; Free surface flow; Interface tracking; Front tracking; Front capturing

Definition

Free-surface and interfacial flows refer to two-phase or multi-phase fluid flow problems that involve two or more immiscible fluids (e. g., liquid–liquid or liquid–gas systems) separated by sharp interfaces which evolve in time. Typically, when the fluid on one side of the interface is a gas that exerts negligible shear (tangential) stress upon the interface, the latter is referred to as a *free* surface. Interface capturing schemes are methods that are able to locate the interface, not by *tracking* the interface in a Largrangian sense (e. g., by following marker points that reside on the interface), but by *capturing* the interface by keeping track, in an Eulerian sense, of the evolution of an appropriate field such as a level-set function, a volume-fraction field, a phase-indicator field or a so-called color function.

Overview

Broadly speaking, there are two computational approaches to solving fluid flow problems that include an evolving interface between two fluid phases. These can be categorized as *interface tracking* and *interface capturing*. The former refers to methods that explicitly parameterize the interface and follow the points on the surface precisely in time. Examples include boundary-integral methods for Stokes or potential flows in which, in the case of two-dimensional or axisymmetric geometries, the interface is simply a curve and is often parameterized via arclength and followed in time. Another example is the use of *markers* on an interface which are tracked in a Lagrangian sense as the interface evolves, although the underlying flow field may be solved on a fixed Eulerian grid. The other approach, which is the subject of the present contribution, treats such problems by *capturing* the interface via an implicit representation. Examples include the level-set method, in which the interface is considered to be a level surface of a function that is defined over all space, and the volume-of-fluid method, in which the location of the interface is captured by keeping track of the volume fraction of each computational cell in the grid with respect to one of the fluid phases: cells that have a volume fraction of zero or unity do not contain an interface, whereas those that have a fractional value do.

In this contribution, first a number of fundamental concepts that are central to interface capturing are presented, including definitions of level-set functions and unit normal and curvature at an interface. This is followed by consideration of kinematic and dynamic boundary conditions at a sharp interface separating two immiscible fluids and various ways of incorporating those conditions into a continuum, whole-domain formulation of the equations of motion. Next, the volume-of-fluid (VOF) and level-set methods are presented, followed by a brief outlook on future directions of research and other interface capturing/tracking methods such as the diffuse interface model and front tracking.

Basic Methodology

In this section, we begin by reviewing the implicit representation of an interface as the level surface of a function defined over all space, together with appropriate definitions of the unit normal vector and the curvature at that interface. We then present a key result from vector calculus that is needed in deriving the proper boundary conditions at an interface. This sets the stage for the formulation of two-phase flow problems including the governing equations and boundary conditions, as well as a whole-domain formulation that combines the two.

Level-Set Functions

The set of points that reside on a two-dimensional interface in three-dimensional space can, at times, be given explicitly in a certain convenient coordinate system, e. g., $z = z(x, y)$ in a Cartesian system or $r = r(\theta, \phi)$ in spherical coordinates. However, such a description is not always practical. For instance, describing a spherical surface of radius a in a Cartesian system would require a multi-valued function: $z = \pm(a^2 - x^2 - y^2)^{1/2}$. The more general way of describing such an interface is as the set of points on which a function $\phi(x, y, z)$ is a constant, that is, as the constant-level set of the function. This function is not unique; for instance, the above sphere can be represented by $x^2 + y^2 + z^2 = a^2$, or by $(x^2 + y^2 + z^2)^{1/2} - a = 0$, among others. When the interface evolves in time, we can simply add the time variable t to the argument of the function. Also, without loss of generality, one can take the constant to be zero. Thus, an evolving two-dimensional interface in three-dimensional space can be considered as the set of points which satisfy the constraint

$$\phi(\boldsymbol{x}, t) = 0 \tag{1}$$

in which $\boldsymbol{x}$ is the position vector and t is time. It is often convenient to choose functions ϕ that change sign across the interface, being negative on one side and positive on the other.

One particular such function that has been found convenient in level set applications [10, 12] is the so-called signed distance function (SDF) which is the simply the minimum distance (or the negative thereof) from any point in space to the interface, usually taken with a positive sign in the region outside a closed surface and negative inside. For a circle of radius a in 2D, the SDF would be given by $\phi(x, y) = r - a$ where $r = (x^2 + y^2)^{1/2}$. This conical surface is plotted on the left side in Fig. 1 for a circle of radius $a = 0.2$ centered at $(0.5, 0.5)$ in the (x, y)-plane. Alternatively, the same circle can also be represented in a different form as the level-curve of a phase-field function [9, 13] such as $\phi = 0.5\left[1 - \tanh((r - a)/W)\right]$, with the boundary of the circle corresponding to $\phi = 0.5$ and with the property that $\phi \to 0$ far away from the circle and $\phi \approx 1$ well inside. The parameter W controls the steepness of the hyperbolic tangent profile in the vicinity of the interface. The right panel in Fig. 1 is a plot of such a representation of the above circle.

Normal and Curvature

From elementary vector calculus, it is known that the vector $\nabla\phi$ is normal to surfaces of constant ϕ. Therefore, the unit normal to the interface, which points in the direction of increasing ϕ, can be written in the form

$$\hat{\boldsymbol{n}} = \frac{\nabla\phi}{|\nabla\phi|} \quad \text{on } \phi = 0\,. \tag{2}$$

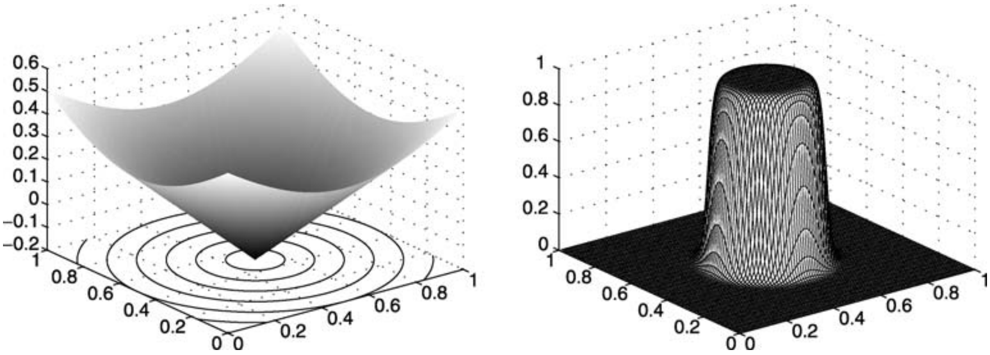
Along the interface, one can define the surface gradient operator ∇_s (cf. [8]) by projecting the usual gradient operator onto the surface using the operation $\nabla_s = (\mathbf{I} - \hat{\boldsymbol{n}}\hat{\boldsymbol{n}}) \cdot \nabla$, which removes any component parallel to $\hat{\boldsymbol{n}}$ from the gradient. Here, $\mathbf{I}$ is the unit isotropic tensor in three-dimensional space and the combination $\mathbf{I} - \hat{\boldsymbol{n}}\hat{\boldsymbol{n}} \equiv \mathbf{I}_s$, which is a surface-projection operator, can be thought of as the unit tensor in the two-dimensional surface. Strictly speaking, the unit normal $\hat{\boldsymbol{n}}$ given by (2) is only defined on the interface $\phi = 0$; therefore, one may only 'differentiate' it with respect to surface coordinates. If one adopts a locally orthogonal coordinate system on the surface with s_1 and s_2 denoting the arclengths along the two coordinate curves and with $\boldsymbol{i}_1$ and $\boldsymbol{i}_2$ unit vectors along the two directions, the surface gradient of $\hat{\boldsymbol{n}}$ (referred to as the curvature tensor) can be written as

$$\nabla_s\hat{\boldsymbol{n}} = \left(\boldsymbol{i}_1\frac{\partial}{\partial s_1} + \boldsymbol{i}_2\frac{\partial}{\partial s_2}\right)\hat{\boldsymbol{n}} = \frac{\boldsymbol{i}_1\boldsymbol{i}_1}{R_1} + \frac{\boldsymbol{i}_2\boldsymbol{i}_2}{R_2}\,, \tag{3}$$

in which it is recognized that $\partial\hat{\boldsymbol{n}}/\partial s_k = \boldsymbol{i}_k/R_k$ $(k = 1, 2)$, with R_k the radius of curvature of the coordinate curve. Upon taking the trace of the above tensor one finds that the surface divergence of the normal is exactly equal to twice the mean curvature of the interface:

$$\kappa = \nabla_s \cdot \hat{\boldsymbol{n}} = \mathbf{I}_s : \nabla_s\hat{\boldsymbol{n}} = \frac{1}{R_1} + \frac{1}{R_2}\,, \tag{4}$$

providing a convenient starting point for computing the mean curvature of any curved surface. More generally, if one defines an *extension* of $\hat{\boldsymbol{n}}$ which is identical to $\hat{\boldsymbol{n}}$ on the interface itself, is well-defined in the immediate neighborhood of the surface, and is a *unit*-vector throughout that



Interface Capturing Schemes for Free-Surface Flows, Figure 1 A circle represented by a signed distance function (left panel) and with a phase field function (right panel)

region, the mean curvature can also be calculated by taking the regular divergence of the extended vector field $\hat{\boldsymbol{n}}$ and evaluating the result at the surface. Namely,

$$\nabla_{\mathrm{S}} \cdot \hat{\boldsymbol{n}} = (\nabla - \hat{\boldsymbol{n}}\hat{\boldsymbol{n}} \cdot \nabla) \cdot \hat{\boldsymbol{n}} = \nabla \cdot \hat{\boldsymbol{n}}\,, \tag{5}$$

as long as $\hat{\boldsymbol{n}} \cdot \hat{\boldsymbol{n}} = 1$ everywhere for the extended field. Generally, the function $\phi(\boldsymbol{x}, t)$ is well-defined away from the interface as well, being negative on one side and positive on the other, and exactly zero on the surface. Thus, expression (2) (prior to evaluation on $\phi = 0$) defines a vector field which coincides with the normal on the surface and is normalized throughout the domain. Hence, the curvature of the surface can be calculated using the convenient formula

$$\kappa = \nabla \cdot \left(\frac{\nabla \phi}{|\nabla \phi|} \right) = \frac{\nabla^2 \phi - \hat{\boldsymbol{n}}\hat{\boldsymbol{n}} : \nabla\nabla\phi}{|\nabla \phi|}\,, \tag{6}$$

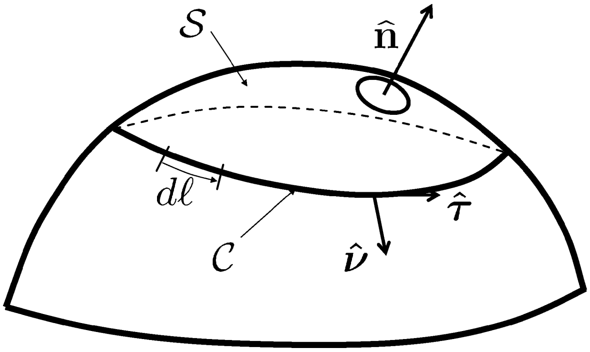
provided that the final result is evaluated on $\phi = 0$.

Surface Divergence Theorem

An important vector identity which is useful in deriving the dynamic boundary condition at a fluid–fluid interface is the two-dimensional generalization of the three-dimensional Gauss divergence theorem. The equivalent result for a curved two-dimensional surface S (see Fig. 2) must have the integral over the bounding curve C on its right-hand side, with the unit normal *to the curve* tangent to the surface (i.e., $\hat{\boldsymbol{\nu}}$ in Fig. 2) appearing therein. This surface divergence theorem can be obtained starting from the well-known Stokes curl theorem [8]. It is given in the form:

$$\int_S \left[-\hat{\boldsymbol{n}}(\nabla_{\mathrm{S}} \cdot \hat{\boldsymbol{n}}) + \nabla_{\mathrm{S}} \right] \square\, \Psi \,\mathrm{d}S = \oint_C \hat{\boldsymbol{\nu}} \square\, \Psi \,\mathrm{d}\ell\,. \tag{7}$$

Here, Ψ is an arbitrary scalar, vector or tensor field and the operation $\square$ can be a dot or cross product or a simple polyadic (tensor) multiplication. Upon noting that $\nabla_{\mathrm{S}} \cdot \mathbf{I}_{\mathrm{S}} = -(\nabla_{\mathrm{S}} \cdot \hat{\boldsymbol{n}})\hat{\boldsymbol{n}}$, the surface divergence theorem can also be written in the more compact form



Interface Capturing Schemes for Free-Surface Flows, Figure 2 Schematic of surface patch S bounded by directed curve C

$$\int_S \nabla_{\mathrm{S}} \cdot (\mathbf{I}_{\mathrm{S}} \square \Psi)\,\mathrm{d}S = \oint_C \hat{\boldsymbol{\nu}} \square\, \Psi\,\mathrm{d}\ell\,. \tag{8}$$

As an example, suppose Ψ is simply the surface tension σ which is a scalar field defined at every point of the surface. This yields

$$\oint_C \hat{\boldsymbol{\nu}}\,\sigma\,\mathrm{d}\ell = \int_S \left[\nabla_{\mathrm{S}}\sigma - \hat{\boldsymbol{n}}(\nabla_{\mathrm{S}} \cdot \hat{\boldsymbol{n}})\sigma \right] \mathrm{d}S\,, \tag{9}$$

which is used in the derivation of the normal and tangential stress balances at an interface.

Boundary Conditions at a Fluid–Fluid Interface

The kinematic boundary condition on the evolving interface described by $\phi(\boldsymbol{x}, t) = 0$ is simply that

$$\frac{\mathrm{D}\phi}{\mathrm{D}t} = \frac{\partial \phi}{\partial t} + \boldsymbol{v} \cdot \nabla \phi = 0 \tag{10}$$

with $\boldsymbol{v}$ the interface velocity field. That is, the value of ϕ remains constant (equal to zero) as seen by an observer that moves with the interface.

To derive the corresponding dynamic boundary condition, suppose that the surface patch S depicted in Fig. 2 separates two fluids (called fluid 1 and fluid 2) at some instant of time, with the unit vector $\hat{\boldsymbol{n}}$ pointing into fluid 2. The balance of forces on the surface patch S thus takes the form:

$$\int_S \hat{\boldsymbol{n}} \cdot \Pi_2 \, \mathrm{d}S + \int_S (-\hat{\boldsymbol{n}}) \cdot \Pi_1 \, \mathrm{d}S + \oint_C \hat{\boldsymbol{\nu}}\sigma \, \mathrm{d}\ell = 0 \,. \quad (11)$$

The first term is the force on the interface by bulk fluid 2, with Π_2 referring to the total stress tensor in that fluid; the second term is the force on the interface by bulk fluid 1 on the other side of interface; and the third term is the force due to surface tension σ acting along the closed contour C that bounds the surface patch. Ordinarily, the sum of such forces must be equated to the *mass* of the surface patch multiplied by its acceleration, according to Newton's second law of motion. However, since the interface S is massless, the sum of the forces is zero not just under static conditions, but also in dynamic conditions when the surface is evolving. Using Eq. (9) to convert the contour integral to a surface integral, combining all three terms in Eq. (11) under a single integral sign, and recognizing that the combined integral is zero regardless of the choice of the surface patch S, one obtains the differential form of the surface force balance:

$$\hat{\boldsymbol{n}} \cdot (\Pi_2 - \Pi_1) = -\nabla_\mathrm{s} \cdot (\mathbf{I}_\mathrm{s}\sigma) = \hat{\boldsymbol{n}}(\nabla_\mathrm{s} \cdot \hat{\boldsymbol{n}})\sigma - \nabla_\mathrm{s}\sigma \,. \quad (12)$$

If the surface tension is uniform along the interface, its surface gradient (which is responsible for Marangoni flows) vanishes and the stress balance takes the simplified form:

$$\hat{\boldsymbol{n}} \cdot (\Pi_2 - \Pi_1) = \sigma\kappa\hat{\boldsymbol{n}} \,, \quad (13)$$

with $\kappa = \nabla_\mathrm{s} \cdot \hat{\boldsymbol{n}}$ as defined earlier.

Governing Equations

The equations of motion governing the flow of a single incompressible Newtonian fluid, known as the Navier–Stokes equations, consist of the conservation of mass:

$$\nabla \cdot \boldsymbol{v} = 0 \,, \quad (14)$$

and conservation of momentum equation:

$$\rho\frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} = \rho\boldsymbol{g} + \nabla \cdot \Pi = \rho\boldsymbol{g} - \nabla p + \nabla \cdot \left[\mu(\nabla\boldsymbol{v} + \nabla\boldsymbol{v}^T)\right] , \quad (15)$$

in which $p(\boldsymbol{x}, t)$ and $\boldsymbol{v}(\boldsymbol{x}, t)$ are the pressure and velocity fields, respectively, and ρ and μ are the fluid density and viscosity, and $\boldsymbol{g}$ is the gravitational acceleration. The stress tensor Π includes contributions from pressure and viscous stresses in the form:

$$\Pi = -p\mathbf{I} + \mu(\nabla\boldsymbol{v} + \nabla\boldsymbol{v}^T) \,, \quad (16)$$

with superscript T referring to the transpose. For the case of two immiscible fluid phases separated by an interface, Eqs. (14) and (15) are written for each fluid phase with its respective density and viscosity, and kinematic and dynamic boundary conditions (10) and (11) are applied at the interface where, in addition, continuity of velocity between the two phases is assumed.

In contrast, in interface capturing methods, it has been found convenient to formulate a *whole-domain* [11] or *one-fluid* [6] model that automatically captures the appropriate conditions at the interface between the fluids. The momentum equation is this formulation can be written as

$$\rho\frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} = \rho\boldsymbol{g} + \nabla \cdot \Pi + \delta_S\nabla_\mathrm{s} \cdot \Pi_\mathrm{s} \,, \quad (17)$$

in which $\Pi_\mathrm{s} = \sigma\mathbf{I}_\mathrm{s} = \sigma(\mathbf{I} - \hat{\boldsymbol{n}}\hat{\boldsymbol{n}})$ is the surface stress tensor and δ_S is the Dirac delta function centered on the surface (more precisely, the Dirac delta function of the signed distance from the interface). The last term on the right-hand side of Eq. (17) captures surface tension effects as an effective body-force term in the momentum equation. It can be written in several equivalent forms:

$$\delta_S\,(\nabla_\mathrm{s} \cdot \Pi_\mathrm{s}) = \nabla_\mathrm{s} \cdot (\delta_S\Pi_\mathrm{s}) = \nabla \cdot (\delta_S\Pi_\mathrm{s}) = -\delta_S\sigma\hat{\boldsymbol{n}}\kappa \,, \quad (18)$$

with the last two forms yielding the continuum surface stress [11] and continuum surface force [2] models, respectively. To see that the whole-domain formulation captures the correct boundary conditions at the fluid–fluid interface, one can simply integrate Eq. (17) over the volume occupied by a so-called *pillbox* that might straddle the surface patch S in Fig. 2 (not drawn). In the limit as the thickness of the pillbox tends to zero, the contributions from the first and second term in (16) to the volume integral tend to zero, whereas the third and fourth terms in (17) reproduce the dynamic stress boundary condition (12).

The fluid density and viscosity in the whole-domain formulation are expressed as functions of a phase-indicator function χ. For instance, with $\chi = 1$ in fluid 1 and $\chi = 0$ in fluid 2, the fluid properties can be written in the forms:

$$\rho = \rho_1\,\chi + \rho_2\,(1 - \chi) \quad \text{and}$$
$$\mu = \mu_1\,\chi + \mu_2\,(1 - \chi) \,. \quad (19)$$

The phase-indicator or color function χ can be related to a level set function ϕ which changes sign across the interface. For instance, if ϕ is negative in fluid 1 and positive in fluid 2, the appropriate relation is $\chi = 1 - H(\phi)$ where H is the Heaviside step function. Note that with the help of the phase-indicator function χ, the combination $\delta_S \hat{\boldsymbol{n}}$ that appears in the continuum surface force model is given by $\delta_S \hat{\boldsymbol{n}} = -\nabla \chi$.

The phase indicator function χ satisfies the simple advection equation

$$\frac{\mathrm{D}\chi}{\mathrm{D}t} = \frac{\partial \chi}{\partial t} + \boldsymbol{v} \cdot \nabla \chi = 0\,, \tag{20}$$

as do, in consequence, the fluid density and viscosity fields.

Key Research Findings

Numerical interface capturing methods consist of various techniques for integrating the above system of conservation of mass and momentum equations, together with advection of an appropriate level set or phase-indicator function, to enable an approximate localization of the interface and proper assignation of fluid properties. We now describe two widely used methods to accomplish this: volume-of-fluid and level-set methods.

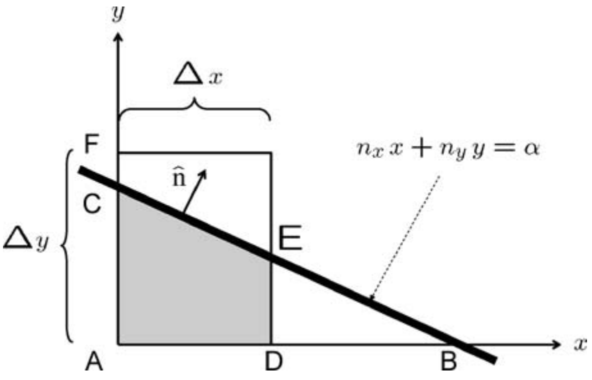
Volume-of-Fluid Method

In the volume-of-fluid (VOF) method [3, 4, 11], a discretized analog of the phase-indicator function χ is used to track or capture the location of the interface. This analog is the volume-fraction field, defined as the fraction of each computational cell that is occupied by fluid 1, say, at any given instant. For instance, in a three-dimensional grid with cell $\{i, j, k\}$ having volume V_{ijk}, the volume fraction C_{ijk} is defined by

$$C_{ijk} = \frac{1}{V_{ijk}} \int_{V_{ijk}} \chi(\boldsymbol{x}, t)\, \mathrm{d}V\,. \tag{21}$$

Thus, cells in which $C_{ijk} = 1$ are fully within fluid 1, those where $C_{ijk} = 0$ are entirely in fluid 2, whereas those having $0 < C_{ijk} < 1$ contain a portion of the interface.

The evolution of the interface and advection of the phase-indicator function is accomplished by reconstructing the interface within each computational cell and computing the volume flux that occurs from each cell to its immediate neighbors under the prevailing flow. The surface reconstruction problem [11] is one of finding an interface with the correct unit normal vector which divides the computational cell into two regions, each occupied by the respective fluid phase. One popular way to accomplish this is using the Piecewise Linear Interface Calculation or Construction (PLIC) in which a linear interface with a given normal is found in each of the cells with a fractional value of C_{ijk}.



Interface Capturing Schemes for Free-Surface Flows, Figure 3
Piecewise Linear Interface Calculation (PLIC) in two dimensions.

The two-dimensional version of this calculation (cf. [11]) can be understood by referring to Fig. 3. Suppose that the unit normal to the interface in computational cell $\{i, j\}$ in 2D has been calculated by numerical differentiation of the volume fraction field: $\hat{\boldsymbol{n}}_{ij} = -\nabla C_{ij}/|\nabla C_{ij}|$, pointing away from fluid 1. Dropping the subscript ij for convenience, with a local origin chosen at the lower left corner of the computational cell (of width Δx and height Δy, as shown in Fig. 3), the equation for the straight line representing the interface would be given by $n_x x + n_y y = \alpha$, where parameter α represents the distance from the origin (lower left corner of the computational cell) to the line. As α varies for a fixed $\hat{\boldsymbol{n}}$, a family of parallel straight lines are generated, each cutting the cell at different places and thus representing a different volume fraction value. The relation between α and the volume fraction is obtained by finding the area of the shaded region *ADEC* in Fig. 3 as a function of α. For the particular case shown in the figure, this area is the difference between the area of the triangle *ABC*, which is given by $\frac{1}{2}|AB||AC| = \frac{1}{2}(\alpha/n_x)(\alpha/n_y)$, and the area of the smaller triangle *DBE* which is 'similar' to the original triangle with area ratio $|DB|^2/|AB|^2 = (\alpha/n_x - \Delta x)^2/(\alpha/n_x)^2$. However, the smaller triangle *DBE* only exists if point B falls to the right of point D, i. e., if $\alpha/n_x > \Delta x$. The area of the shaded region is thus given by:

$$\frac{1}{2}\frac{\alpha}{n_x}\frac{\alpha}{n_y}\left[1 - H\left(\frac{\alpha}{n_x} - \Delta x\right)\left(\frac{\alpha - n_x \Delta x}{\alpha}\right)^2 - H\left(\frac{\alpha}{n_y} - \Delta y\right)\left(\frac{\alpha - n_y \Delta y}{\alpha}\right)^2\right]. \tag{22}$$

The leading term in the square brackets provides the area of the triangle ABC and the next two terms subtract the area of triangle DBE (only if point B is to the right of D) and a similar triangle that might form above the computational cell if point C happened to be above point F. The Heaviside step functions H in Eq. (22) properly account for these conditions. We thus have the expression relating parameter α to the volume fraction C_{ij}, which is the ratio of the above shaded area to the cell area $\Delta x\, \Delta y$. In practice, we need the inverse of this result. That is, given the volume fraction C_{ij} and the normal $\hat{\boldsymbol{n}}_{ij}$, we must find the parameter α_{ij} which uniquely determines the straight line. The piecewise-quadratic expression in α is relatively easy to invert. However, some logic needs to be incorporated into such calculations to account for cases when the normal vector is directed such that the shaded region surrounds one of the other cell corners. Also, in situations when one component of the normal is nearly zero and the line is nearly vertical or horizontal, care must be taken to avoid subtraction of two large numbers (triangle areas) to calculate the relatively small remainder (shaded region). Similar calculations are required in three dimensions when the interface is represented by a plane that intersects a cube.

Advection of the volume fraction field (i. e., the discretized phase-indicator or color function) is usually effected in separate steps in x and y (and z, if three-dimensional) directions [11]. In each step, one-dimensional velocities defined on cell faces or edges are used to calculate the velocity throughout the cell by linear interpolation. Translation of the points on the interface by their local velocities for one time-step leads to affine transformation of the straight line, leaving it straight but with a new unit normal vector that is easily calculated. One then calculates the fluid volumes (of fluid 1, say) that have been transported to the neighboring cells in that dimension, as well as the volume that has stayed within the current cell. By summing the appropriate volumes, updated volume fraction fields can be computed. Upon repeating this for the remaining space dimensions, provided that the overall velocity field had been divergence free, excellent volume conservation is achieved and the volume of the final deformed fluid body is in good agreement with its starting volume. Upon coupling such a volume advection scheme with standard approaches to solving the fluid flow equations, the combined VOF-PLIC method is capable of simulating complex flows in multiphase systems.

Level Set Method

The level set method [10, 12] is an interface capturing scheme in which the evolution of an interface is tracked by evolving a level set function $\phi(\boldsymbol{x}, t)$ throughout space but focusing on the location of a specific level surface (or curve in 2D) of ϕ to capture the position of the desired interface. In contexts other than two-phase fluid flow, the evolution equation for the level set function can account for advection by a specified external velocity field $\boldsymbol{v}(\boldsymbol{x}, t)$, as well as propagation of the interface in the direction of the local normal vector at a constant speed a, and the motion of the interface in the normal direction at a speed proportional to the local curvature κ with proportionality constant $-b$. The resulting evolution equation for ϕ then takes the form:

$$\frac{\partial \phi}{\partial t} + \boldsymbol{v} \cdot \nabla \phi + a\ |\nabla \phi| = b\kappa\ |\nabla \phi|\ , \tag{23}$$

where curvature κ is given by Eq. (6). This equation is usually solved numerically by treating the advection terms using various upwind Essentially Non-Oscillatory (ENO) methods or Weighted versions thereof (WENO) [10] and by discretizing the curvature term on the right-hand side with central differences, using 5-point or 9-point stencils for the Laplacian operator.

If the level set function ϕ happens to be a signed distance function (SDF), one can show that (away from possible *kinks* that occur at points that are equidistant to two or more points on the interface), ϕ satisfies the nice conditions that:

$$|\nabla \phi| = 1 \text{ and } \kappa = \nabla^2 \phi \quad (\text{if } \phi \text{ is an SDF})\,. \tag{24}$$

This simplifies Eq. (23) into the much simpler convection-diffusion form

$$\frac{\partial \phi}{\partial t} + \boldsymbol{v} \cdot \nabla \phi + a = b\nabla^2 \phi\,. \tag{25}$$

However, even if one starts with an SDF for ϕ, after each time-step of Eq. (25), the resulting level set function will not remain a signed distance function. Thus, to take advantage of the simpler form provided by Eq. (25), after every time step, one also needs to *reinitialize* the resulting level set function into an SDF. An efficient procedure for doing so is based on the Fast Marching Method [12] in which, starting with the grid points in the immediate neighborhood of the interface, the level set function in a narrow band of cells near the interface is updated to become a signed distance and this is propagated out until an SDF is established throughout the desired computational domain. Another popular method is to solve a so-called re-initialization equation in pseudotime τ to relax the given level set function into an SDF. The re-initialization equation has the form:

$$\frac{\partial \phi}{\partial \tau} = S(\phi)\big(1 - |\nabla \phi|\big)\,, \tag{26}$$

where $S(\phi)$ is the sign function or an approximate or smeared version thereof [10].

In the context of fluid flow, the Navier–Stokes Eqs. (14) and (17) are integrated numerically, together with the advection equation $\mathrm{D}\phi/\mathrm{D}t = 0$ for the level set function (i. e., Eq. (24) or (25) with $a = 0$ and $b = 0$) and the re-initialization Eq. (26) is applied periodically or at every time step to keep the level set function well behaved. While this is more straightforward that the procedures involved in the volume-of-fluid method, it has been found that the VOF method has better mass conservation properties that the simple level set method.

Recent work has therefore focused on modifying the level set method appropriately in order to improve its mass (or volume) conservation properties when applied to two-phase flow. For general interface capturing using a level set function, one promising approach has been to replace the SDF function with a phase-field function ϕ that is forced to maintain a hyperbolic tangent profile near the interface [13]. This is called *sharp interface tracking* and is achieved by changing the evolution equation for ϕ to the form [13]:

$$\frac{\partial\phi}{\partial t} + \boldsymbol{v}\cdot\nabla\phi + a\,|\nabla\phi| = b\left[\nabla^2\phi + \frac{\phi(1-\phi^2)}{W^2}\right] . \quad (27)$$

The right-hand side of this equation approximates the curvature-drive motion for the case when the function ϕ is approximately possesses a hyperbolic tangent profile near the interface in the form

$$\phi = -\tanh\left(\frac{n}{\sqrt{2}\,W}\right) ,$$

with W a measure of the width or steepness of the profile and n the signed distance from the interface. Note that in this case, the interface is still a zero-level surface of ϕ but ϕ tends to ± 1 as one moves away from the interface into the two bulk regions.

For cases when one does not desire the interface to have any curvature-driven motion, the term on the right-hand side is still maintained in order to keep the sharp, hyperbolic tangent profile near the interface; however a so-called *counter term* is subtracted from the right-hand side in order to cancel the main curvature-driven flow. The resulting equation then becomes [13]:

$$\frac{\partial\phi}{\partial t} + \boldsymbol{v}\cdot\nabla\phi + a\,|\nabla\phi| = b\left[\nabla^2\phi + \frac{\phi\left(1-\phi^2\right)}{W^2} - \kappa\,|\nabla\phi|\right] , \quad (28)$$

in which the very last term in the square brackets on the right-hand side cancels a main portion of the curvature-driven flow generated by the first two terms in the bracket. In this context, interface speed a is set to zero to avoid constant-speed normal propagation of the surface and coefficient b is taken to be rather small in order to provide some numerical diffusion. Optimal values of b and W are explored in [13] and are found to be approximately $b \approx \Delta x$ and $W \approx 2\Delta x$, where Δx is the grid-size in a Cartesian grid. Good volume conservation properties have been achieved by this approach.

Another promising approach for the case of two-phase fluid flow, with some similarities to the above, has been to work with a level set function ϕ that varies from zero to unity, with the interface of interest being the constant surface of level 0.5 [9]. This level set function is updated in two steps during the flow. The first step is simple advection by the underlying incompressible flow, which is numerically implemented in its conservation form:

$$\frac{\mathrm{D}\phi}{\mathrm{D}t} = \frac{\partial\phi}{\partial t} + \boldsymbol{v}\cdot\nabla\phi = \frac{\partial\phi}{\partial t} + \nabla\cdot(\boldsymbol{v}\phi) = 0 , \quad (29)$$

with the final form integrated on a staggered grid with velocities defined on cell surfaces (or edges) used to calculate the flux of function ϕ from one cell to the neighboring cell, thus keeping the overall 'amount' conserved. This is followed by a second step in which the level set function is evolved in pseudotime τ to achieve an interface of constant profile and thickness. In contrast with [13], this step is also formulated in the form of a conservation equation [9]:

$$\frac{\partial\phi}{\partial\tau} + \nabla\cdot\boldsymbol{F} = 0 , \quad (30)$$

where vector flux $\boldsymbol{F}$ is given by

$$\boldsymbol{F} = \phi(1-\phi)\hat{\boldsymbol{n}} - \varepsilon\nabla\phi . \quad (31)$$

The first term in the flux expression provides an *artificial compression* that keeps the interface profile sharp; the second term provides a small amount of viscosity that controls the final thickness of the interface. The combined equation is thus of the form:

$$\frac{\partial\phi}{\partial\tau} + \nabla\cdot\left[\phi\,(1-\phi)\,\frac{\nabla\phi}{|\nabla\phi|}\right] = \varepsilon\nabla^2\phi . \quad (32)$$

Parameter ε which characterizes the diffusion (or viscosity) is chosen in accordance with the grid size in the form $\varepsilon = 0.5(\Delta x)^{1-d}$ with $d \geq 0$ (e. g., $d = 0$ or $d = 0.1$) to obtain good convergence and conservation properties [9].

Applications

Level set and VOF methods are often applied to a number of test problems such as propagation of a curve (e. g., a cosine function) in the normal direction at a given speed, advection of a circle in a translating or rotating flow, rotation of a *slotted disk,* or curvature-driven motion of a dumbbell-shaped region [9, 13]. Actual two-phase flow problems such as rising bubbles [9], settling droplets [3, 9], drops and bubbles passing through an interface, break-up of liquid jets [11], liquid sloshing in a container, and pinch-off of drops from a nozzle [3] have also been studied. Recently, applications of interface capturing methods to microfluidic problems have also begun to appear in much of the literature on nanotechnology, micro- and nano-fluidics, sensors and actuators, emphasizing problems of micro-droplet or bubble movement in micro-channels and Lab-on-a-Chip devices.

Future Directions for Research

The aforementioned interface capturing methods are finding use in fundamental studies and numerical simulations of microfluidic devices that involve two or more fluid phases separated by sharp interfaces in which capillary effects are important. Additionally, such problems often involve movement of contact lines that occur when a fluid-fluid interface meets a solid boundary. Models are being devised to incorporate contact line dynamics in the simulations though this is a challenging issue since the usual no-slip boundary condition at a solid interface is not compatible with contact line motion (resulting in infinite stresses at the contact line) and therefore some degree of slip in the neighborhood of the contact line needs to be allowed.

There are a number of limitations in interface capturing schemes that continue to be addressed by researchers. One is the problem of so-called parasitic or spurious currents [11] which can be attributed to the interfacial regions being under-resolved. These currents can be reduced via formulations that strictly enforce energy conservation and account for exchanges of kinetic and surface energies [5]. There are also difficulties in computations at small values of surface tension when the computed objects (drops, filaments, bubbles) become very small and cannot be properly resolved on the mesh [11]. The major short-coming of the level-set method has been its difficulty in conserving mass, though recent conservative formulations [9] appear to have overcome this issue to a reasonable extent.

Other approaches that combine concepts from the volume-of-fluid and level set methods [14] are also likely to be developed further. In parallel, interface tracking methods which follow the sharp interface in a Lagrangian sense through an Eulerian grid (e. g., [15]) or use adaptive grids that fit the instantaneous shape of the interface and provide grid refinement in regions of flow that require better resolutions [7] will also be highly competitive techniques for modeling interfacial and free-surface flow problems. Finally, approaches based on diffuse interface models (both single-component and binary) [1] appear to be equally promising for simulations of multiphase flows in microfluidics.

Coupling microfluidic devices to mass spectrometers; Interfacing Lab-on-a-Chip platforms with mass spectrometers using MALDI and ESI

Definition

The ▶ mass spectrometer (MS) is an analytical tool that provides information about sample composition based on the mass-to-charge ratio (m/z). In order to analyze biological samples by MS, the relevant analytes must be driven into the gas phase, and ionized (charged). Two techniques are currently the most popular for the ionization of biological analytes are ESI (▶ Electrospray Ionization) and MALDI (Matrix-Assisted Laser Desorption/Ionization). In ESI, an electric field is applied to a solution of analyte to form a spray of charged droplets. Subsequent solvent evaporation and ion release enables analysis by MS. In MALDI, the analyte is co-crystallized with a solid matrix to form a dry spot on a surface. Under vacuum, the sample is then irradiated with a laser, which desorbs the sample from the surface and ionizes it. The developers of these so-called *soft* ionization techniques, which enabled, for the first time, the capacity to analyze large biomolecules such as proteins, were awarded the 2002 Nobel Prize in Chemistry.

I

Overview

In the last decade, mass spectrometry has emerged as one of the most powerful tools in bioanalysis. MS is commonly integrated with high performance liquid chromatography (HPLC) and other separation tools; as separations has been the most popular application for microfluidics, it is perhaps natural that interest has grown in interfacing mass spectrometry with microfluidics. While the focus of this chapter is on the microfluidics-MS interface, we note that one of the most popular applications for mass spectrometry is in the field of proteomics (the study of the complement of proteins expressed in a system), which has emerged as the next great scientific challenge in the post-genome era. Thus, many of the descriptions in this essay are viewed through the lens of proteomics; for more comprehensive information on this topic we refer the reader to other chapters of the Encyclopedia (▶ proteomics in microfluidic devices, ▶ integrated micro devices for biological applications).

Basic Methodology

Mass Spectrometers

The principle of operation of mass spectrometers is that electric and/or magnetic fields can be used to manipulate ions in space, and that their trajectory is a function of mass and charge. Ions of interest can be manipulated as a beam or trapped by confining electrodes, leading to different mass resolution and accuracy depending on the type of MS used. Although mass spectrometers have been used for approximately a century, the analysis of high molecular weight compounds has only become possible with advances in electronic instrumentation and the development of soft ionization techniques. Currently, it is possible to characterize analytes with molecular weight over 500 kDa [1].

Of special importance is the technique of tandem mass spectrometry (MS/MS), which integrates two stages of mass analysis. A particular ion of interest (called the parent or precursor ion) is selected in the first MS stage, allowed to fragment, and then analyzed further by the second MS stage. This technique has become important in proteomics, as protein sequences can be elucidated from the pattern of fragmentation. The ultimate identification of proteins requires complex database searching algorithms (e. g., SEQUEST [2]), and presents big challenges for data analysis (► mass spectrometry).

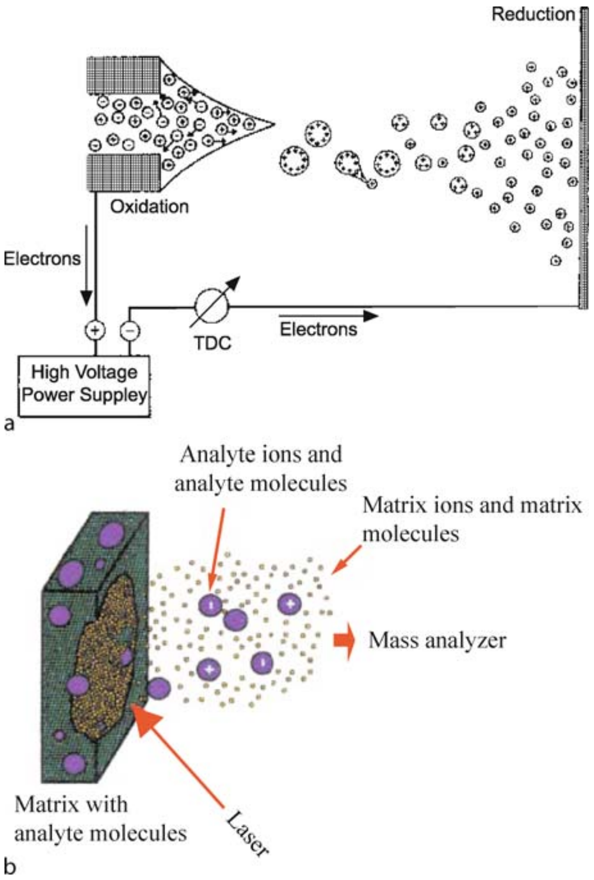
Ionization Methods

Several methods can be used to ionize samples, enabling the analysis by mass spectrometry. Two *soft* ionization methods are currently the most popular, ESI and MALDI. In ESI [3], an electric field is used to generate an aerosol of charged droplets from the end, or *tip*, of a fluid-filled tube. A schematic depicting the ESI process [4] is shown in Fig. 1a. The applied field leads to accumulation of charge close to the edge of the ESI tip. When the forces generated by charge repulsion overcome those associated with surface tension, the meniscus of the liquid assumes a conical shape, called a Taylor cone. When working properly, the shape of the cone is well defined, and results in a spray of droplets leading to the spectrometer.

After spraying, each charged droplet shrinks due to solvent evaporation. As the forces driven by coulombic repulsion and surface tension become similar, the surface-charged liquid droplet becomes unstable and disintegrates. This phenomenon is called coulombic fission, and can be predicted by the Rayleigh stability limit [3] As the droplets reduce to nanoliter volumes after successive bursts of fission, charged analytes are released into the gas phase. Two mechanisms have been proposed to explain this process: solvent evaporation from droplets containing just one ion; and direct release of ionized samples from droplets. As microfluidic devices handle volumes of liquids in the order of nanoliters, integrating microchannels with ESI requires dedicated nozzles (called nanoelectrospray, or nanospray, tips) capable of spraying minute volumes. The principles that apply for the stability of nanospray tips are the same as for conventional ESI.

A second popular soft ionization method is MALDI. In this technique, analytes are co-crystallized with a matrix (typically a small, acidic, organic molecule), with an absorption maximum close to the wavelength of a laser used to irradiate the substrate. This process is typically performed in vacuum (although it has been shown to be feasible at atmospheric pressure); after the analytes have been desorbed and ionized (in MALDI, fast heating caused by the laser pulse desorbs analytes into gas phase; however, the process by which proteins become charged is still a topic of study), they are guided to the MS for analysis [5] (Fig. 1b).

ESI and MALDI have distinct advantages and disadvantages, such that they are complementary for many applications. Of the two techniques, ESI is the softer one, allowing for ionization of intact multi-molecule complexes; however, in the presence of high concentrations of salts or other unwanted constituents, the formation of ions can be suppressed (making analysis impossible). This effect is less pronounced in MALDI, which can produce ionized products even in the presence of salts; but MALDI spectra



Interfaces between Microfluidics and Mass Spectrometry, Figure 1 Schematic depictions of (**a**) ESI and (**b**) MALDI mass spectrometry. In (**a**), the electric field causes an accumulation of positive charges at the liquid meniscus. When coulombic repulsion forces overcome the forces associated with surface tension, a spray is formed. Additional mechanisms (see text) lead to the release of analytes from the droplets. In (**b**), analytes are co-crystallized with a matrix which has an absorption maximum near the wavelength of the laser used to desorb the analytes for analysis by MS. Reproduced by permission of Annual Reviews [5]

tend to be very noisy in the mass range below 500 daltons (Da), due to the presence of matrix ions. MALDI usually generates singly charged analytes, making data analysis trivial; ESI generates many differently charged species for each analyte, which makes interpretation of spectra more challenging, as complex mixtures lead to spectra with hundreds of peaks. Finally, in MALDI, the intensity of the signal associated with a particular analyte is not easily related to the amount of sample; this contrasts with ESI, where the intensity of the signal increases linearly with the analyte concentration over a wide range.

ESI and MALDI are considered to be the most appropriate candidates for coupling microfluidic devices to mass spectrometry. In what follows, we present a survey of the different kinds of microfluidic-MS interfaces reported in the literature and discuss the most promising geometries.

Key Research Findings

Electrospray Ionization

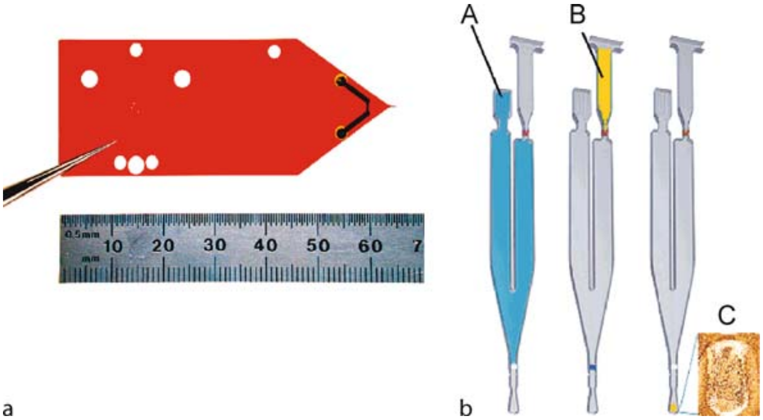
A variety of strategies for integrating microfluidic devices with nanoelectrospray ionization have been reported. Proteomic sample solutions are pumped through microchannels pneumatically or by electroosmotic flow (EOF) at $\sim 100 - 300\,\mathrm{nL/min}$; samples are typically dissolved in low-pH buffers modified with organic solvents suitable for positive mode mass spectrometry, with detection limits in the fmol-amol range. These methods can be broadly classified by how the electrospray is generated, including: direct spray from channels [6]; spray from mated, conventional tips [7]; and (3) spray from microfabricated tips [8–12].

The simplest approach for interfacing microchannels with mass spectrometry is to electrospray directly from a channel (i. e., the unmodified edge of a device). As reported by Xue et al. [6] the first microchannel-ESI interface exhibited limited performance due to eluent spreading at the edge of the chip resulting from the non-tapered geometry and the hydrophilicity of the substrate. Others improved the method by mechanically tapering the edge of substrates and by integrating hydrophobic coatings on the edges of the devices. However, these methods do not match the performance of conventional nanospray tips, and the strategy of spraying directly from channels has been largely abandoned.

A second strategy for interfacing microchannels with mass spectrometry is the coupling of microfluidic devices to conventional pulled glass capillary tips. These devices are capable of efficiently sampling analytes into the spectrometer, generating mass spectra with sensitivities similar to those of conventional techniques. For example, Lazar et al. [7] reported sub-attomole detection of peptides using a glass microfluidic device mated to a conventional electrospray tip. A major drawback for this strategy, however, is in separation resolution: bands of analytes mix as they pass through dead volumes in the interface between chip and capillary. As a result, this device geometry is not likely to be useful for most applications.

Reprinted with permission from Kameoka et al. [10]

A third strategy for microfluidic-nanospray interfaces, microfabricated, tapered electrospray tips [8–12] is the most promising that has been reported. In fact, several devices with this configuration are now available commercially (for example, from Advion Biosciences and Agilent Laboratories). Several authors have fabricated devices capable of sustaining a stable spray with no dead volume between the channel and tip. For example, Fig. 2a shows a micro-milled electrospray nozzle in poly(methyl



Interfaces between Microfluidics and Mass Spectrometry, Figure 3 Two commercial microfluidics-MS interfaces: (**a**) a polyimide microchannel device with integrated ESI tip formed by laser ablation. methacrylate) (PMMA) fabricated by Schilling et al. [8] The performance of the spray is dependent on the nozzle diameter and apex angle. Large diameter nozzles (100 μm) have to be coated with fluorinated polymer to prevent liquid spreading, and performance depends on the state of the coating. The best performing tip geometry had a 30 μm wide nozzle with a 60° angle, with no coating; this device was capable of generating a stable spray for several hours. Xie et al. [9] used vapor-deposited parylene-C to fabricate ESI tips on silicon microfluidic devices, enabling integrated liquid chromatography with mass spectrometry detection with comparable performance to conventional techniques. The drawback for these devices is the complexity involved in their fabrication, requiring many sequential photolithography steps in a cleanroom. However, parylene is a material with high chemical resistance, and may be a useful choice for the construction of nanospray tips in future work. For example, Kameoka et al. [10] constructed a nanospray tip comprising a parylene film sandwiched between two plastic plates (Fig. 2b). This device is relatively easy to fabricate, and demonstrates that a 3D hydrophobic nozzle is not required; a stable spray of bioanalytes can be obtained by using a planar, triangular parylene tip.

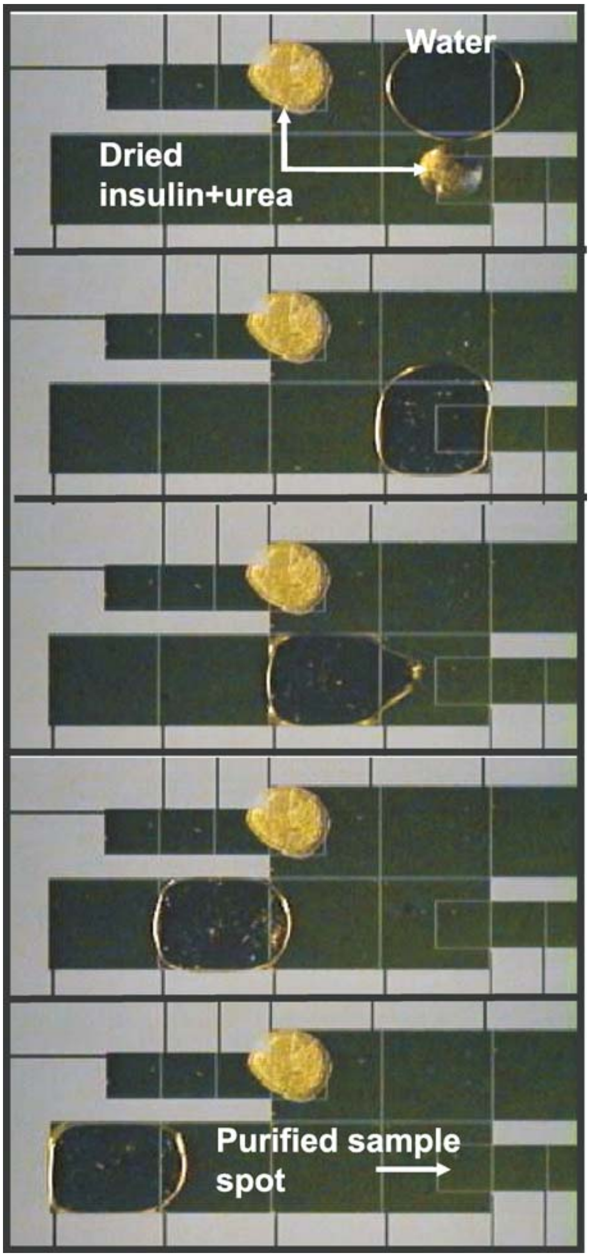
The most promising microfabricated ESI interface may be the one developed by Yin et al. [11], which features a nanospray tip formed by laser ablation (355 nm) of a polyimide substrate (Fig. 3a). The fabrication required to form these tips is relatively simple, and the devices integrate separation and sample enrichment modules which lead to mass spectrometry analysis with peak resolution, limits of detection and signal-to-noise ratio (S/N) similar to those obtained by conventional macro-scale methods. Complex protein mixtures from blood plasma were characterized using this platform [12], with a detection limit in the low femtomole range; this device is now commercially available (Agilent Laboratories).

MALDI

MALDI is an alternative to ESI for an interface between microfluidic platforms and MS. The geometry of MALDI detection targets features arrays of crystallized sample spots on an open surface, and the process is (in general) performed under vacuum. Thus, MALDI is not an obvious match for interfacing with microfluidics; despite this, several interfaces with microfluidics have recently been developed.

Enclosed microchannels are by definition not accessible to laser desorption/ionization, which requires an open surface from which analytes can be sampled into the spectrometer. Several strategies have been adopted to circumvent this challenge, including the elution of bands of analytes from microfluidic devices onto an open substrate, where they are dried and analyzed. Alternatively, Brivio et al. [13] developed means to desorb analytes directly from enclosed channels through sub-micron pores in the device cover. Musyimi et al. [14] employed a rotating ball to transfer analytes from polymer microchannels to a MALDI-MS system without compromising the vacuum required for mass spectrometry.

In one of the most complete microfluidic systems developed for mass spectrometry applications to-date, Gustafsson et al. [15] developed a MALDI interface for compact disk (CD)-based microfluidics, a technology in which reactions and separations are powered by centrifugal forces on a spinning device (CD Lab-on-a-Chip). Fig. 3b demonstrates the operation of an individual analysis region (each CD contains 96 such regions). The sample



Interfaces between Microfluidics and Mass Spectrometry, Figure 4 Video sequence (top-to-bottom) depicting digital microfluidics-based analysis of a sample containing insulin and urea. The large electrodes are used to move a water droplet to the dried spot, where it selectively dissolves the urea. Because the rinsing droplet primarily touches clean surfaces on the surrounding electrodes, it is easily moved away, leaving behind an (invisible) insulin film, ready for analysis by MALDI-MS. Reproduced by permission of [20]

is loaded (A), and then washed and eluted from a reversed-phase column (B). Finally, the sample is co-crystallized with a MALDI matrix (C) for analysis by mass spectrometry. In proof-of-principle experiments, the CD technology enabled the identification of tryptic digests with higher certainty than in identical analyses using conventional techniques (i. e., steel MALDI target), with better sequence coverage, and the same resolution and mass accuracy. This platform is now commercially available.

Future Directions for Research

Two factors favor the use of nanoelectrospray ionization for coupling microfluidic devices to mass spectrometers. The first is the similarity between the conventional pulled-glass capillary tips and the nanospray nozzles developed for microdevices discussed in the previous section; the second springs from the linear geometry of microfluidic channels. Thus, we believe that nanospray ionization techniques are the most likely to be used for the construction of robust interfaces between microfluidics and mass spectrometry for most applications in the future [16].

Despite the assessment above, we can't help but imagine that MALDI will continue to be an important tool used with Lab-on-a-Chip devices, given how amenable it is to high-throughput analysis (i. e., probing densely packed arrays of sample spots). The solutions that have been developed for interfacing MALDI-MS with enclosed microchannels (described above) are ingenious; however, such solutions are probably not practical for widespread use. Several alternative solutions have recently emerged that are not *microfluidics* per se, but may be a better match for MALDI-MS. For example, some authors have demonstrated the construction of arrays of patterned hydrophobic regions [17] or the use of piezoelectric pipets to dispense nanoliter amounts of liquid in silicon etched wells [18] Others have used electrospray to deposit homogeneous protein spots directly on MALDI targets; using this approach, Wang et al. [19] characterized 3.5 fmol of Angiotensin by mass spectrometry.

Digital microfluidics (DMF) is a related technique in which droplets are moved on a substrate by means of electrowetting and/or dielectrophoretic forces (► digital microfluidics, ► applications based on electrowetting). DMF been used to process proteomic samples and form arrays of spots for analysis by MALDI-MS [20]. As shown in Fig. 4, the technique has been used to perform in situ sample cleanup on an open substrate, after which, samples were interrogated by MALDI-MS, with similar detection efficiencies, resolution, and S/N as conventional techniques. DMF may enable the processing of several analytes at the same time, and is thus a promising tool for implementing high-throughput profiling proteomics using MALDI-MS.

The trend towards laboratory miniaturization is leading to the necessity of robust and reliable interfaces between MS and microfluidics. Although general tools for wide-

spread use are not yet available, it is clear that technologies are becoming more effective and reproducible. (see Freire and Wheeler [16] for a review). Of paramount importance in future work will be functional characterization of the devices when in contact with complex proteomic samples, evaluating, among other things, undesirable non-specific adhesion, long term operation, and the capacity to deliver the analytes of interest to the MS for analysis. In particular, the latter requires an efficient release of sample from MALDI targets or ionization when sprayed from a liquid containing salts, impurities and large abundance proteins that may conceal the desired signal.

Definition

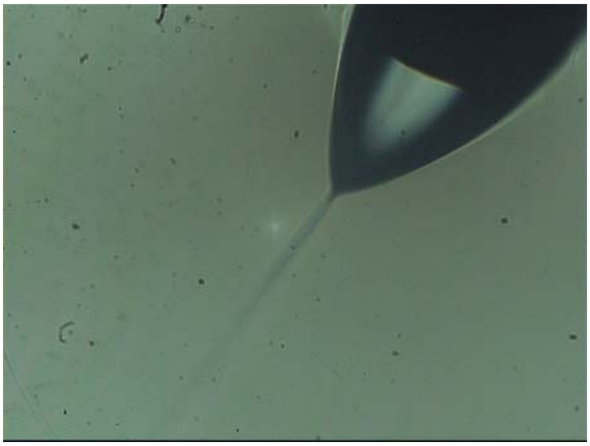
The term interfacial electrokinetic flow here encompasses all electrokinetically driven flows involving free-surfaces or freely deforming boundaries, i. e., gas–liquid interfaces or immiscible liquid–liquid interfaces.

Overview

Free surfaces are commonly encountered in many microfluidic applications. One class of free surface microfluidic applications involves individual or discrete drops and sprays, the former being termed *digital microfluidics*. Another class of free surface microfluidic applications is that which involves two-phase microchannel flows wherein either a gas bubble or stream flows within or adjacent to a liquid stream, or, a liquid phase flows within an immiscible liquid continuum (i. e., a *microemulsion*), or, a liquid stream stratifies another immiscible liquid stream. These classifications are, however, not mutually exclusive. For example, discrete drops or sprays are not just limited to open microfluidic systems, where they are exposed to an ambient environment. Often, to prevent evaporation, for example, the discrete drops are housed within an oil layer. Alternatively, a liquid spray can be encased within an immiscible liquid medium as a means for generating microemulsions.

In addition to the usual mathematical difficulties associated with free surface problems, the consideration of free surfaces becomes extremely important in microfluidics, especially given the increasing dominance of surface forces over body forces as the surface area to volume ratio increases with miniaturization. In addition, the curvature of the free surface becomes commensurate with the characteristic length scale of the system at these small scales. For example, the bubbles generated due to electrode reactions in electrokinetic microdevices can have dimensions which are on the same order as the microchannel width or height.

Electrokinetics is currently the preferred method for moving and transporting fluids in microchannels due to the ease of electrode fabrication and since electrokinetic mechanisms involve no moving mechanical parts which are prone to reliability concerns. Whilst significant progress has been achieved in understanding electrokinetic phenomena in the context of microfluidic technology, there is still a significant need to increase our fundamental understanding concerning the underlying complex hydrodynamic and physicochemical behavior associated with



Interfacial Electrokinetic Flow, Figure 1 Liquid meniscus issuing from a 100 μm capillary in DC electrospraying showing its conical shape and a thin jet that emanates from the meniscus tip. interfacial electrokinetic systems such as electrospraying or electrohydrodynamic atomization, electrospinning, electrocapillarity, electrowetting, electrokinetically-driven bubble transport and electrohydrodynamically-induced surface and bulk recirculation.

Basic Methodology

Governing Equations

For a Newtonian, incompressible fluid, the governing hydrodynamic equations are stipulated by the conservation of mass and momentum:

$$\nabla \cdot \boldsymbol{u} = 0 \,, \tag{1}$$

$$\rho \left(\boldsymbol{u}_t + \boldsymbol{u} \cdot \nabla \boldsymbol{u} \right) = \nabla \cdot \mathbf{T} \,, \tag{2}$$

where $\boldsymbol{u}$ is the velocity vector, ρ the fluid density and the subscript t denotes a time derivative. In Eq. (2),

$$\mathbf{T} = -p\mathbf{I} + \mu \left[\boldsymbol{n} \cdot \left(\nabla \boldsymbol{u} + \nabla \boldsymbol{u}^{\mathrm{T}} \right) \cdot \boldsymbol{t} \right] + \mathbf{T}_{\mathrm{M}} \,, \tag{3}$$

is the total stress tensor, comprising of the hydrostatic stress component, in which p is the fluid pressure and $\mathbf{I}$ the identity tensor, the viscous stress component, in which μ is the fluid viscosity, and, $\boldsymbol{n}$ and $\boldsymbol{t}$ the unit outward normal and tangential vectors, respectively, and, a electric (Maxwell) stress component $\mathbf{T}_{\mathrm{M}}$. In the above, the superscript T denotes the transpose of the tensor $\nabla \boldsymbol{u}$.

The coupling between the hydrodynamics and the electric field therefore arises through the Maxwell stress tensor. The total electric force density comprises the sum of the

Coulombic force arising from the presence of free charges and the dipole force arising due to the existence of bound charges:

$$f = \rho_e E + P \cdot \nabla E \,, \tag{4}$$

where ρ_e is the free space charge density, $E = -\nabla\phi$ the electric field vector and P the polarizability vector; ϕ is the electric potential. It can then be shown that for an electrically linear and isotropic medium, Eq. (4) can be expressed as [1]

$$f = \rho_e E - \frac{\varepsilon_0}{2} \nabla \left(\varepsilon - \rho \left. \frac{\partial \varepsilon}{\partial \rho} \right|_T \right) E \cdot E \,, \tag{5}$$

in which ε is the dielectric constant and ε_0 is the permittivity of free space. The second term in the parenthesis comprises a ponderomotive force term arising due to the inhomogeneity of the dielectric permeability, represented by a jump in ε, and an electrostrictive term at constant temperature T which accounts for the compressibility of the media. For incompressible fluids, electrostriction effects are negligible and hence this term can be omitted. Equation (5) can be expressed in terms of a divergence of a tensor $f = \nabla \cdot \mathbf{T}_M$, from which we obtain an expression for the Maxwell stress tensor:

$$\mathbf{T}_M = \varepsilon\varepsilon_0 EE - \frac{\varepsilon\varepsilon_0}{2} (E \cdot E) \mathbf{I} \,. \tag{6}$$

The net Maxwell stress at an interface then has the following normal and tangential components:

$$\mathbf{T}_{M_n} = n \cdot \mathbf{T}_M \cdot n \tag{7}$$

$$= \frac{1}{2} \left[\varepsilon (E \cdot n)^2 - \varepsilon (E \cdot t_1)^2 - \varepsilon (E \cdot t_2)^2 \right]_i^o \,,$$

$$\mathbf{T}_{M_t} = n \cdot \mathbf{T}_M \cdot t_i = \varepsilon \left[E \cdot n \right]_i^o (E \cdot t_i) \,, \tag{8}$$

respectively, where t_1 and t_2 are the unit vectors orthogonally tangent to the interface. The square parenthesis $[\cdot]_i^o$ denotes a jump in the inner quantity across the interface, obtained by subtracting the quantity of the inner phase i from that of the outer phase o.

In both phases, the electrostatic behavior can be described by Gauss' law:

$$\nabla \cdot E = \nabla \cdot (-\nabla\varphi) = -\nabla^2\varphi = \frac{\rho_e}{\varepsilon\varepsilon_0} \,. \tag{9}$$

In addition, the condition of electric field irrotationality also holds:

$$\nabla \times E = 0 \,. \tag{10}$$

Charge conservation also requires

$$\nabla \cdot i = \frac{\partial \rho_e}{\partial t} \,. \tag{11}$$

in which

$$i = -\sigma E - D\nabla\rho_e + \rho_e u \,, \tag{12}$$

is the current density. In Eq. (12), σ is the electrical conductivity and D is the ion diffusivity.

Boundary Conditions

A free surface or a deformable interface between two fluid phases requires that fluid particles move only tangentially along the interface. As such, if the position of the interface Γ in a Cartesian coordinate system (x, y, z) is geometrically defined by $z = h(x, y, t)$, then, given that the interface itself is a streamline, a Lagrangian description of a fluid particle as it follows the streamline can be geometrically described by the implicit function

$$F(x, y, z, t) = z - h(x, y, t) = 0 \,. \tag{13}$$

In the Eulerian reference frame, the material derivative of F, i. e., $DF/Dt = (\partial F/\partial t) + u \cdot \nabla F$ must be equal to zero, which then leads to the kinematic boundary condition [2]:

$$\frac{\partial h}{\partial t} + u_n n \cdot \nabla h = 0 \,, \tag{14}$$

where u_n is the normal velocity and $n = \nabla h / |\nabla h|$ is the outward unit vector normal to the interface.

The hydrodynamic boundary condition at the interface Γ is given by

$$n \cdot [u]_i^o = 0 \,. \tag{15}$$

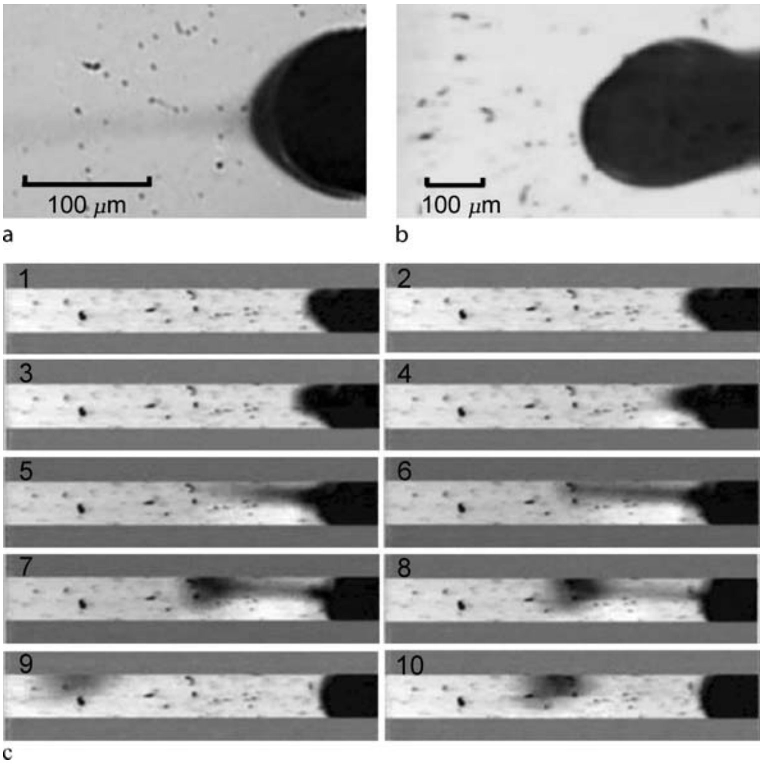
In addition, we also require continuity of shear stresses and the jump in the normal stress across the interface at Γ:

$$[n \cdot \mathbf{T} \cdot t]_i^o = 0 \,, \tag{16}$$

and

$$[n \cdot \mathbf{T} \cdot n]_i^o = \gamma\kappa \,, \tag{17}$$

where γ is the interfacial tension and $\kappa = \nabla_s \cdot n$ is twice the mean curvature of the interface in which $\nabla_s \equiv \nabla \cdot (\mathbf{I} - nn)$ is the surface gradient operator.



Interfacial Electrokinetic Flow, Figure 2 AC electrospray modes [11, 12]. (**a**) Tip streaming mechanism by which aerosol drops are periodically ejected from a resonating meniscus due to viscous-capillary forces. (**b**) Electrowetting phenomenon at high voltages which causes liquid to recede up the capillary thus suppressing drop ejection. (**c**) Sequence of images at 6000 fps showing the formation of a long slender microjet due to viscous-inertia forcing from which a drop is ejected

The remaining boundary conditions are given by the continuity of electric potential and electric stresses at the interface at Γ:

$$[\varphi]_i^o = 0\,, \tag{18}$$

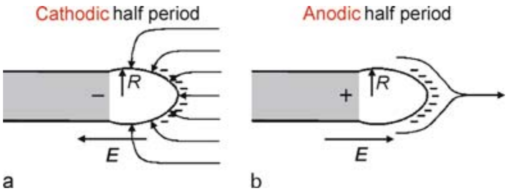
$$[\boldsymbol{E} \cdot t]_i^o = 0\,, \tag{19}$$

$$[\varepsilon \boldsymbol{E} \cdot n]_i^o = q\,, \tag{20}$$

in which q is the surface charge density at the interface Γ, which from Eq. (11), obeys

$$q_t + \boldsymbol{u} \cdot \nabla_s q = q\boldsymbol{n} \cdot (\boldsymbol{n} \cdot \nabla)\,\boldsymbol{u} - [\sigma \boldsymbol{E}]_i^o \cdot \boldsymbol{n}\,. \tag{21}$$

In the above, the subscripts i and o refer to the inner and outer phases respectively. The terms on the right of Eq. (21) represent the changes in the interfacial charge density due to surface dilation and electromigration, respectively. Also, the diffusion term has been neglected in Eq. (21), which is justifiable for sufficiently high field strengths typical in electrokinetic applications where the dimensionless field intensity $eV/k_\mathrm{B}T \gg 1$, in which e is the electron charge, V the applied potential, k_B the Boltzmann constant and T the absolute temperature [3].



Interfacial Electrokinetic Flow, Figure 3 Plasma polarization mechanism in AC electrospraying [11]. (**a**) In the cathodic half period of the AC forcing cycle, the negative plasma generated forms a thin conducting layer surrounding the meniscus. As a result, the external electric field coincides with the interface in a normal orientation. (**b**) In the anodic half period, no plasma is generated. However, because there is insufficient time for the plasma to disperse due to diffusion, the plasma layer remains, thereby screening the external electric field. Consequently, the electric field is predominantly tangential to the interface

Key Research Findings

In this section, we discuss recent developments on various interfacial electrokinetic flow phenomenon that have

potential applications in microfluidic devices. In particular, we focus on electrohydrodynamic atomization (or more commonly known as electrospraying) and electrospinning, electrokinetic bubble transport, and, electrohydrodynamically driven surface and bulk microflows. Electrocapillarity and electrowetting which are other examples of interfacial electrokinetic flows will not be discussed here; the reader is referred to the more detailed entries on electrocapillarity and electrowetting, as well as that on electrowetting applications. The reader should also consult the reviews on electrowetting by Mugele and Baret [4] and Yeo and Chang [5].

Electrospraying/Electrohydrodynamic Atomization

Electrospraying or electrohydrodynamic atomization is a mechanism for the generation of micron or nanometer dimension aerosols with the use of an applied electric stress [3]. DC electrospraying has been the subject of intense investigation over the past decade, in particular, due to its use as a soft ionization technique for the characterization of large complex and non-volatile biomolecules such as proteins and DNA in mass spectrometry. This technique is now known widely as electrospray ionization mass spectrometry or ESI-MS [6]. A balance between the Maxwell stress in Eq. (6) and the capillary stress gives an estimate of the critical voltage V_c required for electrospraying:

$$V_c \sim \sqrt{\frac{\gamma d^2}{\varepsilon \varepsilon_0 R}}\,, \qquad (22)$$

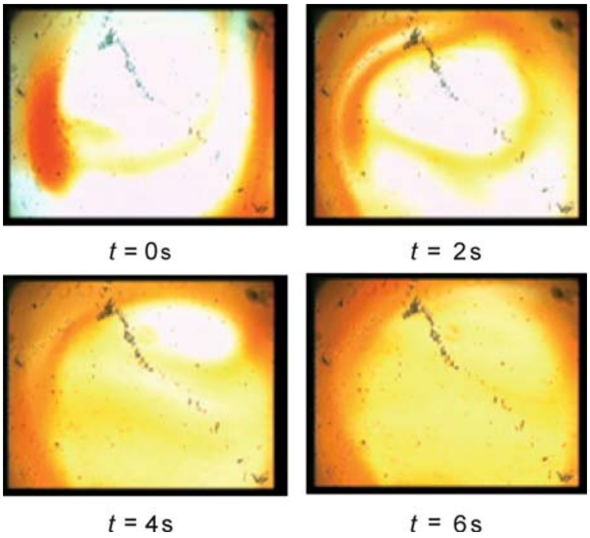
where d is the separation between nozzle and the ground electrode, and, R is the radius of curvature of the meniscus. Typically, $\gamma \sim 10^{-2}\,\mathrm{kg/s^2}$, $d \sim 10^{-2}\,\mathrm{m}$, $\varepsilon\varepsilon_0 \sim 10^{-10}\,\mathrm{C^2/Jm}$ and $R \sim 10^{-4}\,\mathrm{m}$, thus suggesting that extremely large voltages of order 10 kV are required for the onset of electrospraying.

In DC electrospraying, the absence of any external periodic forcing permits sufficient time for charge separation to occur within the liquid meniscus emanating from the nozzle orifice. Tangential ion conduction along a thin electric double layer at the meniscus interface is then responsible for co-ion accumulation, the repulsion of which then results in Coulombic fission wherein a thin liquid jet emanates from the tip once the Rayleigh limit is reached where the charge repulsion exceeds the surface force. This charged jet then undergoes various hydrodynamic or Coulombic instabilities leading to its breakup and hence the generation of charged drops. These drops suffer from further disintegration when the drop evaporates leading to higher charge densities and hence the possibility of successive break up when the Rayleigh limit for Coulombic fission is exceeded. This disintegration cascade therefore gives rise to very small drops of nanometer order.

For perfectly conducting liquids, Taylor [7] showed that a conical meniscus with a half angle of 49.3° is produced by considering the static equilibrium balance between the capillary and Maxwell stresses in Eqs. (3), (6) and (17). In the perfect conducting limit, the drop is held at constant potential and hence the gas-phase electric field at the meniscus interface is predominantly in the normal direction. It can then be shown that the normal gas phase electric field $E_{\mathrm{n,g}}$ scales as $1/R^{1/2}$ in which R is the meniscus radius which then stipulates from Eq. (7) that the Maxwell pressure $p_{\mathrm{M}} \sim E_{\mathrm{n,g}}^2$ scales as $1/R$, therefore exactly balancing the azimuthal capillary pressure $p_{\mathrm{C}} \sim \gamma/R$ for all values of R. This exact balance, and absence of a length scale selection, is responsible for the formation of a static Taylor cone (Fig. 1) in the dominant cone-jet mode in DC electrosprays [8].

Li et al. [9] and Stone et al. [10] later extended Taylor's perfectly conducting limit to allow for the effect of finite liquid conductivities, showing in these cases that the tangential electric field within the slender conical liquid meniscus dominates. However, the tangential liquid phase electric field $E_{\mathrm{t,l}}$ also scales as $1/R$ and thus an exact bal-



Interfacial Electrokinetic Flow, Figure 10 Demonstration of rapid micro-mixing via the electrohydrodynamically induced surface microvortices in a microfluidic chamber 8 mm in diameter and 4 mm in height. After Yeo et al. [18]

ance between the Maxwell stress $p_M \sim E_{t,1}^2$ and the capillary stress p_C is again obtained, giving rise to a cone-like structure [11]. The cone angle, however, depends critically on the liquid to gas permittivity ratio $\beta \equiv \varepsilon_1/\varepsilon_g$; the Taylor angle is then recovered in the perfectly conducting limit as $\beta \to \infty$.

High frequency ($10\,\text{kHz} \leq \omega \leq 200\,\text{kHz}$) AC electrosprays [11–13], on the other hand, behave very differently from DC electrosprays. The drops generated are larger (of order microns) than the nanometer dimension DC electrospray drops. In addition, the Taylor cone characteristic of DC electrosprays is not observed. Instead, the drops are ejected from a curved meniscus or from a peculiar microjet that protrudes intermittently from the meniscus, as shown in Fig. 2. The high frequency periodic forcing does not permit sufficient time for charge separation to occur and hence co-ions accumulate at the meniscus tip, thereby rendering the ejected drops electroneutral. This explains the absence of Coulombic fission and hence the observation of larger drops since the Coulombic fission disintegration cascade does not occur. The drop electroneutrality allows the AC electrospray to be used for drug delivery applications in which charged aerosols that could possibly lead to surface adsorption and compound ionization are undesirable [13]. Moreover, the absence of drop charge also stipulates that the current and hence power requirement is negligible, allowing the technology to be miniaturized for portable consumer use [11–13].

The absence of tangential ion conduction also results in a weaker liquid phase tangential electric field. As such, the AC electrospray behavior was found to be insensitive to liquid conductivity [12]. This passivity of the liquid phase is compounded by the formation of a thin, highly-conducting, permanent negatively charged plasma polarization layer that envelopes the liquid meniscus, giving rise to a dominant normal gas phase electric field in one AC half period [11]. This negative charge does not originate within the drop due to the insufficient time for charge separation within the liquid phase. In addition, the drop ejection time, roughly 10^{-3} s, is much larger than the period associated with the AC forcing frequency thus allowing any charge within the drop to essentially equilibriate during the ejection event [12].

Given that the AC electrospray requires a working liquid of sufficiently high volatility (e.g., alcohols), the negatively charged plasma cloud could possibly arise due to evaporation and subsequent ionization of the liquid from the meniscus when the applied voltage exceeds a threshold voltage associated with the ionization potential. In the cathodic half period, when the meniscus and capillary have the same polarity as the plasma cloud forming a thin highly conducting layer enveloping the meniscus, the local gas phase normal electric field at the interface is significantly enhanced, as illustrated in Fig. 3a, since the meniscus and the plasma layer both resemble constant potential bodies in which the interfacial field is predominantly normal. On the contrary, plasma is not generated in the anodic half period. Nevertheless, a plasma layer still surrounds the meniscus unless there is sufficient time for it to be dispersed. The plasma layer is now oppositely charged to the meniscus and capillary, effectively screening the external field such that a weak tangential gas phase field arises, as shown in Fig. 3b. However, the enhanced normal gas phase field in the cathodic half period dominates and hence, averaged over many cycles, produces a net Maxwell stress that is responsible for the meniscus dynamics observed [11].

This plasma polarization mechanism also explains the appearance of a minimum in the frequency dependent critical voltage of approximately 165 kHz for spraying to occur. Below this optimum frequency, as $\omega \to 0$, there is adequate time for the dispersion of the plasma generated away from the meniscus. Above this optimum frequency, as $\omega \to \infty$, there is insufficient time for the dispersion to occur. Maximum interfacial plasma polarization therefore occurs at the optimum frequency, therefore producing the largest enhancement of the local normal Maxwell field at the meniscus interface [11].

Since both meniscus and plasma layer resemble constant potential bodies, the solution of the Eq. (9) governing the gas phase electrostatics in the weak polarization limit

where ρ_e is negligible gives rise to a specific scaling for the normal interfacial gas phase electric field $E_{n,g}$. Assuming an arbitrary axisymmetric meniscus shape but not precluding the existence of a conical geometry, it can be shown from spheroidal harmonics that $E_{n,g} \sim 1/R^{1/2}$ for a sharp conical meniscus. On the other hand, $E_{n,g} \sim 1/R$ is obtained for more slender bodies such as an elongated ellipsoid or cylinder. Nevertheless, given that the more singular $1/R$ scaling for a slender geometry dominates at the meniscus tip, as $R \to 0$, the Maxwell pressure $p_M \sim E_{n,g}^2$ scales as $1/R^2$ and hence an exact balance with the azimuthal capillary pressure $p_C \sim \gamma/R$ is only possible for one specific value of R [11]. This length scale selection therefore excludes the possibility of a cone-like meniscus and instead suggests that the meniscus is stretched to a more elongated cylinder-like geometry such as that of the microjet shown in Fig. 2, thus suggesting why a non-steady microjet is produced in AC electrosprays instead of a steady Taylor cone [11].

The role of the Maxwell pressure resulting from a normal gas phase interfacial electric field that scales as $1/R$ in elongating the liquid meniscus into a cylindrical microjet structure can also be verified through a dynamic simulation in which the equations governing the coupled interactions between the hydrodynamics (Eqs. (1)–(3)) and electrodynamics (Eq. (9)) are solved simultaneously for a constant potential liquid meniscus in the longwave limit in axisymmetric polar coordinates $(r, 0, z)$, subject to the boundary conditions given by Eqs. (14)–(20). The polarization in the bulk gas phase is assumed to be weak, i. e., $\rho_e \sim 0$, such that Eq. (9) reduces to the Laplace equation. Further details of the model are given in [11]. A typical spatio-temporal evolution profile is illustrated in Fig. 4 in which an axial pressure gradient resulting from the interfacial distribution of the normal Maxwell stress with a $1/R^2$ scaling along the meniscus is observed to stretch the initially curved meniscus and pull out a slender microjet resembling that in Fig. 2. After a short transient, the microjet is observed to propagate forward at roughly constant velocity whilst maintaining an approximately constant radius [11].

Electrospinning

The electrospinning of micron and nanometer dimension fibers is a hybrid technology that arose out of electrospraying. In the past decade, fiber electrospinning has observed exponential growth in interest. However, the concept and technique has not evolved much from the original setup, shown in Fig. 5, which is very similar to that for electrospraying. A wide variety of polymer and polymer composite fibers with different morphologies (e. g., beaded, pored, hollow, core-shell, etc.) have since been electrospun, examples of which are summarized in [14]. The AC electrospray setup has also been modified to synthesize fibers of micron order thickness from biodegradable polymeric excipients [13], although it should be mentioned that the mechanism by which the fibers are generated, predominantly due to extensional stresses that lead to the stretching of the microjet in Fig. 2 and subsequent solvent evaporation and hence jet solidification into a fiber, differs from that in DC electrospinning where the mechanism is largely due to evaporative solidification of the solvent from the thin jet that emanates from the Taylor cone as a result of Coulombic fission.

Electrospinning has been modeled through an analysis of electrically forced axisymmetric liquid jets [15], in which the asymptotic limit requirement of either assuming the liquid as a perfect conductor or a perfect dielectric is relaxed such that the existence of interfacial charge can be accounted through Eq. (21). This is because whilst bulk conduction can be neglected in the small free space charge density ρ_e limit, interfacial charge and hence conduction is not usually negligible. The existence of such charge also gives rise to a finite tangential Maxwell stress given by Eq. (8) which can only be balanced by the viscous stress.
A similar axisymmetric model to that described above, assuming the jet to be slender such that the longwave approximation holds ($R_0 \ll L$, in which R_0 is the initial meniscus height and L the characteristic length scale of the jet), is then derived. In this limit, the external electric field can be simplified such that a slender dielectric meniscus can essentially be described as an effective axial line distribution of free and interfacially bound charges λ. An electric field flux balance on Gaussian surfaces S_1 and S_2 around and encompassing the meniscus interface then leads to [15]

$$\oint_{S_1} \boldsymbol{E}\cdot\boldsymbol{n}\,\mathrm{d}A = \left[\left(\pi R^2 E_{\mathrm{t},1}\right)_z + 2\pi R E_{\mathrm{n},1}\right]\mathrm{d}z = 0\,, \quad (23)$$

and

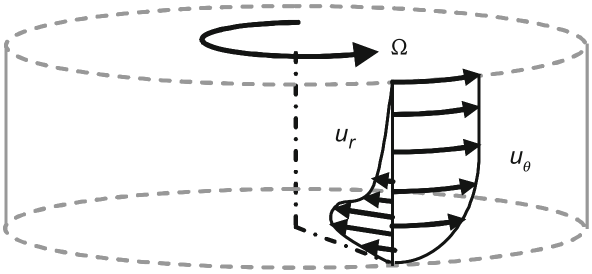
$$\oint_{S_2} \boldsymbol{E}\cdot\boldsymbol{n}\,\mathrm{d}A = \left[\left(\pi R^2 E_{\mathrm{t},1}\right)_z + 2\pi R E_{\mathrm{n,g}}\right]\mathrm{d}z = 4\pi\lambda\,\mathrm{d}z\,, \quad (24)$$

in which A denotes the area and the subscript z denotes derivatives in the axial direction. Equations (23) and (24) can be substituted into Coulomb's Law describing the gas phase electric potential in the region far from the interface [15]:

$$\Phi_g = \Phi_\infty + \int \frac{\lambda\left(z', t\right)}{\sqrt{r^2 + (z - z')^2}}\,\mathrm{d}z'\,, \quad (25)$$

where Φ_∞ is the applied potential, to yield a second order ordinary differential equation for the tangential electric field in the liquid phase [15]:

$$E_{\mathrm{t},1} - \ln\frac{R_0}{L}\left[\frac{1}{2}\left(\frac{\varepsilon_1}{\varepsilon_g} - 1\right)\left(R^2 E_{\mathrm{t},1}\right)_{zz} - 4\pi\,(qR)_z\right] - E_\infty = 0\,, \quad (26)$$



Interfacial Electrokinetic Flow, Figure 12 Schematic depiction of the azimuthal and radial velocity profiles, u_θ and u_r, respectively, in Batchelor flows (liquid flow between rotating and stationary circular disks; the angular rotation is Ω). After Yeo et al. [19]

in which E_∞ denotes the applied electric field. The choice of boundary conditions at the nozzle orifice is also critical to the stability of the numerical solutions. A detailed discussion can be found in [15] and is also summarized in [14].

Electrokinetic Bubble Transport in Microchannels

Chang [16] showed that the pressure drop across a bubble translating in a microcapillary with speed U, as illustrated in Fig. 6, scales as $(\gamma/R)\mathrm{Ca}^{2/3}$, which is essentially the difference in the capillary pressures between the cap pressures at the front and rear of the bubble; R is the capillary radius and $\mathrm{Ca} \equiv \mu U/\gamma$ is the capillary number. Given that the pressure drop required to drive a liquid slug of length L at speed U is $\mu UL/R^2$, then the pressure drop across a bubble corresponds to an equivalent slug length of $R\mathrm{Ca}^{-1/3}$, obtained by balancing the pressure drop in both cases. Since Ca is typically between $10^{-8} - 10^{-4}$ in microcapillaries, this means that the pressure drop required to drive a bubble is extremely large to overcome the viscous dissipation associated with the bubble, and is equivalent to driving a liquid slug with a length that is several orders of magnitude of the capillary radius [16].
As the usual parabolic velocity profile of pressure-driven Poiseuille flow leads to the flowrate scaling as R^4 whereas the flat velocity profile obtained in pure electroosmotic flow gives rise to a flowrate that scales as R^2, it can be seen that it is more efficient to drive microchannel flows where R becomes very small using electrokinetic flows as opposed to pressure-driven flow. However, there are some design issues to be considered in electrokinetic bubble transport.
From Ohm's law,

$$i = \frac{I}{A_c L} = \sigma E\,, \quad (27)$$

where i is the current density, E the local electric field, I the corresponding current, and, A_c and L are the cross-sectional area and length of the capillary, respectively, we observe that $E \sim 1/A_c$. The electroosmotic slip velocity is given by

$$u_s = \frac{\varepsilon\varepsilon_0 \zeta E}{\mu}\,, \tag{28}$$

where ζ is the electrokinetic (or zeta-) potential, which stipulates that $u_s \sim 1/A_c$. It then follows from Eqs. (27) and (28) that the volumetric flowrate is

$$Q = u_s A_c = \frac{\varepsilon\varepsilon_0 \zeta I}{\mu \sigma L}\,, \tag{29}$$

which suggests that the flowrate due to electrokinetic flow is independent of the capillary cross-sectional area. This, and the fact that the electrokinetic flow velocity profile is virtually flat across the channel, is quite unfortunate because it requires the flow in the thin annular film around the bubble to be equal to the flow behind it. As a result, it is impossible to build up a back pressure driving force behind the bubble. The electrolyte simply flows around the bubble, rendering it stationary [16].

Thus, in order to drive bubble transport using electrokinetic flow, the flow invariance to the cross-section must be eliminated such that the flow in the annular film is less than the flow behind the bubble. Chang [16] proposes several ways to reduce the annular film flow by introducing drag at the bubble interface to retard the annular film (however, this only works if the bubble is essentially a viscous liquid drop) or by adding surfactants that reduce the local interfacial tension and hence generate Marangoni stresses (stresses arising due to interfacial tension gradients). Alternatively, it is also possible to introduce an ionic surfactant that resides at the bubble interface such that the double layer at the interface has an opposite charge to that of the capillary tube surface. Thus, the ζ-potential at the interface would have an opposite sign to that at the capillary surface. From the Smoluchowski slip in Eq. (28), we then note that the velocity at the bubble interface is in the opposite direction to that at the capillary surface. Careful control of the amount of ionic surfactants could also give rise to equal but opposite velocities, thus eliminating the flow in the annular film completely.

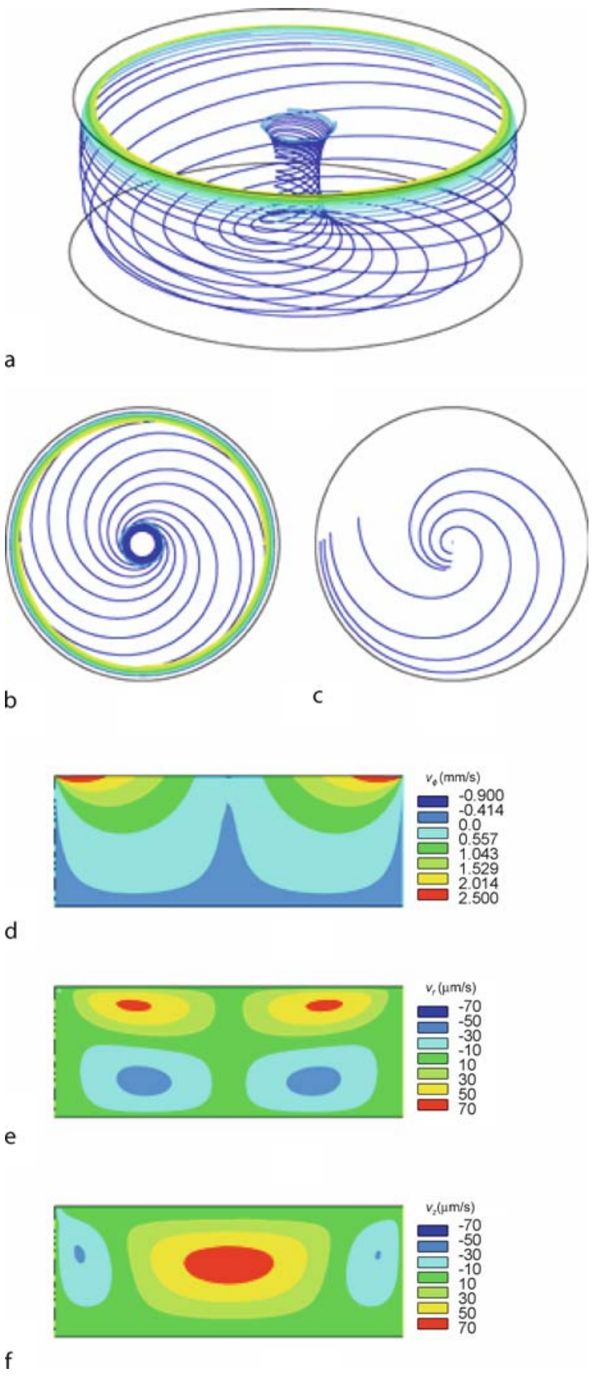
Figure 7 shows the dimensionless bubble translation speed Ca as a function of the surfactant (anionic surfactant since the glass capillary used has positive surface charge) ionic concentration for various electric field strengths [17]. At low concentrations, given that the Debye screening length scales as the inverse of the square root of the concentration, the electric double layer thickness becomes comparable to the thickness of the annular film. The overlapping double layers of different polarities then leads to Coulombic attraction which causes the annular film to collapse. As such, there is a critical value for the ion concentration of approximately 10^{-5} mol/l before which bubble motion is observed. At high concentrations, however, the bubble speed again diminishes due to the vanishing electric double layer.

Electrohydrodynamically-Induced Interfacial Recirculation

Very recently, a novel way of driving liquid recirculation has been developed by exploiting a bulk electrohydrodynamic air thrust generated from a nearly singular electric field at a sharp electrode tip mounted a small height (~4 mm) above the liquid surface [18], as depicted in Fig. 8a. This air propulsion, also known as *corona wind* or *ionic wind*, arises when the voltage at the electrode tip exceeds the threshold ionization voltage leading to the breakdown of the air surrounding the electrode tip. Counter-ions are then repelled away from the electrode, colliding into the electroneutral air molecules along the way, as illustrated in Fig. 8b. The momentum transfer arising from these collisions then gives rise to the bulk air flow. By inclining the electrode such that the air flow is directed towards the liquid surface, interfacial shear then results in recirculation at the surface. Depending on the positioning of the needle, a clockwise or anti-clockwise motion or a pair of surface vortices can be generated (Fig. 8c). Figure 8c also shows the secondary bulk recirculation generated due to the primary surface flow; this will be discussed subsequently.

The voltage-frequency behavior is depicted in Fig. 9. We observe that the critical voltage to obtain liquid recirculation decreases with increasing applied frequency until approximately 145 kHz before increasing again. This optimum frequency is associated with the inverse RC time scale of the plasma charging mechanism [18], where R is the resistance and C the capacitance. At low frequencies as $\omega \to 0$, there is sufficient time for any plasma generate to diffuse away. At high frequencies as $\omega \to \infty$, on the other hand, there is insufficient time for plasma to be generated in each half AC period.

Moving diagonally across the voltage-frequency characteristic of Fig. 9 in the direction of increasing voltage and frequency also yields interesting behaviour in which the vortices become increasingly unstable, breaking down to spawn off additional vortex pairs. At yet higher voltages and frequencies, the vortex breakdown continues to produce a cascade of vortices with a continuum of length scales, similar to that observed in vortex shedding [18]. The stability of the original vortices can however be recovered by reducing the voltage at a fixed frequency.



Interfacial Electrokinetic Flow, Figure 13 Numerical flow simulation results of the secondary meridional flow arising from primary surface recirculation of the liquid. (**a**), (**b**) and (**c**) are flow field traces; (**b**) is a cross-sectional plan view of the flow field at the top surface and (**c**) is a cross-sectional plan view at a small distance just above the base. (**d**), (**e**) and (**f**) are circumferential θ, radial r and vertical z velocity profiles, respectively. Bright shades indicate motion along the respective axis directions and dark shades indicate motion against the axis direction. After Yeo et al. [19]

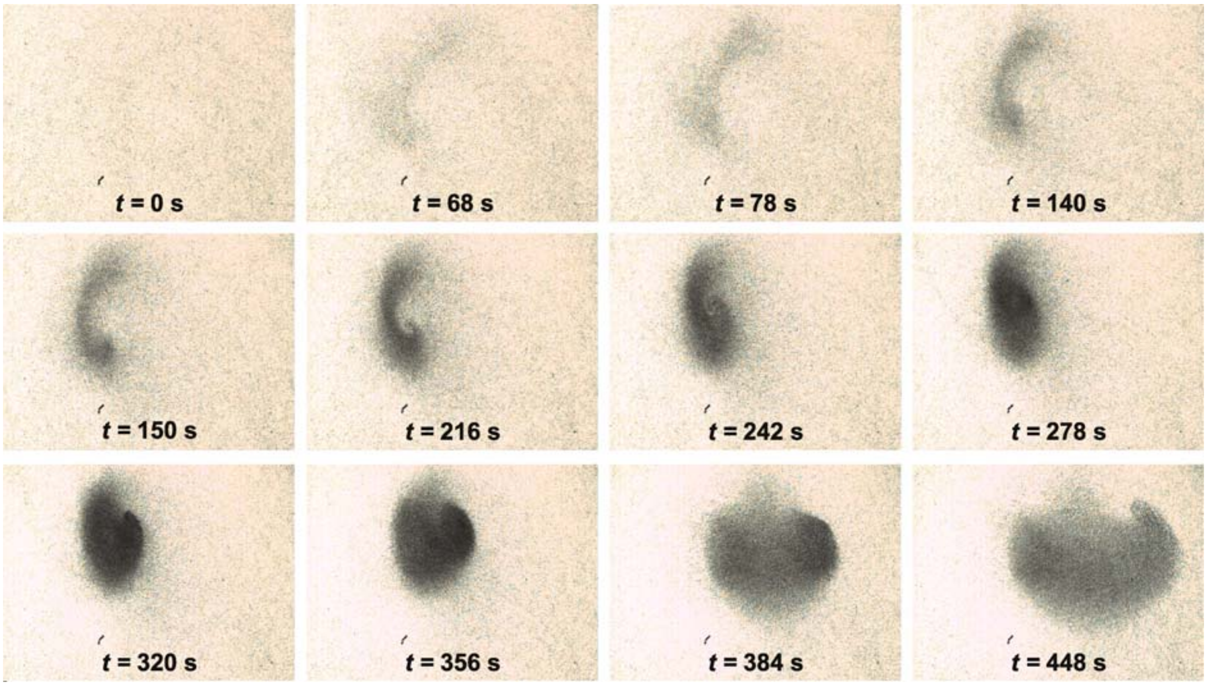
These surface vortices provide an efficient means for microfluidic mixing, as shown in Fig. 10 where a dye is rapidly mixed within several seconds. The mixing can be enhanced by inducing the vortex instabilities wherein turbulent-like mixing efficiencies are observed [18]. In addition, particles dispersed in the flow are also observed to be drawn into the vortices due to positive dielectrophoresis towards a point on the interface closest to the needle where the field is most intense. Once a sufficient particle concentration is achieved within the vortex, shear-induced migration leads to cross-streamline transport such that the interior of the vortex is populated [18], as shown in Fig. 11a. Upon relaxation of the electric field and hence termination of the flow, we observe the particle aggregate to remain intact, possibly due to van der Waals attraction (Fig. 11b). This therefore provides a mechanism for particle trapping and concentration.

The induced surface flow also gives rise to secondary bulk fluid motion, in the same way that bulk meridional vortices are generated in a fluid trapped between rotating and stationary disks in Batchelor flows [19], as depicted in Fig. 12. In this flow recirculation mode, particles dispersed in the flow are convected to the bottom by the bulk meridional recirculation. However, due to the inward radial velocity in the Ekman boundary layer (see Fig. 13), the particles begin to swirl in a helical-like manner towards the center of the base [19]. Although the flow recirculates back up a central spinal column, the gravitational force on the particle is sufficient to trap the particles at a pseudo-stagnation point at the base. This was demonstrated to be another mechanism for particle trapping and concentration. Figure 14 shows the efficient trapping of red blood cells for microfluidic blood plasma separation in several minutes [19].

These surface and bulk electrohydrodynamic recirculation, whilst having the usual advantages of electrokinetic devices wherein mechanically moving parts are absent, also benefit from low field penetration into the liquid given that the field is predominantly in the gas phase, thus posing little threat in lysing biological cells. In addition, the absence of electrode-sample contact also minimizes sample contamination through electrolytic reactions, non-specific adsorption of biological compounds or Joule heating [19].

Future Directions for Research

Electrokinetic flows in microchannels has been extensively studied over the past decade. However, there is still a need for a greater understanding of electrokinetic flows involving freely deforming surfaces such as electrospraying, electrospinning, electrowetting and electrohy-



Interfacial Electrokinetic Flow, Figure 14 Sequence of images showing the separation of red blood cells from blood plasma via the secondary meridional bulk liquid recirculation. The final plasma effluent above contains a hematocrit less than 0.003%. After Yeo et al. [19]

drodynamically induced surface flows. In particular, the complex physicochemical behavior at the interface and its coupling to the bulk flow is still not well understood. One example is how surface polarization and tangential ion conduction affects the flow behavior. There is also a further need for accurate theoretical models that are underpinned by a correct fundamental physical understanding of such systems. For example, free surface models developed for investigating the behavior of interfacial flows driven by Marangoni and thermocapillary stresses have been extended to study the effects of electrical stresses (see, for example, [20]). It is anticipated that these models will form the basis of other more complex free-surface electrohydrodynamic models to investigate interfacial flow behavior and stability.

Rayleigh instability; Bridging instability; Electrohydrodynamic instability; Rosensweig instability

Definition

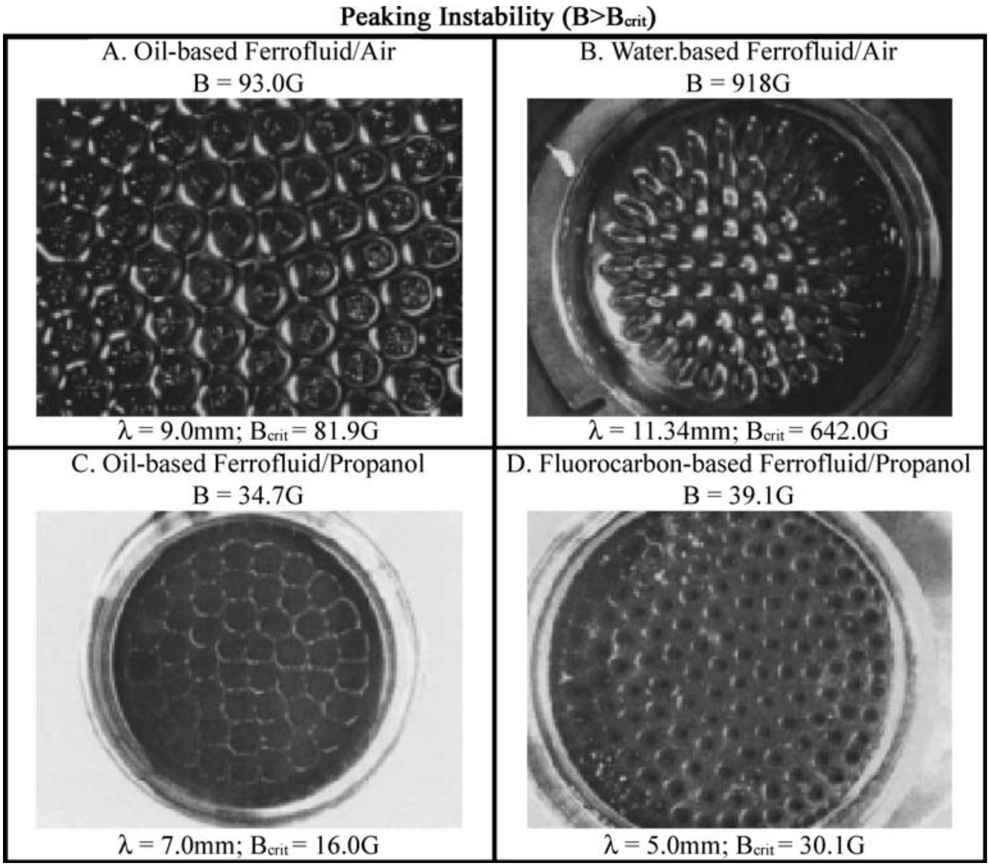
Interfacial instabilities develop at an fluid–fluid or fluid–gas interface due to the unstable growth of interfacial perturbations. These instabilities may be surface tension driven (Rayleigh, liquid bridge instability), electrically driven (electrohydrodynamic instability) or magnetically driven (Rosensweig instability). These instabilities have been used in applications as diverse as inkjet printing to surface tension measurements. Interfacial instabilities are modeled using classical linear stability analysis considering momentum transport equations and both kinematic and interfacial stress boundary conditions. These models test the stability of the interfacial perturbations to infinitesimal disturbances.

Overview

The Rayleigh instability [1] is an example of a capillary driven instability which causes droplet breakup and has been used extensively for inkjet printing. Other interfacial instabilities such as a liquid bridge instability [2] have been studied to explore the stability criteria of coalescing two droplets from binary capillaries and determining whether the droplet will form a stable liquid bridge between the two capillary ends or if the bridge will rupture to have a droplet suspended on a single capillary end. Electrohydrodynamic instabilities occur when electrical stresses are applied at an interface. The electrical stresses develop at the interface primarily due to a conductivity or permittivity gradient between two fluid phases. The early work on modeling electrohydrodynamic instabilities performed a linear stability analysis of the electrical and fluid interfacial boundary conditions using the transfer relations developed by Melcher [3]. Melcher developed a dielectric model which describes liquids as being both polarizable and having free charge in an imposed electric field. Finally instabilities have been demonstrated using ferrofluids [4] which are colloidal suspensions of magnetic nanoparticles with a high magnetic susceptibility. When a ferrofluid is exposed to a magnetic field which is strong enough to promote instability, the surface of the fluid will spontaneously form a regular pattern of vertical spikes (peaking instability) consisting of the ferrofluid protruding from the initially flat interface.

Basic Methodology

The Rayleigh instability is the basis for most inkjet printing applications. When fluid is forced through an orifice (such as an inkjet printer head) a cylindrical fluid jet is produced with a fluid–air interface. As the jet falls under the influence of gravity it accelerates and is stretched so



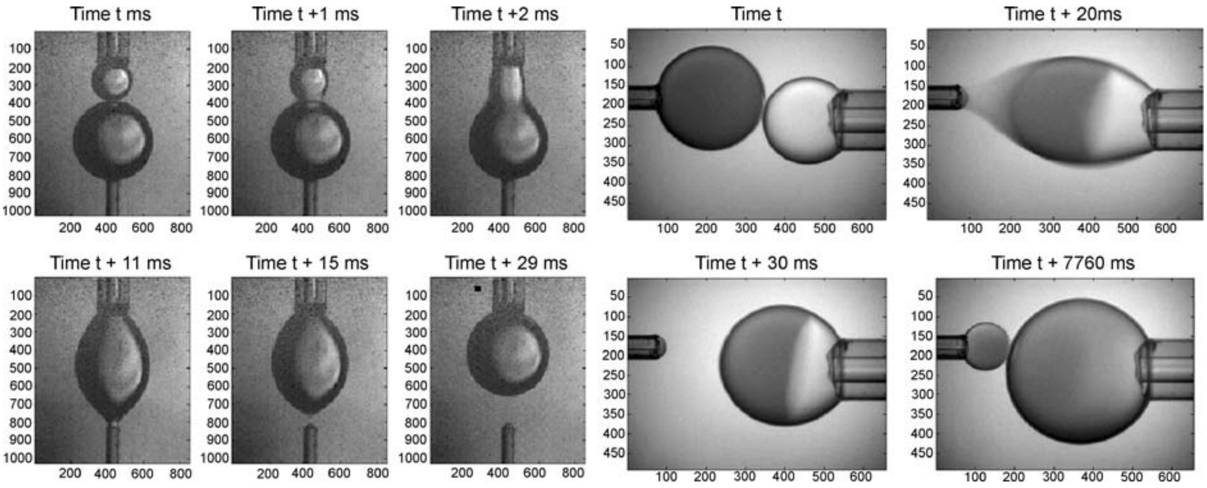
Interfacial Instability, Figure 1 Images of the peaking instability of different ferrofluids with applied magnetic fields above the critical values needed for instability. Images taken from [6]

that the jet radius decreases. At a critical radius the surface tension of the fluid causes spherical droplet breakup so that the volume of the droplet is the same as that of the cylindrical element protruding in the jet but minimizes surface area between the fluid and air. Inkjet printing uses this principle to create small ink droplets which are dispensed onto paper in a well defined pattern to produce printed characters and images made up of many droplets. A review of the evolution of inkjet printing technology is presented in [5]. Many different methods for actuating inkjet printer heads to dispense the proper amount of liquid, control drop size and maximize droplet dispensing (printing speed) have been investigated. Two of the most popular methods for dispensing droplets are using thermopneumatic actuation, where a portion of the fluid is heated to cause a gaseous phase change through liquid boiling to produce a pressurized gas bubble which forces a volume of ink through the printer head (bubble jet printers) or using piezoelectric actuation using a piezoelectric element to produce the appropriate pressure for droplet dispensing.

Hoburg and Melcher [7] demonstrated electrohydrodynamic instabilities in macroscale systems at an oil-oil interface with a discrete conductivity change at the interface under the influence of an applied electric field. In the presence of an applied electric field, charge accumulates at the fluid–fluid interface and the electrical force on the interface is balanced by the fluid interfacial stress tensor. At a critical field strength the electrical force exceeds the interfacial fluid forces and interfacial perturbations grow exponentially. Melcher determined a natural velocity scale for this instability, termed the electroviscous velocity which represents a balance between the electrical and viscous stresses at the fluid–fluid interface defined as

$$U_{\text{ev}} = \frac{\varepsilon E_0^2 H}{\mu} \quad (1)$$

where ε is the fluid dielectric constant, μ is the fluid viscosity, E_0 is the applied electric field and H is the characteristic length scale of the system (e. g., the half width of a microfluidic channel for a two layer stratified system).



Interfacial Instability, Figure 2 *(Left)* High speed images of liquid bridge rupture after droplet coalescence. *(Right)* The mixing of a dye containing drop with an undyed droplet. The image at $t + 7760$ ms shows a mixed droplet after six instability injections of the dyed fluid. Images taken from [2]

Next, in macroscale systems the spiking phenomena of instabilities in magnetic fluids has been extensively studied [4, 6] (Fig. 1). These spikes will occur when the applied magnetic force promoting the instability is large enough to overcome the surface tension and gravitational force on the ferrofluid interface. Amin, et al. [6] studied the peaking instability of several ferrofluid configurations: an oil-based ferrofluid in air, a water-based ferrofluid in air, an oil-based ferrofluid, and fluorocarbon-based ferrofluid, both below a blend of 50% propanol and 50% deionized water. From the peaking instability and spacing between the peaks they were able to accurately determine the interfacial tension between the ferrofluid and air when compared to surface tension determined by tensiometry. They determined their surface tension as

$$\gamma = \frac{g\left(\rho_{\text{ferro}} - \rho_{\text{air}}\right)}{k_{\text{c}}^2} \quad (2)$$

where g is the gravitational constant, ρ is the fluid density where the subscript refers to either the ferrofluid or air and k_{c} is the critical wavenumber at the incipience of the instability defined as

$$k_{\text{c}} = \frac{2\pi}{\lambda} \quad (3)$$

where λ is the measured spacing between the spikes, the Taylor wavelength of the instability.

Key Research Findings

In microfluidic systems interfacial instabilities are promoted in immiscible multiphase flow systems. A review of many of the applications of multiphase flows in microfluidics is presented by Baround and Willaime [8]. They review many of the relevant challenges to integrating multiphase flows in microfluidic devices including how wetting and surface tension affects the multiphase flow regimes. One of the critical challenges is controlling droplet breakup and sizes due to the large surface tension forces between the liquid phases driving droplet formation. One critical area of investigation being pursued is understanding how to precisely control droplet size and patterns. There are many applications of droplet based devices in microfluidic systems.

Another area of investigation is coalescing droplets using liquid bridges [2]. Here the authors would combine two reagent containing aqueous droplets suspended from microcapillary tips under density matched silicone oil. When the droplets are brought in contact they coalesce into a single droplet. If different reactants are placed in each fluid then the merged droplets may be thought of as individual microreactors. They authors are exploring the use of droplets to dispense Polymerase Chain Reaction (PCR) reactants required for DNA amplification. The authors modeled the liquid breakup by considering surface energy minimization to predict the stability limits. Figure 2 shows both the coalescing of two droplets with liquid bridge breakup as well as mixing within the droplets due to their merging. They considered the stability of the liquid bridge as a function of the droplet slenderness (the ratio of the capillary tip separation to the mean diameter of the supporting capillary) and a volumetric ratio (ratio of actual droplet volume to the volume of a cylinder of liquid with the same radius as the supporting capillaries). The authors also investigated the effect of having different

supporting capillary radii (i. e. one capillary has a larger radius than the other). They found that the liquid bridges are stable at higher volumetric ratios and lower slenderness ratios (i. e., more fluid is dispensed and the capillaries are placed closer together). They also demonstrated that as the ratio of the capillary radii change, they needed an even higher volumetric ratio or lower slenderness to obtain stable bridges. However, using different radius capillaries, they could induce directional liquid bridge rupture, where the bridge would always rupture in the necking region closest to the smaller diameter capillary, so that a reactant containing fluid could be dispensed into a host droplet without the host fluid contaminating the dispensing capillary tip.

Other areas of interest are in using interfacial instabilities for materials production. Gans and Schubert describe the use of inkjet technology for the production of polymer microarrays [9]. They describe how droplet dispensing may be used in the fabrication of polymer microarrays (Fig. 3), polymer microoptical parts (microlenses), combinational polymeric materials production, polymer LED displays or polymer electronic devices. They also cite reports of inkjet printing technology applied to the production of microarrays of luminescent materials, catalyst combination for carbon nanotube (CNT) production, and patterning of DNA or other biological molecules. The polymers droplets are produced through a Rayleigh instability as previously described and dispensed onto a printing surface. Afterwards, the polymers are solidified either through solvent evaporation or UV curing of curable resins.

Another area which applied microfluidics to materials production is reported in [10]. Here the authors coinfused solutions of adipoyl chloride in xylene and hexamethylenediamine in 0.1 NaOH for laminar flow pattern-

ing of nylon 6,6 membranes (Fig. 4). Using this method, the reactants in the different fluid phases would diffuse to the organic-aqueous interface where they would react in a polycondensation reaction to form nylon 6,6 (Fig. 4a). The authors also tested the stability of the interface with just the organic and aqueous solvents (Fig. 4b). Of particular interest to the authors was the stability of the flow due to the jump in viscosity and density across the interface which may destabilize the flow patterns. They were also concerned about how the polycondensation of the nylon membrane may cause time varying changes in the local density and viscosity close to the fluid–fluid interface. The authors tested a variety of device geometries in the production of nylon 6,6 membranes and found that in devices where the flow channels converge in ether a 90° angle in a 'T'-junction or at a smaller angle in a 'Y'-junction they were able to produce stable flows with well formed nylon membranes at the fluid–fluid interface. Thicker polymer films were reported at lower flow rates, and the authors suggest that at higher flow rates there is a higher shear force on the membrane leading to the removal of nascent polymer leaving only a more consolidated core film. Unstable flow patterns were also observed in other channel geometries. One geometry in particular was wider at the point of entry where the two fluids merged and the channel thinned along its length. Only uneven, fragmented and laterally displaced membranes were produced in this geometry. The authors suggest that the velocity gradient along the length of the channel contributed to the loss of flow stability.

Recently electrohydrodynamic instabilities have been demonstrated and analyzed in both two layer [11, 12] and

three layer stratified flows [13]. The two layer system consisted of glycerine and corn oil, while the three layer system consisted of a low conductivity organic layer (phenol:chloroform:isoamyl alcohol 25 : 24 : 1 mixture by volume) sandwiched between two high conductivity aqueous layers. In these two configurations the two fluid layers are immiscible. These two geometries have been modeled using linear stability analysis and an analytical stability criteria for the two configurations were determined [11, 13]. Experimentally, these instabilities were demonstrated within similar microfluidic configurations. Each system consisted of a converging channel geometry for introducing the respective fluids and electrodes for applying electrical excitation. For the two layer system shown in Fig. 5, once the electrodes are energized an electric field is generated which causes interfacial deflections (Fig. 5b–g). The authors report that for sufficiently high electric fields the interface ruptures when the top fluid (corn oil) periodically touches the opposite wall (Fig. 5h–i). Each time the interface contacts the wall glycerine droplets are formed and are convected downstream by the flow. It is noted that the droplets retain the deformed shape seen in Fig. 4h–i while they are in the region of the device with the applied electric field. Once the droplets enter a downstream portion of the device without electrodes their shape changes into spherical droplets under the action of surface tension as shown in Fig. 5j–k. The authors note that droplet size may be controlled by controlling both the applied voltage and the relative fluid flow rates. At higher applied field strengths the droplet sizes decrease due to the larger interfacial force causing the interface to contact the wall at a higher frequency, thus decreasing the volume in the droplets and hence their size.

Future Directions for Research

Interfacial instabilities in microsystems are complex phenomena and may be promoted by many different means. Future work requires a further development of experimental models and expansion of computational simulations to better understand the criteria under which instabilities develop. In addition, specific applications using interfacial instabilities for fluid manipulation, analysis and materials production should be continued to be explored.

Ion Channel

CHAN HEE CHON , DONGQING LI
Department of Mechanical Engineering, Vanderbilt University, Nashville, TN, USA
Chanhee.chon@vanderbilt.edu

Synonyms

Gate in the cell wall

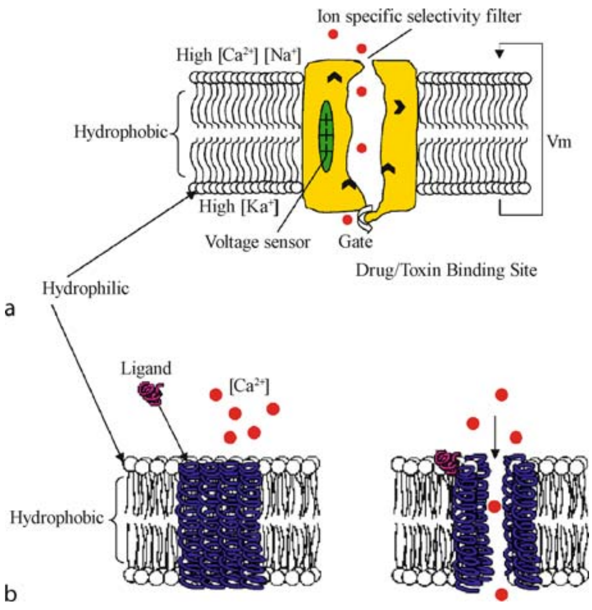
Definition

Ion channels are passageways for ions to be transported across cell membranes. They are nanometer-sized channels.

Overview

Ions, charged particles, have a significant effect on many biological cell processes. Cells use inorganic ions for transmitting signals across the cell membranes or along the surfaces of the cells. However, it is difficult for ions to pass through the membranes by simple diffusion because cell membranes consist of hydrophobic phospholipids that oppose the passage of hydrophilic ions. Furthermore, the negatively charged phosphate head groups of the phospholipids tend to repel negatively charged anions and trap positively charged cations. Therefore, ions require a specific gate to pass through the membrane [1]. Such a gate constituted of a large and diverse group of pore-forming membrane proteins is called an ion channel (Fig. 1). Ion channels are present in the membranes that surround all biological cells. Ion channels govern the electrical properties of all living cells and help to establish and control the small voltage gradient across the plasma membrane of all living cells by allowing the flow of ions down their electrochemical gradient.

Each ion channel species is characterized by its ion selectivity sequence (K^+ channels, Na^+ channels, Ca^{2+} channels, Cl^- channels, and nonselective cation channels). Highly specific ion channels only allow passage of a single ion species and less specific ion channels allow passage of a few or several ion species. Functionally, ion channels are broadly divided into voltage- and ligand-gated channels, referring to the type of physiological stimulus that activates the channel [2, 3]. Voltage-gated ion channels are a class of transmembrane ion channels that are activated by changes in electrical potential difference near the channel (Fig. 1a). These are typical in neurons. Ligand-gated ion channels are a group of intrinsic transmembrane ion channels that are opened or closed in response to binding of a chemical messenger (Fig. 1b).



Ion Channel, Figure 1 Schematic of (**a**) voltage-gated ion channel [2] and (**b**) ligand-gated ion channel [3]

Dysfunction of ion channels causes many diseases. Some ion channel diseases are genetic. Channelopathies are caused directly by mutations in genes coding for ion channels [4–7]. Examples of channelopathies are cystic fibrosis, epilepsy, and arrhythmias such as the long QT syndrome. Some other ion channels may be involved in nongenetic diseases such as diarrhea, which is mediated by toxicological effects on ion channel function [8].
The human genome was sequenced with at least 400 ion channel structures. However, currently only about 100 have been identified. Because specific ion channels interact with selective drugs, it is important to identify new ion channels and validate these as novel drug targets.

Ion Exchange Membranes

Dominic S. Peterson
Chemistry Division, Los Alamos National Laboratory,
Los Alamos, NM, USA
DominicP@lanl.gov

Definition

Ion Exchange Membranes are semi-permeable membranes in which an ionic functionality is fixed to the backbone of the membrane. These ionic species enable the concentration, separation, or exclusion of ionic species from a fluid flow. The two types of ion exchange mem-

branes are cationic- and anionic-exchange membranes. Ion exchange membranes are used for a wide range of industrial processes.

Chemical and Physical Properties

Ion exchange membranes have been in use since their discovery over 100 years ago. Large ion-exchange membranes are widely used by industry and have many commercial uses including water purification (desalination, water softening, etc), separation and preconcentration of food products and pharmaceutical products and in the manufacture of basic chemical products [1]. Because of their diversity and high efficiency, their use has been investigated in microfluidic systems as a way to enable sample cleanup of small volumes of analytes and solvent streams.
There are two main types of ion-exchange membranes, they are classified into the type of ions that they interact with in solution. ► Anion exchange membranes interact with anions and typically consist of amine functionalities ($-NH_3^+$, $-NRH_2^+$, etc). ► Cation exchange membranes interact with cations and have a variety of anion functional groups affixed to the membrane ($-COO^-$, $-SO_3^-$, $-PO_3^{2-}$, $-C_6H_4O^-$, etc). The ion exchange allows the passage of the charges opposite to those on the membrane while preventing the passage of ions of the same charge. In addition, different ions of the opposite charge will be retained to different degrees depending on its ability to interact with the ionic functionalities on the membrane surface. This binding will be dependant to large extent on the pH of the solution and the ions of interest.
In addition to classifying ion exchange membranes according to their ionic functionalities, it is also useful to identify how the support membrane has been formed to understand how the ionic functionalities will interact with a solution. A homogenous membrane has ionic functionalities bound to the surface of the membrane, but the support structure is non-ionic. A ► heterogeneous membrane has the charged functionalities mixed into the membrane support structure, which gives the structure an ionic character throughout the membrane.
The preparation of a homogeneous membrane can follow one of several approaches. The first method involves using a monomer that contains an ionic functionality or is easily converted to an ionic functional group. This starting monomer is then copolymerized with other monomers to form the ion exchange membrane. Another method that can be used to make an ion exchange membrane is to use a polymer film and then to modify the polymer directly or by a grafting reaction in order to introduce the ionic functional groups to the membrane. The third method that can be used to make a homogeneous ion-exchange membrane is to dissolve an ionic moiety into a polymer and then casting the polymer into a film to form the membrane.
In making ion-exchange membranes it is also important to consider the materials that the support membrane is composed of. The most common materials that are used to produce ion-exchange membranes are organic polymers, such as poly(styrene-co-divinylbenzene), poly(propylene), poly(ethylene), etc. It is also possible to utilize organic–inorganic composite materials to form the membrane material. These are called hybrid ion exchange membranes. The organic constituent of these composite materials provide structural flexibility and simplified processing. The inorganic component of composite membranes provide mechanical rigidity, thermal stability, and the potential for various properties such as magnetic, and high carrier motilities. Hybrid materials can be made from a variety of methods including blending, in situ polymerization, self assembly, or by a sol-gel process, which is the most common technique.
It is also possible to mix multiple functionalities into a single ion exchange membrane. One of these types of membranes is called a ► bipolar membrane. This type of membrane is a composition membrane that consists of a layered ion –exchange structure composed of a cation exchange layer and an anion exchange layer. The use of these compositions enables a large number of functionalities, such as anti-fouling, water dissociation, and the separation of mono and divalent ions. In particular it is possible to separate acids and bases into their component salts. These types of membranes have shown utility primarily in electro dialysis and have application in chemical production and separation. However, bipolar membranes tend to be instable in high current conditions. The fabrication of bipolar membranes is most directly performed by the use of a commercially available cation exchange membrane and anion exchange membranes. It is also possible to prepare this type of membrane by casting a polyelectrolyte solution onto a commercial exchange membrane of the opposite charge (cation solution on an anion membrane, or vice versa).
There is also a type of ion-exchange membrane that includes both a weak anion exchange and a weak cation exchange functionalities into the same membrane. These types of membranes are called ► amphoteric ion exchange membranes since they contain both anion and cation functionalities. In these membranes the anion exchange and cation exchange portions are randomly distributed throughout the membrane matrix. Amphoteric ion exchange membranes have the advantage that they are capable of passing both cations and anions. The passage and the separation of these analytes is controlled simply by controlling the pH within a relatively narrow range. The

pH change can control precisely the surface charge that is exhibited by the ion exchange membrane. In addition, amphoteric membranes prevent the adsorption of organic compounds and biological macromolecules onto the surface of the membrane.

An alternative to an amphoteric membrane is a mosaic ion exchange membrane, which consists of both anion exchange and cation exchange functionalities in the same membrane. However, where amphoteric membranes involve randomly distributed anion exchange and cation exchange functionalities, a mosaic ion exchange membrane involves anion and cation exchange elements that are arranged in parallel to one another. Because the two different exchange elements are arranged in parallel it is possible for both anions and cations to flow through the membrane through the individual channels. Mosaic exchange membranes have several unique properties such as negative salt rejection and osmotic pressure which can be used for different separation approaches for waste streams or other high salt solutions. The synthesis of a mosaic exchange membrane is quite complex, and even large scale membranes are not yet commercially available. Several synthetic methods are available to produce mosaic exchange membranes, but they are not typically suited to industrial production techniques.

There are several parameters associated with the ion-exchange membrane and the solvent that analyze ions are dissolved in that affect the ability of the membrane to retain or pass the ions or to separate them in the case of ion-exchange chromatography operations. The structure of the membrane directly affects the introduction of the ions to the functional ion-exchange medium. The overall capacity of the membrane to retain analyte ions will affect how much can actually be retained. If the ion-exchange membrane becomes saturated with ions its effectiveness will be greatly diminished. The strength of the eluent refers to the ability to elute sample ions. For instance, carbonate (a bivalent anion) has a greater eluting strength than monovalent anions. The eluent concentration will also have an effect on the release of the sample ions, with higher concentrations resulting in shorter release times. Finally, it is possible to include a small percentage of organic solvent (10% to 20%) in elution solutions. The organic solvent ensures that samples remain in solution and do not precipitate out.

Key Research Findings

The key to using ion-exchange membranes in microfluidic systems is finding a way to simply, effectively, and reproducibly incorporate the membrane into the system. The simplest method that can be devised to integrate a membrane into a microfluidic system is to place it in line with the microchannels. This can be done by placing it at the entrance or exit of a microchannel [2]. This type of system has been used to desalt protein samples prior to their analysis by electrospray ionization mass spectrometry. Another method that can be used is to place the membrane between two chips that have the channels fabricated on them [3]. By sandwiching the membrane between the two plates makes the fabrication simple and allows a wide range of ion-exchange membranes to be used. These devices have been used previously to perform sample cleanup steps before a sample is introduced to the microfluidic system. This can be a simple pre-concentration of the analyte and removal of any interferences, or it can involve a minimal separation of analytes from one another on the membrane and their introduction into the device. Another approach that has been used when interconnecting microchannels via a membrane is to connect channels that are orthogonal to one another [4]. This approach allows more complex systems of channels to be constructed and the incorporation of the ion-exchange membrane enables sample clean up to be performed between steps or it allows only a particular analyte or reagent to be introduced into a microchannel.

An interesting and challenging way to incorporate a membrane into a microchannel is to fabricate the membrane directly within the channel. This can be accomplished by forming an aqueous/organic phase interfacial boundary within the channel [5]. A condensation reaction can then be performed to make the membrane. This approach was used to fabricate a nylon membrane, but it should be possible to extend the approach to ion-exchange membranes. Alternatively, a polymerization mixture can be placed in a microchannel and a thin membrane can be polymerized by using a focused laser [6]. These methods for fabricating a membrane within a channel are still in the process of being developed, and in the future it should be possible to use a wide range of chemistries to produce a diverse set of membranes. These membranes will enable microfluidic devices to be used with more complex solutions eventually including environmental samples.

Examples of Applications

While ion exchange membranes have been studied for many decades and have been applied to many areas, they are only beginning to be applied to microfluidic applications. The primary area that ion exchange membranes have been applied to in microfluidics has been for the pre-concentration of analytes in microfluidic systems. Pre-concentration is of critical importance in microfluidic systems because the analyte concentrations are typically too low for the detection methods used. This requires that the

analytes be concentrated prior to separation and/or detection in order to enhance the detection limits of the systems. In addition to pre-concentration applications, ion-exchange membranes have started to be demonstrated for other applications in microfluidic devices. One application is using ion-exchange membranes in conjunction with electrokinetic pumps [7], which are devices that pump liquid in a microdevice when an electric field is applied. In this device, the ion-exchange membrane served to electrically isolate the pump from the rest of the solution while still enabling the liquid flow that is generated by the device to flow through the system. This extends the utility of on-chip electokinetic pumps because the solvent requirements for the electrokinetic pump can be separate from the solvent needs for the rest of the device.

Another microfluidic application for ion-exchange membranes is ion suppression [8]. This approach involves allowing excess ions in one solvent to flow through ion-exchange into another waste solvent. This has the effect of suppression of the unwanted ions, and allows the conductivity of the solution to be measured and to measure the presence and concentrations of analytes of interest, such as heavy metals.

Isentropic Flow

Definition

Formally, a flow which is both adiabatic and reversible, and hence entropy remains constant. In practice, this is a flow in which sources of irreversibility (e. g., friction, thermal diffusion, chemical non-equilibrium) are considered negligible. Shock-free compressible flows are typically modeled as isentropic.

Non-directional etching

Definition

Isotropic etching includes all etching processes with equal etch rates for all spatial directions. Isotropic etch processes are rate controlled either by transport processes with direction-independent transport rate (most frequent case of isotropic etching) or by surface processes in the case of removing completely isotropic built materials. Isotropic etching includes wet chemical processes as well as dry etching processes.

Overview

Microlithographic etching represents a class of key processes of planar technology. Etching plays a very important role in microsystem technology and in the fabrication of integrated circuits. All etching processes are applied for removing material from solid films in order to generate small well-defined structures of functional material. Therefore, microlithographic etching is one of the so-called subtractive micropatterning techniques. In this process, firstly, a complete film of a certain material (functional material) is deposited at the surface of a substrate. Secondly, this film is covered by a light- or radiation-sensitive film *(resist)*, which is exposed and developed for patterning. And thirdly, the functional film is etched through the openings *(windows)* of the resist.

Etching processes can be applied for thin films, but also for ultrathin films, thick films and bulk materials. It is frequently applied for the generation of microstructures but can also be used for the preparation of features down to the nanometer range.

All etching processes are based on the conversion of a solid material in a movable form and the removal of the atoms of the material from the surface. Two general types of etching processes are distinguished. The first, micropatterning by liquids *(etching baths)*, is called *wet etching*. Sometimes the wet etching techniques are also summarized as *chemical etching*. This is not completely correct, because the dry etching processes are also frequently determined by specific chemical processes. The second process, etching by transfer of the released material into the gas phase, a plasma or vacuum, is called *dry etching*. Frequently, dry etching processes are classified as *physical etching* due to the predominance of physical effects in the etching process and in contrast to chemically dominated wet etching.

Basic Methodology

Modern microtechnology uses a wide variety of etching techniques (Fig. 1). There are two main classes of etching processes. Corrosive liquids are used in wet etching. Highly reactive corrosive gases, plasmas and ion beams are applied in dry etching processes. In addition, etching procedures are distinguished by selectivity of material removal and by the isotropic or anisotropic character of pattern transfer. Anisotropic etching can take place in wet and in dry etching processes. The principal difference between anisotropic and isotropic etching processes consists in the angle of the side walls and the distance of underetching under the resist mask. Crystallographic etching represents a special case of anisotropic processes (Fig. 2). A significant undercutting of mask edges always takes place in isotropic etching (Fig. 2a). Etch grooves are marked by rounded profiles. In contrast, particular crystal planes with high etch resistance are prepared during crystallographic etching. Different variants of trapezoid profiles are formed during time-controlled crystallographic etching if the crystal planes with low etch rate are inclined (Fig. 2b). V-grooves or pyramidal holes are obtained in such materials (for example Si(100)) after complete removal of material following crystal planes with higher etch rate. The depth of these V-shaped grooves or pyramidal holes is determined by the lateral width of the mask window (Fig. 2c). The shapes of grooves formed in isotropic etch processes are marked by considerable underetching (at least in the dimension of the etch depth) and – in most cases – by a smaller angle of the side walls (Fig. 3).

Wet etching processes use the conversion of solids into a state of solvated ions or molecules or into dissolved coordination compounds. In many cases metals or semiconductors have to be removed. Therefore, the formation of coordination compounds or ions must be accompanied by an electron transfer step. Wet etching of metals and semiconductors is an electrochemical process (Fig. 4). The removal of material is caused by the transition of metal atoms at the surface to metal ions and the formation of a soluble species (anodic partial process). The remaining electrons must be removed by a second electrochemical process, in which an oxidizing agent is reduced at the surface (cathodic partial process). Both electrochemical partial processes are coupled by a common electrode potential. So, an electric current flows from the cathodic to the anodic active surface sites. Oxidizing agents of sufficient high oxidation power (redox potential) are necessary for keeping the electrode potential high enough for the anodic process of metal dissolution.

Wet etching processes work isotropically, if the material is isotropic or the etching process is transport-controlled. Isotropic etching results in equal etch rates in all directions. An undercutting of the resist edges in the dimension of the film thickness is always observed. The isotropic character of etch processes makes it impossible to generate openings with high aspect ratios. But, it can be applied for the controlled release of cantilevers, air bridges and other movable structures for micromechanics by underetching. In contrast, anisotropic etching is observed if a single-crystalline material is etched with rate control of the anodic surface process. The alkaline etching of silicon single crystals is a typical example of an anisotropic wet etching process. It supplies characteristic features like V-grooves, trapezoid channel cross-sections, pyramidal grooves and rhomboid patterns, depending on the crystal cut and orientation of the lithographic pattern in relation to the crystal planes (see Fig. 2). The etching characteristics (isotropic or anisotropic) can be adapted by choosing a suitable etch bath.

Dry etching processes can be based on purely mechanical removal of material by ion impact (physical or sputter etching (PE) and ion beam etching (IBE)) or on the removal of material by very reactive gases or plasmas (plasma etching) or by combinations of both process types (reactive ion etching (RIE), reactive ion beam etching (RIBE) or chemical-assisted ion beam etching (CAIBE)). Plasma etching occurs in a moderate vacuum (typically around 1 torr). The active etching species are radicals in most cases. Therefore, this etching technique shows comparatively high selectivity, but only a low anisotropy. As a rule, considerable underetching is observed. A higher precision of pattern transfer from the resist into the functional layer is achieved by sputter or ion beam etching. In these processes, highly accelerated ions impact the material and evaporate clouds of atoms and clusters. The particle energies are in the range between several hundred and several million eV. Energies of several keV are typical for many processes. Therefore, the pressure has to be in the region of a millitorr or below. Sputtering and ion beam etching are not selective. RIE, RIBE and CAIBE combine the sputter effect of accelerated ions with the specificity of plasmochemical reaction. With optimized devices and protocols, comparatively high etching rates, high anisotropy and a certain material specificity can be achieved. The pressure is typically in the range between about 0.1 and 10 mtorr. The etch rates depend on the material, on the ion current density and on the reactivity and concentration of active radicals. For RIE, RIBE and CAIBE, reactive gases are fed into the etch equipment. Typical etching gases are chlorine (for aluminum), CF_4 or other fluorine-containing small molecules for etching of silicon and some other semiconductors and metals, and oxygen for etching of polymers. In contrast to these tech-

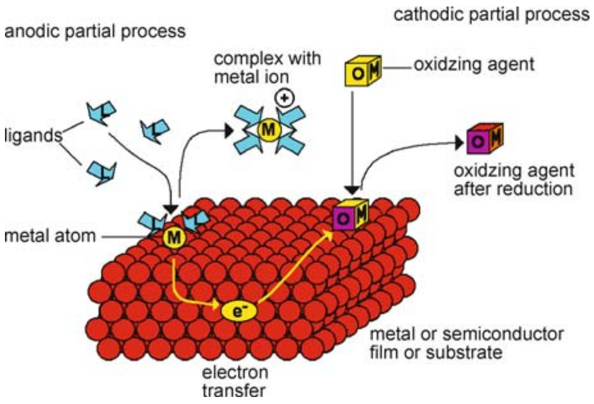
niques, the plasma technique is the only isotropic dry etch technique.

Key Research Findings

Wet Etching

Isotropic wet etching can be applied for nearly all materials, in principle. Wet etching consists in the transfer of solid material into the liquid phase by the formation of molecular dispersed species. A crucial precondition for this transfer is solvation. Therefore, all etch baths have to contain solvent molecules or other components with high solvation power in relation to the material to be etched. For oxides, hydroxides and similar materials, special coordinating ligands are necessary, in most cases, for dissolution in addition to the solvent. The ligands must form stable and soluble complexes with the metal atoms of the material. Stable oxides can be etched mostly only by substitution of oxygen from the coordination sphere by an element with a higher stiffness electron shell (low polarizability). Fluorine is the only element that meets this demand. That is the reason that many etch baths contain hydrofluoric acid or fluoride ions (see Spierings [6]). Fluoride ions are necessary as ligands in all baths for the etching of oxides of metals with higher oxidation number, which means ions with the character of a hard Lewis acid. The fluoride ion represents a very hard Lewis base and forms fluoro complexes which are completely solvated and can diffuse into solution. In particular, silicon dioxide as well as silicate compounds and inorganic glasses are etched isotropically by etch baths containing fluoride ions. Thereby, the hexafluorosilicate complex is formed from the stable oxidic material. In analogy to silicon oxide, other stable metal



Isotropic Etching, Figure 4 Partial processes during the open-circuit wet etching of metals and semiconductors (schematic): M, metal; OM, oxidizing agent; L, ligand; e^-, electron

and semiconductor oxides of low polarizability ions can be etched by fluoride-containing solutions, for example titanium dioxide.

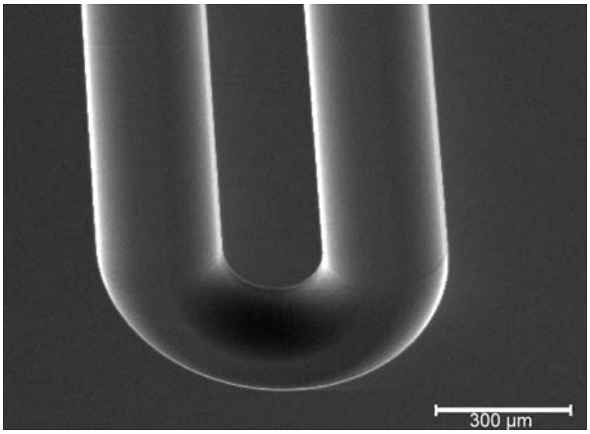
Frequently, the interface between oxidic materials and photo or electron beam resists is sensitive to etch baths containing fluoride ions. So, in these cases the resist mask cannot be used directly for patterning of oxidic materials like silicon dioxide and glass. This is also the case for the fabrication of fluidic microchannels in glass substrates. Therefore, an auxiliary metal or semiconductor film is applied for patterning. This film is first patterned lithographically. The resist is then stripped and the metal film is used as an etch mask for the oxide. Films of chromium, nickel–chromium, polysilicon or titanium are used frequently as masks for the isotropic etching of glass.

Softer Lewis bases have to be applied in etch baths for oxides and salts of metals or semiconductors with a softer Lewis acid character of their cations. Materials consisting of compounds of heavier metals frequently become dissolvable in the presence of higher halogenide ions like chloride or bromide. So, Cu(I) which is not well solvated in water as the unbound ion, becomes dissoluble in the presence of, for example, chloride ions by forming Cu(I) chlorocomplexes. The choice of suitable complex ligands depends on the particular coordination chemistry of the heavier metals or semiconductors inside the oxidic or salt-like functional materials. In some cases, ammonia or amines are suitable. So, the formation of a silver diamine complex can be used for the etching of Ag(I) compounds, for example. Also, sulfur-containing compounds (thiols, thiourea) are efficient additives for the dissolution of some soft Lewis acids because of their soft base character. In many cases, chelate ligands as diamines support dissolution efficiently.

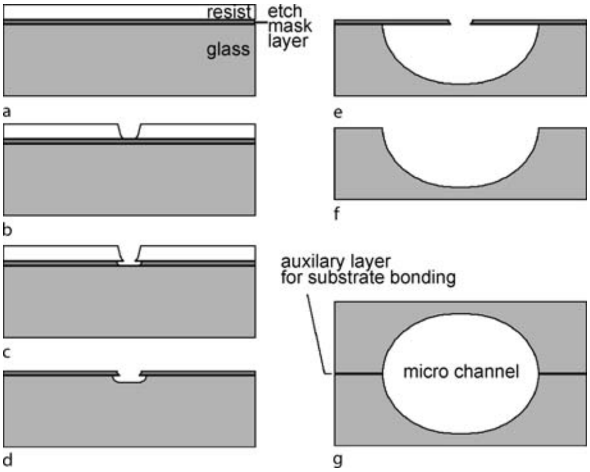
Low molecular weight organic materials can be dissolved simply by application of suitable organic solvents. As a rule, the dissolution of linear polymers also succeeds by choosing suitable solvents. In contrast, covalently cross-linked polymer matrices cannot be dissolved by simple dissolution. In this case, etch baths must contain components that are able to break the chemical bonds inside the polymer chains or inside the molecular bridges. This breaking of bonds demands oxidizing agents of high redox potential. Such agents are not compatible with organic solvents by reason of their redox reactions with the solvent. So, they are applied in aqueous solution in most cases. However, this means that the organic matrix must be decomposed completely by the etching bath. Typical oxidizing agents for removal of polymer layers are the same as components of cleaning baths for the removal of organic contaminations. Therefore, strong oxidizing water-soluble agents like hydrogen peroxide, peroxosulfates or dichromate are applied. Organic resist masks cannot be used for the application of these etching baths, because they are damaged or destroyed. So, inorganic films like silicon dioxide, silicon itself or metals like titanium or chromium are used as the mask layer in these cases. Isotropic etching of polymers by these baths can also be applied for the removal of polymers as sacrificial layers below functional structures of inert materials.

Oxidation is also needed in addition to solvation in all etching processes of metals and semiconductors. In most cases, this process is performed without an outer current. This means that the anodic subprocess which corresponds to the formation of metal cations is completely compensated by a cathodic partial current, which must be realized by the electrochemical reduction of an oxidizing agent of suitable electrochemical potential. Open-circuit (electroless) wet etching processes lead to the formation of a mixed electrode potential, which depends on the involved materials, composition of the etching bath, temperature and transport conditions inside the liquid. The etch rate corresponds to the anodic partial current density and is, therefore, directly dependent on the electrochemical potential. The selectivity of wet etching of certain metallic materials can be very high. It can be controlled by choosing the redox potential of the oxidizing agent, the selection of suitable ligands, the pH value and the temperature. Additionally, electrochemical passivation can help in achieving selectivity.

The electrochemical character of metal and semiconductor wet etching is responsible for some special features in the etching processes. Electrochemical processes always include a characteristic series of process steps. So, ligands must first diffuse to the solid surface. Than the surface process with the electrochemical charge transition can occur.



Isotropic Etching, Figure 5 Micro channel obtained after isotropic etching in glass (scanning electron micrograph, scale bar: 0.3 mm, IPHT Jena)



Isotropic Etching, Figure 6 Preparation of microchannels with nearly circle-shaped cross-section: (**a**) substrate covered by mask layer and photoresist, (**b**) resist structure after exposure and development, (**c**) etching of transfer layer (mask for isotropic glass etching), (**d**) starting glass etching after removal of photoresist, (**e**) finished near circle-like profile after isotropic glass etching, (**f**) half-shell with channel structure after removal of etch mask (transfer layer) and (**g**) completed microchannel after bonding of two complementary half-shells

Finally, the complexes formed have to desorb from the surface and diffuse into the solution. The slowest of these three steps determines the rate of the overall process. Ideal isotropic behavior is found if one of the diffusion steps is rate-determining. Diffusion is caused by the Brownian motion of particles and therefore is independent of direction. That is the reason that transport control in wet etching results in isotropic etch behavior.

Transport control is always associated with an enhancement of transport efficiency at the edges of etch windows. This effect is due to the additional space for diffusion near the edges of lithographic features. Transport control in the anodic subprocess is therefore always accompanied by edge effects in etching. The central parts of a feature are more slowly removed than peripheral parts. The same effect is responsible for an enhancement of the etch rate of small features in comparison with larger features. Size effects are typical for isotropic etch processes. If the distance between several structures is comparable to or smaller than the characteristic diffusion length (normally some tens up to some hundreds of micrometers), the size effect can lead to pattern-dependent etch rates because then the degree of coverage determines the total diffusion current to or from the surface.

The transition of metal or semiconductor atoms into cations or complexes is the anodic subprocess. The electrons delivered by this process must be consumed by an outer electrical current or by a cathodic subprocess in order to keep the electrode potential high enough for the etching. As well as transport control in the anodic subprocess, the cathodic process can also be transport-controlled. The convection and the concentration of oxidizing agent inside solution are responsible together for the intensity of the cathodic process. The cathodic process does not occur exactly at the same place on the surface as the anodic process. So, a local current also flows in the case of an outer currentless etching process. The local current can also flow to areas of metals which are not dissolving at a certain electrode potential in the case of the presence of two or more metals which are in electrical contact. In this case, the area ratios of different materials can effect additionally the etch rate.

Plasma Etching

Transport control under diffusional limitation is also the precondition for isotropic etching in dry etching processes. At low pressure (below about 0.1 torr), as is applied in all ion beam and ion etching procedures, the probability of collisions between particles is so low that the directed transport dominates. As a result, etching is always anisotropic.

Plasma etching takes place at pressures between about 0.1 and some tens of torr. The plasma contains only low concentrations of ions, but high concentrations of free radicals. These free radicals are the active species for etching. At comparatively high pressure, the radicals move by diffusion. The free path lengths are smaller than the typical dimensions of microfluidic channel structures. So, the diffusive character of radical transport is also given in the direct environment of the etch areas. The reaction rate of suitable radicals with the species at the solid surface is

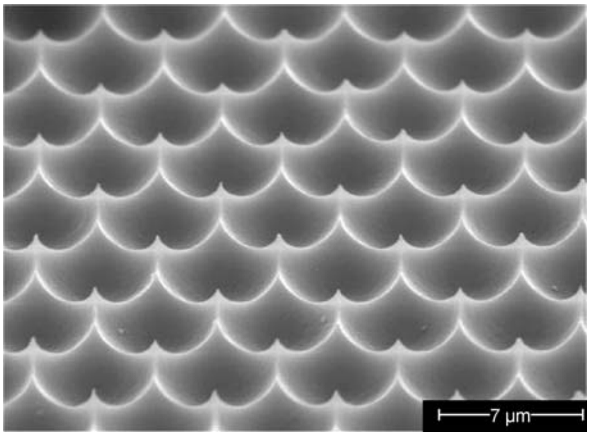
normally very high due to the high reactivity of radical species. As a result, the transport of radicals to the surface or the transport of reaction products from the surface into the gas is slower than the surface reaction itself. So, the conditions for transport-controlled process rates are present.

Analogous to isotropic wet etching processes, plasma processes can be used for undercutting of etch masks and for the preparation of free-standing membranes and other free-standing structures. They can also be used for the preparation of microchannels inside different materials. Fluorine-containing plasmas are mainly applied for the patterning of glass or quartz glass substrates as well as for the patterning of silicon dioxide films. Instead of free fluorine, tetrafluoromethane, difluoroethane or sulfur hexafluoride are mainly applied. The electrical excitation of the plasma leads to the formation of fluorine radicals which are very reactive. They form silicon tetrafluoride by the reaction with glass and similar materials. Silicon tetrafluoride is gaseous, desorbs quickly from surfaces and can easily be removed from the etching vessel by pumping.

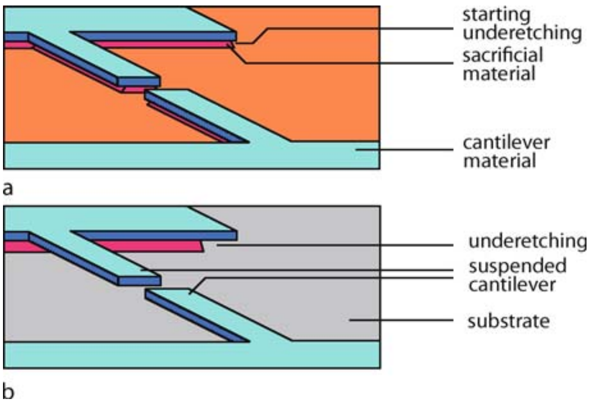
Isotropic Glass Etching for Micro- and Nanofluidic Applications

For micro- and nanofluidics, the wet etching of glass is of particular importance. Isotropic wet etching is applied for the generation of rounded channel structures and for preparation of channels with circular or nearly circular cross-sections. Cross-sections with a nearly circular shape demand etch windows that are much smaller than the resulting channel. The lithographic etch process is an underetch process for the most part. The isotropy of the wet etching process results in equal etch rates in all etching directions. The direction-independent etch rate causes the formation of circle-like geometries. Round structures are obtained in all three spatial directions. Rectangular corners in the windows of the resist mask become a quarter of a circle in the substrate plane. Long slits in the mask are transferred in half-cylindrical etch grooves. Small openings in the resist mask are transferred into a groove with the shape of a half sphere during the underetching.

Round, smooth structures are obtained if there are small openings in the mask layer. In this way, channels of different width and orientation can be prepared (Fig. 5). Circular cross-sections are formed by bonding of complementary half-shells after isotropic etching and removal of the etch mask (Fig. 6). Regular arrays of small openings can also be used for the generation of certain surface topographies. An example of a periodic surface pattern obtained after isotropic etching through an array of small windows with complete lifting of the mask layer is shown in Fig. 7.



Isotropic Etching, Figure 7 Regular microtopography after isotropic etching of a plane substrate through a mask layer with a two-dimensional array of small openings (scanning electron microscopy image of the tilted substrate; scale bar, 7 μm; IPHT Jena)



Isotropic Etching, Figure 8 Preparation of free-standing structures by isotropic etching of a sacrificial layer: (**a**) intermediate etching state after removal of the sacrificial material in the openings of the mask; (**b**) residual sacrificial material under the beam structures; (**c**) final state with free-standing cantilevers after complete removal of the sacrificial material under the beam structures

The selective isotropic etching of glass substrates can be applied in order to generate movable microstructures (bulk micromachining). These structures are of importance, for example for the preparation of valves and pumps in microfluidics. The complete removal of film material below small film elements by isotropic etching is also used for the preparation for free-standing bridges and cantilevers in surface micromachining (Fig. 8).

Future Directions of Research

Etching is an old and very well-established technology, in principle. But, several details of etching mechanisms are not completely known. New challenges arise from new

demands of geometries of microlithographically etched structures and from new types of materials.

New structural demands include

- further miniaturization,
- microstructures with freely defined three-dimensional structures and
- the use of self-organization principles in microstructuring.

Special challenges from new materials are related to

- the etching of very stable materials,
- the improvement of selectivity in the case of two or more materials exposed to etch baths or plasmas and
- the etching of anisotropic materials, nanoheterogeneous materials and nanocomposite materials.

There are several methods for preparing masks in the mid and lower nanometer range. Electron beam lithography (EBL) or focused ion beam lithography (FIBL) can be applied. In addition, scanning probe techniques can used for creating nanometer-sized mask patterns. Etching processes use the conversion of solids into small molecules or atoms which can be taken away by gaseous or liquid media. The only serious problem is that isotropic etching is mainly used for the generation of rounded geometries by matching the required time for material removal. So, the problem of miniaturization is less related to the etching itself but to the time control of etching and to the homogeneity of the materials. Transport-controlled processes are always fast in comparison with surface-controlled processes. Thus, exact rate control and very precise determination of the starting and ending of etching steps is required if ultrasmall structures are to be generated.

Technical micropatterns are mainly generated by the use of lithographic techniques. In contrast, nature uses molecular self-organization for the generation of a wide spectrum of different functional structures. It would be very helpful if patterning by self-organization could be used for the generation of mask structures or directly in etching of a certain micro- or nanopattern. In principle, there are several possibilities for spontaneous pattern generation, for example by relaxation structures in double or multilayer structures under mechanical stress or by formation during autooscillating chemical processes. In most cases, the spontaneous evolved structures are not controlled precisely enough for technical use and the reproducibility is too poor for technical applications. It is assumed that the further miniaturization of lithographic structures down to the mid and lower nanometer range will enforce the challenge for the application of self-organization principles in the generation of micropatterns by etching.

The lithographic etching of highly stable materials remained a serious problem over the whole long tradition of etching. Patterning always requires mask layers. The mask materials must be more stable than the material to be etched in the etch baths or plasmas. Hence, it is necessary to apply special auxiliary layers or special mask materials for highly stable materials. In isotropic etching, in which no highly accelerated ions are applied, the differentiation between stable mask material and patterned functional material must always be realized by chemical specificity. That demands special developments for etching of noble metals and alloys, for passivating metals and, in particular, for highly stable materials like carbides and nitrides.

In most devices a group of materials is involved in order to realize different functions. Isotropic etch processes are mainly marked by high selectivity. But, the majority of materials used in different technical applications now demand the adaptation of etch baths and plasma procedures for the realization of new selectivities. The protection of materials is of particular importance in the case of very thin films and small features. Selectivity also becomes important in the case of integration of a diversity of sensors and actuators consisting of different materials. This is the case, for example, in micro- and nanofluidic devices equipped with special micropatterned transducers. The homogenous etching of inhomogeneous material is the opposite demand to high selectivity and is a real challenge for etching innovations. It becomes more and more important with the increase in use of nanocomposite materials. The problem is related to the fact that the etching procedure must take away all material independently of the specific chemical properties, in particular for the generation of isotropic etch patterns. A general solution leading to a universal etch medium for all classes of materials seems to be excluded. So, the demand remains for developing etch procedures for certain selective material combinations. It is comparatively easy to realize approximately equal etch rates in dry etching processes. In RIE, IBE, RIBE and so on, the removal of substrate atoms by impact of accelerated ions is only slightly dependent on atomic masses and the etch rates of different materials are approximately of the same order of magnitude for a given ion energy and ion density. In contrast, the isotropic plasma etching and the isotropic wet etching are marked by high chemical specificity. So, it is necessary to find suitable complex compositions of etch gases for plasma etching or complex compositions of etch baths with ligands and oxidizing agents in order to obtain equal etch rates of different materials inside composite materials.

Jet Pumping

Definition

Generation of fluid flow by the suction action generated in its surroundings by a fluid jet.

This effect is caused by entrainment of the surrounding fluid into the jet, which carries away this fluid away. It ahs has to be replaced by the fluid pumped into the vicinity of the jet by the jet pumping. The effect is much stronger in turbulent jets, existing at higher values of Reynolds number. In fluidic sampling units built using no-moving-part fluidic valves, the jet pumping is employed to remove fluids from the downstream spaces and thus to ensure purity of the handled fluid samples.

Jet-Type Rectifier

Definition

A device for fluidic rectification based on the inertial effects in a fluid jet formed by fluid flow issuing from a nozzle.

In fluidic pumps with the rectification performed without the action of any moving parts the conversion of an alternating flow into the desirable one-way flow is achieved by utilizing inertial effect if flowing fluids. To obtain these effects, the characteristic Reynolds number of the flow has to be sufficiently high. One way how such rectification is produced is based on the properties of a fluid jet accelerated in a nozzle and incapable of changing its flow direction while the return flow directed back into the nozzle may be easily turned by a quite large flow direction angle.

Joule Heating and Chip Materials

HUI YAN, HONGKAI WU
Department of Chemistry, Hong Kong University of Science and Technology, Hong Kong, China
chhkwu@ust.hk

Synonyms

Joule heating effect; Ohmic heating

Definition

Joule heating is named for James Prescott Joule, the first to articulate what is now Joule's law, relating the amount of heat released from an electrical resistor to its resistance and the charge passed through it. Joule's law gives the amount of heat Q liberated by a current I flowing through a resistor with a resistance R for a time t,

$$Q = Pt = I^2Rt\,.$$

An electrokinetic flow in a chip is a flow of liquid in a channel driven by an electric field.

Overview

When experiments are carried in microfluidic channels, forces are needed to drive liquids to flow through the microchannels. Electrokinetics is now being studied in a variety of forms, such as electroosmosis, dielectrophoresis, and electrowetting, for the purpose of controlling microflows in chips. While electrokinetic methods can greatly simplify species transport in microfluidic systems, a significant characteristic is the internal generation of heat (i. e. Joule heating) caused by current flow through the buffer solution. The equation for calculation of the Joule heating is given below and discussed in detail. The common chip materials, the surface modifications used in microchip electrophoresis, *electro-evoked methods*, and techniques for temperature measurements on chips are summarized. As a typical example of a study of Joule heating and its relation to the chip material, Joule heating and heat transfer in poly(dimethylsiloxane) microfluidic systems is briefly described. Finally, the key research findings in this area are summarized and future directions for research are proposed.

The development of microfluidics-based Lab-on-Chip devices involves the incorporation of many of the necessary components and functionality of a typical laboratory onto a small chip-sized substrate. When experiments are carried out in a Lab-on-Chip, forces are needed to drive liquids to flow through microchannels. Microfluidic flows are readily manipulated using many kinds of external field (pressure, electric, magnetic, capillary, and so on). As the dimensions shrink, the importance of surface forces relative to volume forces increases. Such manipulations of the flow can either be achieved by forces applied macroscopically, for example at appropriate inlets and outlets, or be generated locally within the microchannel by integrated components. Table 1 summarizes the frequently mentioned driving forces for controlling microflows.

Electrokinetics has also been applied in a variety of forms for controlling microflows. Examples include

- electroosmosis, where the fluid moves relative to stationary charged boundaries;
- dielectrophoresis, where an interface (often a particle) moves in a gradient of electric field; and
- electrowetting, where an electric field modifies wetting properties.

Both AC and DC fields can be used, and the system response then depends on the frequency and amplitude of the field. Both capillary-driven and electrically driven flows offer advantages relative to the more familiar pressure-driven flows as the device scale is reduced, though both types of flow may be hindered, or potentially even eliminated, by significant surface contamination or heterogeneities.

However, in the great majority of microfluidic circuits, especially those that use electrophoretic separation, fluid flows are driven and directed using electroosmotic flow. Electroosmotic pumps offer a number of advantages over micromachined pressure-driven pumps, such as ease of fabrication and the absence of moving parts. Moreover, the sample plugs suffer little from dispersion because the fluid velocity is nearly constant across the channel diameter. These pumps are usually controlled by manipulating an externally applied electroosmotic-flow-generating voltage. While electrokinetic means can greatly simplify species transport in microfluidic systems, a significant drawback is the internal heat generation (commonly referred to as Joule heating) caused by current flow through the buffer solution.

Recently, microfluidic systems and biochips made from low-cost polymeric materials such as poly(dimethylsiloxane) (PDMS) and poly(methylmethacrylate) (PMMA), as opposed to traditional materials such as glass or silicon, have become more and more prevalent. The primary attractiveness of these materials is that they tend to involve simpler and significantly less expensive manufacturing techniques (for example casting, injection and replica molding, and hot embossing); however, they are also amenable to surface modification, and the wide variety of physiochemical properties allows the matching of specific polymers to particular applications. While the

development of these systems has reduced the time from idea to chip from weeks to days, and the per-unit cost by a similar ratio (particularly with the advent of rapid prototyping techniques), the low thermal conductivities inherent in these materials ($0.18\,\mathrm{W\,m^{-1}K^{-1}}$ for PDMS, which is an order of magnitude lower than that of glass) retards the rejection of internally generated heat during electroosmosis.

Basic Methodology

Calculation of Joule Heating

If a liquid in an electric field between electrodes has an electrical conductivity σ, then the heating power P per volume element V depends linearly on σ and on the square of the electric field strength E, with E being proportional to the voltage U applied to the electrodes:

$$q = \frac{P_{\mathrm{heat}}}{V} = \sigma \cdot E_{\mathrm{rms}}^2 \propto \sigma \cdot U_{\mathrm{rms}}^2 \,, \tag{1}$$

where *rms* denotes the root mean square value. In the steady state, P_{heat} equals the power P_{diss}which is dissipated through the surface S of the volume under consideration. If P_{diss} is regarded as being mainly determined by heat conduction, then Fourier's law,

$$P_{\mathrm{diss}} = \lambda \cdot \frac{S}{d} \cdot \Delta T \,, \tag{2}$$

applies, where λ denotes the thermal conductivity. At a distance d from the surface S, a temperature rise of ΔT relative to the environment occurs inside the heated volume. Consequently, $P_{\mathrm{heat}} = P_{\mathrm{diss}}$ can be solved for ΔT, which in the case of a cubic volume with side length a yields $\Delta T = k \cdot U^2$, where $k = d/(6 \cdot a \cdot \lambda)$. The center of a cube has a mean distance from its surface of $d = (a/36) \cdot \left(6 \cdot \left(\sqrt{3} + \ln(7 + 4 \cdot \sqrt{3})\right) - \pi\right) \approx 0.64 \cdot a$. However, σ itself varies with the temperature. Therefore, σ ought to be replaced by a linear dependence $\sigma = \sigma_0 \cdot (1 + \alpha \Delta T)$, where $\alpha = 0.022\,\mathrm{K}^{-1}$, which leads to

$$\Delta T = \frac{k \cdot \sigma_0 \cdot U^2}{1 - \alpha \cdot k \cdot \sigma_0 \cdot U^2} \,. \tag{3}$$

The temperature dependence of λ is one order of magnitude smaller than the effect of temperature on the electrical conductivity and, therefore, is neglected in the following. These considerations provide an estimate of ΔT. Only for simple electrode designs can the resulting temperature field be derived analytically. Usually, a numerical approach is required to calculate the distribution of the electric field E and of the T field.

In Jaeger's study [4], a finite difference method was used to iteratively solve the system of complex field equations (charge conservation law for temporal periodicity) $\nabla\left((\sigma + i \cdot \omega \cdot \varepsilon) \cdot \nabla\Psi\right) = 0$ with $\boldsymbol{E}(\boldsymbol{r}, t) = -\nabla \mathrm{Re}(\Psi \boldsymbol{r}) \cdot e^{i \cdot \omega \cdot t}$), coupled via the Joule heating to the temperature T, which was determined by $\nabla(\lambda \cdot \nabla T) = -q$. Here, r and t are the spatial and temporal coordinates, respectively, Ψ is the electric potential, Re denotes the real part, $i = \sqrt{-1}$, and $\omega = 2 \cdot \pi \cdot f$. A fixed temperature and no electric current were assumed at the outer boundaries. The T field thus evaluated describes how far the temperature increase extended along a microchannel. As Eq. (1) shows, the warming is proportional to the square of the electric field strength. Figures 1a and b show fields in a region of size $280\,\mu\mathrm{m} \times 200\,\mu\mathrm{m}$ that were obtained using a grid of size $90\,\mu\mathrm{m} \times 90\,\mu\mathrm{m} \times 50\,\mu\mathrm{m}$ with a $4\,\mu\mathrm{m}$ mesh width. In Fig. 1a, the red areas near the electrodes (white bars) are areas with a high electric field strength, and the thin black lines show equipotential lines. Therefore, as a consequence of Eq. (1), the heat production is maximal in the vicinity of the electrodes. This, however, does not coincide with the region of highest temperature, because in a stagnant liquid the thermal energy can be dissipated only through heat conduction, which in glass is about 1.5 times higher than in a buffer solution (Fig. 1b). As Fig. 1c shows additionally, the warming between two electrodes also depends on their size. The two horizontal solid lines represent electrodes ($U = 1\,\mathrm{V_{rms}}$) which extend infinitely normal to the plane of the paper. They have a width of $40\,\mu\mathrm{m}$ and a distance between them of $40\,\mu\mathrm{m}$. The dashed lines indicate the ceiling and floor of a channel formed in $55\,\mu\mathrm{m}$ thick glass and filled with aqueous buffer ($0.27\,\mathrm{S\,m^{-1}}$). In Fig. 1d, this relationship is quantified numerically. Obviously, ΔT scales almost linearly with the electrode width. In contrast, the dielectrophoretic force experienced by a particle in the vicinity of the two electrodes approaches a constant value. This is because the force F is a function of the gradient of the electric field. A particle of radius R showing negative dielectrophoretic behavior will be levitated to the central plane between the two electrodes. There, the maximum repulsive force can be simplified to $F = 2\pi\varepsilon_0\varepsilon_1(R/d)^3 \mathrm{Re}\,(f_{\mathrm{CM}}) U_{\mathrm{rms}}^2 f_{\mathrm{s}}(x/d)$, where the permittivity of the liquid is ε_1, the distance between the electrodes (channel height) is d, and the complex Clausius–Mossotti factor, which relates the polarizabilities of the particle and the surrounding medium, is $f_{\mathrm{CM}} \cdot f_{\mathrm{s}}$ is a geometric scaling factor for the force and depends on the ratio between the electrode width x and the distance between the electrodes d (Fig. 1d). With increasing electrode width x, the electric field in the central region between the electrodes becomes increasingly homogeneous, like that in an infinitely extended capaci-

tor, and, consequently, does not contribute to the dielectrophoretic force. For a semi-infinite plate capacitor without heating, and not taking the liquid–glass interfaces into account, $\lim_{x\to\infty} f_s = (27\pi)/64$. As shown in Fig. 1d, normalization of the force exerted with the corresponding temperature increase suggests that an electrode width of approximately 15 μm is optimal for the configuration used. Figures 1e and f show the influence of covering the electrodes with a passivation layer, and the normalized electric field strength as a function of the layer thickness, respectively. In Fig. 1e, the electric field strength is normalized to the value that is reached in the absence of an insulating layer. The solid lines denote the results for a layer thickness of 600 nm, and the dashed lines the results for 700 nm ($\varepsilon_{\text{layer}} = 5$, $\varepsilon_{\text{liquid}} = 80$, $\sigma_{\text{layer}} = 10^{-6}\text{Sm}^{-1}$). The electrical conductivity of the liquid was 0.27, 0.546, and 1.5 Sm^{-1} for the red, green, and blue curves, respectively. The solid lines are for 9 MHz and the dashed lines are for 6.58 MHz in Fig. 1f.

Chip Materials

In microfluidic applications, the properties of the material that may be of fundamental importance include machinability, surface charge, molecular adsorption, electroosmotic flow mobility, optical properties, and many others. When a polymer-based substrate is chosen, the properties of the material are critical for both the fabrication process and the successful application of the device.

Material Properties and Fabrication

In many applications in the literature, plastics, rather than pure polymers, are used to fabricate microfluidic devices. Plastics can contain a number of additives that impact on their processing and shelf life, and these should be considered. These additives may include fillers (e. g. mica, talc, and calcium carbonate), plasticizers (e. g. dioctyl phthalate in PVC), heat stabilizers (e. g. organotin compounds in PVC), antioxidants (e. g. phenols and amines), and UV stabilizers (e. g. benzophenones and salicylates).

Different fabrication protocols have different and very specific constraints with regard to the properties of the material. For instance, with hot-embossing and injection-molding methods, the glass transition temperature, melt temperature, and thermal expansion coefficient are some of the most critical parameters for successful fabrication. Cross-linked polymers and thermoplastics that con-

tain very long polymer chains with strong intermolecular attractions do not melt and flow, but remain soft until they decompose. The thermal expansion coefficient is related to the change in length or volume resulting from a specified change in temperature. This parameter is important not only in several fabrication processes, but also in sealing processes, where different materials are thermally bonded.

Material Properties and Applications

Electroosmotic pumping is the most common method used to propagate flow in microfluidic systems. In electroosmotically driven systems, it is critical that the substrate material exhibits good electrical insulating properties so that the electric field will drop across the fluid-filled channel and not through the substrate. This effect may be evaluated in terms of several parameters, including the dielectric strength and electrical resistance. The dielectric strength is the voltage that can be applied across an insulator before breakdown occurs. The dielectric strengths of several common polymers are given in Table 2.

A second consideration when using electrically driven pumping is heating. It is well established that Joule heating can be substantial in systems employing electroosmotic flow. If heat is not effectively dissipated in a microchannel system, elevated local temperatures can dramatically impact on the efficiency of chemical separation, and induce solution degassing and eventually boiling. With plastics that have a low melting temperature, highly localized heating can also cause significant channel deformation. Therefore, heat dissipation in the substrate material is a very important consideration when electroosmotic pumping is utilized. The capacity for heat dissipation is characterized by the thermal conductivity of the material. The thermal conductivities of several polymers are given in Table 2. For comparison, fused quartz has a higher thermal conductivity $(33 \times 10^{-4}\ \mathrm{g\ cal\ cm\ s^{-1}\ cm^{-2}\ {}^{\circ}C})$ and a much higher melting point (1665 °C) than most plastics.

A third consideration when using electrically driven pumping is charge in the microchannel. Electroosmotic flow is generated by the surface charge on the microchannel walls in combination with an electric field along the microchannel. Because polymer materials exhibit a wide range of charge densities, the electroosmotic flow in microchannels made from different polymer materials is highly variable. Electroosmotic flow has been measured in various polymer microchannels fabricated by laser ablation and by imprinting, and in PMMA channels fabricated by LIGA methods. These measurements indicate that the fabrication method, as well as the material itself, can affect the surface charge density and therefore can have a profound effect on the electroosmotic flow. For instance, laser-ablated channels support higher electroosmotic flow than channels that have been hot-embossed in a similar material owing to the fact that reactive species are incorporated into the microchannel surface during the ablation process. The location of charged groups on PMMA substrates has also been determined to be dependent on the fabrication procedure; for example, room-temperature-imprinted channels can have highly charged walls, whereas hot-embossed channels fabricated in a similar material have a low surface charge density on the walls. Finally, the surface charge and electroosmotic flow can also be modulated in polyethyleneterephthalate (PETG) by alkaline hydrolysis and in PDMS by plasma treatment. Charge density, charge location, and electroosmotic flow can therefore be controlled by several parameters including the choice of polymer material, the fabrication protocol, and various surface treatments.

Other material parameters that are critical to the successful application of microfluidic devices include autofluorescence (when optical detection is used), permeability (when living cells are used), chemical resistance (when nonaqueous solutions are used), and analyte adsorption. Table 2 lists the chemical resistances of several common polymeric materials. Analyte adsorption is a parameter that is highly dependent on several material characteristics, including hydrophobicity and surface charge. The biocompatibility of many plastic materials is associated with both of these parameters and has been evaluated and characterized extensively in the biomedical engineering literature.

Surface Modification in Microchip Electrophoresis

Surface chemistry is also of great importance in chip-based microfluidic devices, especially in highly miniaturized and integrated systems, owing to the high surface-area-to-volume ratio. The motivations for performing surface manipulation are similar to those for classical *CE*.

Microchannel wall coatings can be separated into two major categories: permanent coatings and dynamic coatings (physically adsorbed coatings). In permanent coatings, chemical compounds (often polymers) are covalently bound to functional groups on the surface or immobilized (e. g., via cross-linking of a polymer) at the surface so as to become insoluble in the electrolyte. In dynamic coatings, dissolved surface-active compounds are utilized, which adsorb strongly at the surface. This can be accomplished by rinsing with a solution of the modifier prior to analysis or by addition of the modifier to the electrolyte. As the adsorption/desorption process is reversible, the adsorbed compounds will participate in an exchange process with the solution and significant amounts of the surface-active

compounds can be present in the electrolyte. This can be detrimental in the case of affinity studies, *MS*-coupling, and chemical reactions.

Some Electrokinetic Methods

Electrophoresis (see Fig. 2) is the migration of electrically charged particles in solution or suspension in the presence of an applied electric field. Each particle moves toward an electrode of opposite electrical polarity. An electrophoresis experiment may be either analytical, in which case the objective is to measure the magnitude of the electrophoretic mobility, or preparative, in which case the objective is to separate various species that differ in their electrophoretic mobilities under the experimental conditions of the solution. *Capillary zone electrophoresis* is the simplest and most widely used form of capillary velectrophoresis. The capillary is filled with a homogeneous buffer, and compounds are separated on the basis of their relative charge and size. Most often, fused silica capillaries are employed. In this case, an electrical double layer is produced at the capillary surface owing to the attraction of positively charged cations in the buffer to the ionized silanol groups on the capillary wall. In the presence of an electric field, the cations in the diffuse portion of this double layer move toward the cathode and drag the solvent with them, producing an *electroosmotic flow*. The electroosmotic flow is pH-dependent, and it is highest at alkaline pH values. *Dielectrophoresis* is a phenomenon in which a force is exerted on a dielectric particle when it is subjected to a nonuniform electric field. This has allowed, for example, the separation of cells and the orientation and manipulation of nanoparticles.

Some Techniques for Making Temperature Measurements on Chips

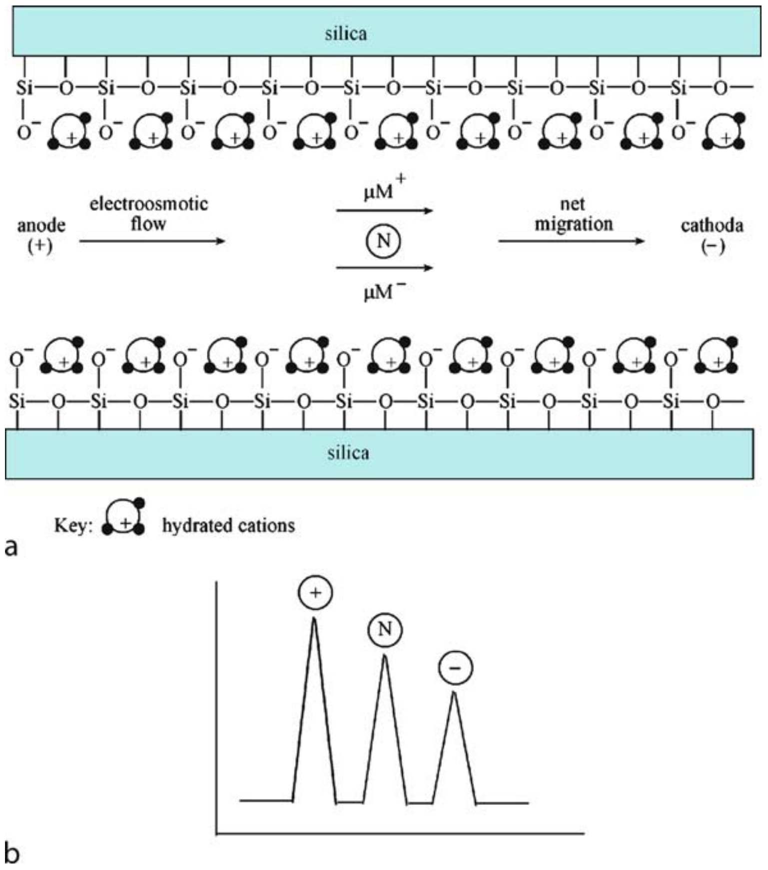
Reliable measurement and control of temperatures on the microscale are required to develop electrically driven microdevices such as microreactors and PCR and μTAS systems. There exist various techniques for temperature measurement in microdevices. These techniques can be largely classified into contact and noncontact ones. While resistance thermometers, thermocouples, thermodiodes, and thermotransistors measure the temperature at a specified point in contact with the sensor, techniques based on infrared thermography, thermochromic liquid crystals (TLCs), and temperature-sensitive fluorescent dyes such as rhodamine-B, whose emission intensity is sensitive to temperature, measure the temperature of the whole field.

Resistance Thermometry

Resistance thermometry, which is based on the variation of resistance with temperature, is one of the most traditional techniques used for temperature measurement on the microscale. It is stable and is applicable to a wide range of temperatures, but it is subject to inaccuracies from self-heating since it requires the use of an electric current to make measurements. Among the various types of resistance thermometry, resistance temperature detectors (RTDs) and thermistors are most frequently used for microscale temperature measurement. In general, RTDs are made from metals, whose temperature coefficients of resistivity are positive and linear, whereas thermistors (semiconducting thermoresistors) are made from ceramic materials whose temperature coefficients of resistivity are much higher than those of metal resistors and show negative and highly nonlinear behavior. The resistance material and the sensor geometry are determined by the temperature range, the accuracy required, the measurement target (i. e., the application, and the fabrication processes available, the latter being particularly important for microdevices), and other factors. Polysilicon with a dopant is frequently used to fabricate microtemperature sensors. This kind of thermometry requires carefully controlled fabrication, including the use of sensor material of high purity; it also requires precise control of dose rate, and calibration of sensors. In particular, it is recommended that calibration of sensors should be performed, since the resistances of the sensor, lead wires, and contact pads can all be dependent on temperature.

Thermocouples

The thermocouple is one of the most common temperature sensors because it is inexpensive, reliable, and interchangeable, and covers a wide range of temperature. The operating principle is based on the well-known Seebeck effect: if two junctions between two different metals (e. g., copper and iron) are held at different temperatures, then an electromotive force (EMF) is generated and an electrical current flows between them. As the temperature increases, the output EMF of the thermocouple rises, though not necessarily linearly. Specifications of typical metal/alloy thermocouples are presented in Gardner. A thermoelectric generator to be applied to low-power devices has been developed, exploiting a working principle based on the Seebeck effect. The application of commercial thermocouples to microscale measurement suffers from some limitations, such as their relatively large spatial resolution of several hundred microns and their physical intrusiveness, especially into the flow. Recently, a microfabricated thermocouple array has been applied to measure the sur-



Joule Heating and Chip Materials, Figure 2 Electrophoresis. (**a**) Separation mechanism showing electrophoretic mobility of a positive ion (μM^{+}) and a negative ion (μM^{-}); N is a neutral molecule. (**b**) Migration order of the ions

face temperature distribution on a microchannel heat sink cooled by an impinging air jet, and served as a flow sensor to measure the velocity profile in the boundary layer very near the wall (about 65 μm from the surface).

Infrared Thermography

Infrared (IR) thermography is one of the most advanced nondestructive methods and is based on the fact that all bodies whose absolute temperature is above zero emit electromagnetic radiation, which ranges over a wide spectrum of wavelengths depending on the temperature of the object. The key element of an IR camera is the detector. IR detectors can be classified into two types: photon detectors, such as detectors based on indium antimonide (InSb) and mercury cadmium telluride (MCT), and thermal detectors, such as those based on deuterated triglycine sulfate (DTGS). There are two basic types of IR imaging system: mechanical scanning systems and focal-plane array (FPA) systems. The major advantages of FPA cameras are their lower price, simpler construction, quicker reading time, and high spatial and thermal resolution. But FPA cameras have some problems, such as the Narcissus effect, problems of cooling the semiconductor devices, and problems of image acquisition and processing. Further, there is no internal temperature reference for FPA cameras. This problem can be successfully overcome by calibrating frequently.

IR thermography has been applied to numerous engineering problems, such as turbulent heat transfer, temperature measurement of electronic systems, and defect diagnosis. Recently, several researchers have applied IR thermography to microscale temperature measurements. IR thermography has also used to confirm the formation of thermally isolated integral microhotplates, which is a key element in the development of arrays of micropellistors and conductivity-type gas sensors. The surface temperature of a heated capillary and the interfacial temperature during phase changes in capillary tubes have been measured using IR thermography. In particular, the

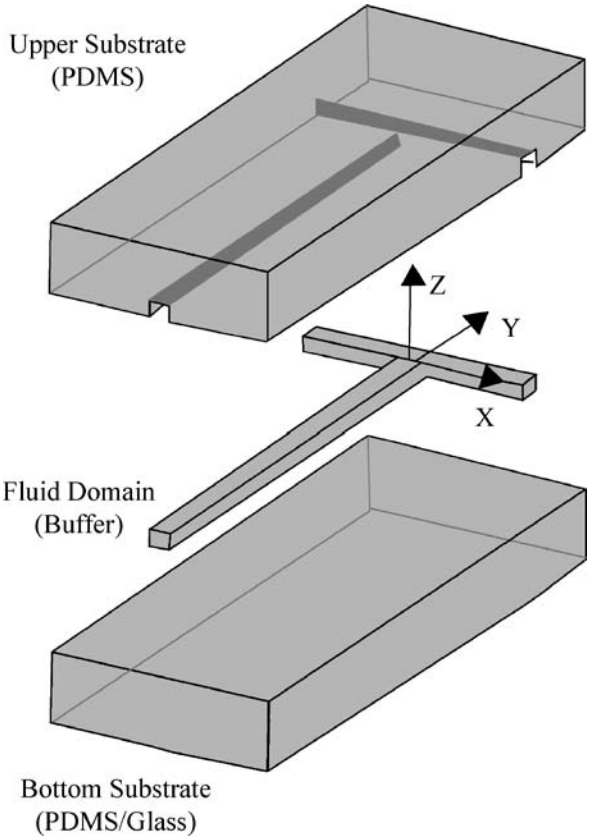
temperature profile generated by differential evaporation cooling along the meniscus interface was measured. The high spatial resolution and sensitivity of IR thermography allowed the strong evaporative cooling at the meniscus to be detected. IR techniques, however, have a critical problem when they are applied to temperature measurement of liquids. That is, the temperature is measured on the basis of the radiation emitted from an object, which means that it is necessary to know the emissivity accurately. However, the emissivity of a liquid is sensitive to the wavelength in the IR range. In addition, the transparent solid media used in windows and magnifying optics strongly absorb IR waves. Therefore, more careful consideration is needed when we use IR thermography.

Thermochromic Liquid Crystal

Thermochromic liquid crystals have the property that their dominant reflected wavelength is dependent on the temperature, and they have been employed for full-field mapping of temperature fields for over three decades. TLCs have been used in the form of a thin layer coated on a surface to visualize heat transfer from obliquely impinging jets on flat plate, to study heat transfer over film-cooled gas turbine nozzle guide vanes under transonic conditions, and to visualize artificially created turbulent spots in a laminar boundary layer over a heated surface under the influence of adverse pressure gradients. Here, special care was taken in relation to calibration and optical settings to obtain accurate temperature distributions. Although the TLC technique is a nonintrusive and cost-effective method for providing whole-field temperature information, there are some problems in applying it to temperature measurements on the microscale. The size of encapsulated TLCs is typically tens of micrometers, which is impractical for use in micron-sized structures. The time response of TLCs varies from a few milliseconds to several hundred milliseconds, according to the material and form of the TLC.

Laser-Induced Fluorescence

Fluorescence is the property that some dye molecules have of absorbing energy at a particular wavelength and emitting energy at another wavelength, longer than that of the absorption, in the wavelength range of visible light. The emitted fluorescence intensity depends on the concentration of the dye molecules, and some fluorescent molecules have the characteristic that their emission intensity is sensitive to temperature and/or pH. Many studies of temperature measurement using laser-induced fluorescence (LIF) have been carried out on the macroscale. However, there have been only a few studies devoted to the measurement of temperature fields on the microscale. In these studies, rhodamine B was used as a temperature-sensitive dye because it has a relatively high dependence of the emission on temperature and is commercially available. For rhodamine B dissolved in an aqueous liquid, the variation of the emission with temperature is reported to be -1.5 to $-3\%\,K^{-1}$. The LIF technique measures the temperature from the fluorescence intensity, rather than from the reflected light intensity as in the case of the TLC technique, so that the effect of illumination is less severe. However, there are several inherent problems affecting the accuracy of the measured temperature, such as variation of the dye concentration in the measurement area, fluctuation of the illumination light, photobleaching, and the shadowgraph effect. Recently, some improvements have been made in the accuracy of temperature measurement by the LIF technique. The most popular method is two-color LIF, which uses two different fluorescent dyes; one is sensitive to temperature and the other is insensitive. However, this technique also has several problems: the dye concentration ratio must be constant throughout the entire liquid, and the spectral bands of the absorption and emission of the two



Joule Heating and Chip Materials, Figure 3 Computational geometry for a PDMS/PDMS or PDMS/glass hybrid microfluidic system

dyes must overlap. Very recently, a multicolor technique, which obtains the temperature from the ratio(s) of two or three intensities measured at different bands with a single fluorescent dye, has been proposed to circumvent the difficulties of using two dyes.

Examples of Studies on Joule Heating with Various Chip Materials

Joule Heating and Heat Transfer in Poly(dimethylsiloxane) Microfluidic Systems

Microchannel Fabrication The PDMS/PDMS and hybrid PDMS/glass microchannel systems (see Fig. 3) used in the study described here were manufactured using a soft lithography technique. An enclosed microchannel was then formed by bonding the PDMS cast to either another piece of PDMS or a glass slide (forming the lower substrate) by placing both sides in a plasma cleaner and oxidizing them. This was done immediately after removal of the PDMS cast from the master to minimize surface-aging effects. Following oxidation, the two halves were brought into contact and an irreversible seal was formed. After sealing, a carbonate buffer solution was introduced into the channels by applying a negative pressure at the downstream end.

Experimental Technique and Image Analysis Rhodamine B dye is one of a class of fluorescent dyes whose quantum yield is strongly dependent on temperature. Therefore, the in-channel temperature profile could be obtained by observing the relative spatial and temporal changes in the local intensity of the dye using a fluorescence imaging technique. Images were captured every 0.25 s for approximately 40 s. Prior to each experiment, the microchannel system was allowed to cool to room temperature and an isothermal *cold-field* intensity image of the system was taken. Following the acquisition of the cold-field image, an electric field was switched on (inducing electroosmotic flow and Joule heating in the microchannel) and full-speed image acquisition was initiated. In all cases, a uniform potential was applied at all upstream inlet reservoirs, while the downstream waste reservoir was grounded. Following the capture of 150 high-resolution images, the excitation light was blocked and the electric field was turned off, allowing the system to cool back down to room temperature. After cooling was complete, a second cold-field image was acquired. The second cold-field image was then compared with the initial image and, in general, it was found that the intensity values of the two images were identical, suggesting that any photobleaching of the dye during the experiment was not significant. To extract the in-channel temperature profiles from the captured intensity images, each image was first normalized by the cold-field image. The intensity values of the treated images were then converted to temperature using an intensity vs. temperature calibration of the kind discussed in the preceding section.

From the experimental results, we can say that electrokinetic pumping can greatly simplify species transport in microfluidic systems; however, Joule heating caused by the current flow through the buffer solution can lead to significant increases in the buffer temperature. The relatively low thermal conductivities associated with polymeric microfluidic substrates (such as PDMS) make the rejection of this heat more difficult. In general, it was found that PDMS/glass microfluidic systems maintained a much more uniform and lower buffer temperature than PDMS/PDMS systems. Also, in general, the analysis revealed that a thinner lower substrate can significantly improve heat rejection, whereas the thickness of the upper substrate had a much smaller effect. The increase in temperature was shown to significantly increase the current load and doubled the volume flow rate through the PDMS/PDMS system. The flow structure and velocity profile remained relatively constant, despite the large temperature gradients, owing to the counterbalancing effects of the decreased viscosity and decreased potential-field gradient in the hotter sections of the channel. In general, it was observed that (except in extreme cases) the channel aspect ratio had only a marginal effect on the temperature rise in the fluid system.

Key Research Findings

Joule heating results from current flow through an electrolyte solution when an electric field is applied to achieve electrokinetic flow. This internal heat generation is useful in some cases, such as in PCR on chip, but very deleterious in other cases, for example electrophoretic separation. So, chip materials should be selected carefully for the particular purpose intended, because of their different heat conductivities. There has been much research on the deleterious effects of Joule heating. The heat is taken away not only by the coolant surrounding the capillary (through convection in either air or a liquid, and by radiation as well), but also by the cold liquid inside the reservoirs connected to the two ends of the capillary (through conduction).

De Jesus et al. [11] found that the Joule-heating dissipation in a separation channel on glass chip was very efficient. The low thermal conductivities of typical polymers (shown in Table 2) used in capillaries result in a less efficient transfer of the heat generated by Joule heating of

the electrolyte to the outside of the channels. This phenomenon is an important consideration for all electrokinetic microfluidic devices, because temperature changes in the electrolyte result in decreases in the precision, accuracy, and robustness of the method. Accurately defined temperatures in microseparation devices are also important for achieving reproducible separation selectivity, since the electrophoretic mobilities of analytes are temperature-dependent. Joule heating and determination of temperatures in CE and *CEC* have been discussed in Rathore's 2004 [12] review article. Evenhuis et al. [13] studied the longer-term objective of studying the heating effects occurring in polymeric microfluidic devices. Also, Li [1] examined Joule heating and heat transfer in a T-shaped microchannel intersection in a PDMS microfluidic system, and experimentally observed dramatic temperature gradients as predicted by a *whole-chip* simulation.

If thermal end effects are neglected, Joule heating is known to cause an increase and a radial gradient in the fluid temperature. The Smoluchowski equation for the electroosmotic flow velocity, $U = [\varepsilon_0 \varepsilon_r \zeta / \mu] E_z$, has been used to accurately predict this velocity at elevated temperatures. Maynes and Webb [14] presented analytical solutions for thermally fully developed electroosmotic flow in circular and parallel-plate microchannels, considering the Joule heating effect, viscous dissipation, and convective heat transfer in thermally (and hydrodynamically) fully developed combined pressure–electroosmotically driven flows in circular microchannels. Li et al. [15] observed that at elevated temperatures, the experimentally measured velocities of electroosmotic flow in microchannels were sometimes considerably higher than those predicted analytically using the Smoluchowski equation, and they characterized the influence of temperature on the zeta potential for a number of commonly used buffers in both PDMS:glass and PDMS:PDMS microchannels. Li and his colleagues derived an analytical formula for the electroosmotic flow, considering only the radial temperature profile in a capillary.

The elevation of the buffer temperature and the induced temperature gradient would in turn affect the temperature-dependent properties of the buffer and sample, including the viscosity, dielectric constant, electrical conductivity, diffusivity, electromobilities, and pH value. Therefore, various cooling methods, such as the use of a liquid coolant in a well-thermostatted system and the use of air by natural or forced convection in a nonthermostatted system, have been developed to maintain the correct capillary temperature and thus minimize Joule heating effects. On the other hand, a potential use of Joule heating effects to precisely control the temperature in microfluidic devices was recently reported. Analyses based on simplified theories and/or empirical correlations have been reported by numerous researchers. Peterson et al. [5] took a closer look at Joule heating effects in microchip-based and capillary-based electrophoretic separation systems. These authors argued that the main influence of Joule heating on separation efficiency is via the radial temperature profile, not the overall temperature rise in the buffer solution. On the basis of the assumption of a parabolic temperature profile, Grushka et al. [16] examined the effect of radial temperature gradients on the efficiency of capillary electrophoretic separation and proposed certain conditions for operating a capillary electrophoretic system to minimize the undesirable effects of thermal gradients. Jones and Grushka derived a simplified 1D model to show that the temperature profile is parabolic for low power inputs but is distorted for high power inputs. An improved thermal model for estimating the Joule-heating-induced band broadening was formulated by Gobie and Ivory [17]. More recently, analytical solutions for the effects of Joule heating on sample band broadening were obtained by Xuan and Li [7] and by Tang et al. [18–20]. Some mathematical formulations of the effects of Joule heating on electrokinetic transportation in capillary electrophoresis have also been presented.

Future Directions for Research

More and more materials with various thermal conductivities can be used to prepare chips with the chip fabrication techniques that have been developed; these provide us with more opportunities to make use of electrokinetic flow. In the future, more methods and techniques should be developed to measure and control the temperatures generated by Joule heating more precisely. New materials should also be studied for with the aim of obtaining faster heat dissipation and easier chip fabrication.

Definition

Joule heating in electrokinetic flow refers to the increase in temperature of a liquid as a result of its resistance to an electrical current. This current arises from the electrical voltage that is applied across a channel to generate liquid electroosmosis and species electrophoresis.

Overview

Joule heating is a ubiquitous phenomenon in electrokinetic flow. This internal heat source can lead to significant increase and non-uniformity in liquid temperature. The elevated liquid temperature may on one hand, denature live biological samples, while on the other, be exploited in heat related physico-chemical processes, for example, the thermal cycling in PCR. Meanwhile, as most liquid properties are temperature sensitive, the induced temperature gradients make the liquid properties non-uniform and thus draw disturbances to the electrokinetic flow of both liquids and species samples [1, 2]. Therefore, it is important to study Joule heating in electrokinetic flow in order for the optimal design and efficient operation of microfluidic devices. This assay is focused on the theoretical models that describe Joule heating and its effect on electrokinetic flow in microfluidic channels. We will begin with a summary of the basic methodology including general transport equations. This will be followed by a detailed review of the analytical modeling of Joule heating in electrokinetic

microchannel flows. After that a few key research findings are briefly presented. Finally we suggest some future directions for research on Joule heating in electrokinetic flow.

Basic Methodology

Provided in this section are the general equations that govern the transport of heat (temperature field), electricity (electric field), momentum (flow field) and mass species (concentration field) involved in electrokinetic flow. These equations form the basis of the theoretical modeling of Joule heating in electrokinetic flow.

Temperature Field Joule heating, the most right term in Eq. (1), takes effects in the liquid domain only (denoted by the subscript l) where the transient energy equation is written as

$$\rho_l C_{p,l}\left(\frac{\partial T}{\partial t}+\boldsymbol{u}\cdot\nabla T\right)=\nabla\cdot(k_l\nabla T)+\Phi+\lambda\nabla\phi\cdot\nabla\phi \quad (1)$$

where ρ is the mass density, C_p the specific heat, T the temperature, t the time coordinate, $\boldsymbol{u}$ the liquid velocity, k the thermal conductivity, Φ the viscous heating, λ the electrical conductivity, ϕ the externally applied electric potential. Generally Φ contributes little to energy equation in low-Reynolds flows and thus is often neglected in electrokinetic microfluidics. Joule heating in the liquid is dissipated in two ways: one is through the channel ends that is reflected in the boundary conditions of Eq. (1), and the other is through the solid substrate (denoted by the subscript s) wherein the energy equation takes the form

$$\rho_s C_{p,s}\frac{\partial T}{\partial t}=\nabla\cdot(k_s\nabla T)\,. \quad (2)$$

Electric Field The electric potential φ in electrokinetic flow can be split into two terms, i. e., $\varphi=\phi+\psi$, where ϕ, the electric potential externally applied along the axis of a channel, produces Joule heating in Eq. (1), and ψ, the double-layer potential internally induced over the channel cross-section, causes liquid electroosmosis via Eqs. (4) and (5). These two electric potentials satisfy, respectively, the Laplace equation and the Poisson equation

$$\nabla\cdot(\lambda\nabla\phi)=0 \quad (3)$$

$$\nabla\cdot(\varepsilon\nabla\psi)=-\rho_e \quad (4)$$

where ε is the liquid permittivity and ρ_e is the net charge density.

Flow Field The transient electroosmotic flow field is solved from Navier–Stokes equations and the continuity equation,

$$\rho_l\left[\frac{\partial \boldsymbol{u}}{\partial t}+(\boldsymbol{u}\cdot\nabla)\,\boldsymbol{u}\right]=-\nabla p+\nabla\cdot(\eta\nabla\boldsymbol{u})-\rho_e\nabla\phi \quad (5)$$

$$\frac{\partial\rho_l}{\partial t}+\nabla\cdot(\rho_l\boldsymbol{u})=0 \quad (6)$$

where p is the hydrodynamic pressure and η is the liquid viscosity.

Concentration Field The electrokinetic transport of sample species is described by the Nernst–Planck equation

$$\frac{\partial c}{\partial t}+\nabla\cdot\left(-D\nabla c-\mu_{ep}c\nabla\phi+c\boldsymbol{u}\right)=0 \quad (7)$$

where c is the species concentration, D the diffusion coefficient, and μ_{ep} the electrophoretic mobility of species.

Obviously the transport Eqs. (1) through (7) are coupled via temperature dependent liquid properties, of which the two most important ones are liquid conductivity λ and viscosity η [1]. Especially, the coupling among temperature field, electric field and flow field in the energy Eq. (1) necessarily forces the use of numerical simulation [3]. Only in few simple cases are analytical solutions available, which will be addressed in the next section. Numerical modeling of electrokinetic transport in microchannels is complicated by the simultaneous presence of three separate length scales: the channel length in millimeters, the channel cross-sectional dimension in micrometers, and the double-layer thickness in nanometers. A full solution on all the three length scales would require a prohibitive amount of memory and computational time. Therefore, either an artificial magnification or a complete elimination of the length scale of double-layer thickness (by imposing an electroosmotic slip condition on channel walls) has been frequently used to resolve the problem. As the conductivity within electrical double layer might be orders of magnitude larger than that in the bulk liquid due to the locally strong accumulation of counter-ions, the magnification of double-layer thickness is anticipated to have a noticeable influence on Joule heating. Hence, the application of electroosmotic slip condition is recommended to simplify the numerical modeling. In addition, thermal diffusion necessarily extends the computational domain for thermal modeling from the fluidic region to encompass the solid substrate (and thus the reservoirs in reality), which significantly complicates the simulation by introducing another length scale of chip dimension in centimeters. This difficulty can be partly alleviated through an

appropriate reduction of the lateral width of the computational domain [4]. However, an approach to the efficient simulation of Joule heating in an entire microfluidic chip is definitely in need.

Simplifications and Analytical Solutions

Analytical modeling of Joule heating in electrokinetic flow can basically be divided into two main categories. In the first category, liquid flow is assumed to have negligible effect on the temperature field that is assumed fully developed in the entire channel. Therefore, liquid temperature varies only in the cross-stream direction. In the second category, the flow effect on temperature field is considered while the transverse variation in liquid temperature is assumed small. Therefore, the local liquid temperature can be replaced by its cross-sectional average. This section reviews in detail the analytical solutions of Joule heating in electrokinetic microchannel flows with axially uniform or non-uniform cooling. These two cases correspond to the capillary electrophoretic separation with and without thermostating, respectively. The channel cross-section could be of either cylindrical or rectangular shape while only the former is discussed in this article. Hence, the axisymmetric structure and boundary condition reduces the energy Eq. (1) and thus Eqs. (2) through (7) to two-dimensional at most, which certainly facilitates the development of analytical solutions.

Joule Heating in Electrokinetic Flow with Uniform Cooling

In capillary electrophoresis without thermostating, the whole channel is uniformly cooled by the free air around its outer surface. In such a circumstance, the theoretical studies of Joule heating in electrokinetic flow are divided into two main groups: the first group concerns the electrophoretic separation in an infinitely long channel where only radial temperature non-uniformity exists [5]; the second group studies the electrokinetic transport in a relatively short channel (e. g., on-chip electrophoresis) where the reservoir-based cooling effects, i. e., thermal end effects, have to be considered that gives rise to axial temperature gradients [6].

Without Thermal End Effects Neglecting the flow effect and considering only the steady-state radial temperature variation reduce Eq. (1) to

$$\frac{1}{y}\frac{\mathrm{d}}{\mathrm{d}y}\left(y\frac{\mathrm{d}T}{\mathrm{d}y}\right) = -\frac{\lambda E_0^2 R_1^2}{k_1} \tag{8}$$

where $y = r/R_1$ is the non-dimensional radial coordinate with R_1 being the lumen radius, and E_0 is the strength of the applied electric field. Assuming a linear relationship of liquid conductivity λ to temperature

$$\lambda = \lambda_0\left[1 + \alpha\,(T - T_0)\right] \tag{9}$$

where λ_0 is the liquid conductivity at room temperature T_0 and α is the temperature coefficient, the radial temperature profile can be derived as

$$T = T_0 + \frac{1}{\alpha}\left[\frac{J_0(qy)}{J_0(q) - qJ_1(q)/\mathrm{Bi}} - 1\right] \tag{10}$$

where $q = \sqrt{\alpha\lambda_0 E_0^2 R_1^2/k_1}$ may be called *Joule number* (dimensionless), $\mathrm{Bi} = UR_1/k_1$ is the Biot number (dimensionless), and J_0 and J_1 are the Bessel functions of the first kind. In the definition of Biot number, U is the overall heat transfer coefficient between the liquid and the external coolant given by $1/R_1\left[\ln\left(R_w/R_1\right)/k_w + \ln\left(R_p/R_w\right)/k_p + 1/hR_p\right]$ where h is the convective heat transfer coefficient of the coolant. Note that the subscripts l, w and p indicate the liquid, capillary wall and polyimide coating, respectively. It is apparent that the applied electric field strength E_0 must not be too high. Otherwise, the term $J_0(q) - qJ_1(q)/\mathrm{Bi}$ would become zero or even negative, causing a physically unrealistic temperature (i. e., thermal runaway). It is also clear from the definition of q that the effect of capillary internal radius R_1 on Joule heating is similar to that of the electric field strength while stronger than the liquid conductivity. As the Joule number q is typically small, Eq. (10) can be approximated as

$$T = T_w + \Delta T(1 - y^2) \tag{11}$$

where $T_w = T_0 + qJ_1(q)/\alpha[J_0(q) - qJ_1(q)/\mathrm{Bi}]$ is the liquid temperature at the capillary wall and $\Delta T = q^2/4\alpha[J_0(q) - qJ_1(q)/\mathrm{Bi}]$ is the temperature difference between capillary center and wall. In other words, the radial temperature distribution in capillary electrophoresis follows an essentially parabolic profile.

The fully developed, steady-state electroosmotic velocity u_{eo} is now available from Eq. (5) in conjunction with Eq. (4),

$$\frac{\mathrm{d}}{\mathrm{d}y}\left(y\eta\frac{\mathrm{d}u_{eo}}{\mathrm{d}y}\right) = \varepsilon E\frac{\mathrm{d}}{\mathrm{d}y}\left(y\frac{\mathrm{d}\psi}{\mathrm{d}y}\right) \tag{12}$$

As liquid viscosity varies with temperature by $\eta = A\exp(B/T)$, its inverse can be approximated by a Taylor series around T_w, i. e., $1/\eta = [1 + \omega(1 - \eta^2)]/\eta_w$ where A and B are both empirical constants, $\omega = B\Delta T/T_w^2$, and

η_w is the viscosity at the temperature T_w. Therefore, integrating Eq. (12) gives rise to

$$u_{eo} = \mu_{eo,w} E_0 \times \left\{ 1 - \frac{\psi}{\zeta}\left[1+\omega(1-y^2)\right] - 2\omega \int_1^y \frac{\psi}{\zeta} y' dy' \right\} \quad (13)$$

where $\mu_{eo,w} = -\varepsilon\zeta/\eta_w$ is the electroosmotic mobility at the capillary wall. As ω is normally very small, Eq. (13) may be safely simplified to [5]

$$u_{eo} = \mu_{eo,w} E_0 (1 - \psi/\zeta) \quad (14)$$

which holds the same form as that in the absence of Joule heating. Following the distribution of double layer potential ψ that is also slightly affected by Joule heating, the electroosmotic flow profile is therefore still plug-like except very close to the capillary wall. It is, however, noted that $\mu_{eo,w}$ is enhanced by Joule heating because of the reduced liquid viscosity. Similarly, the electrophoretic velocity of species can be approximated to

$$u_{ep} = \mu_{ep,w} E_0 \left[1 + \omega(1-y^2)\right] \quad (15)$$

where $\mu_{ep,w} = z_v e / 6\pi\eta_w a$ is the electrophoretic mobility calculated at the wall temperature T_w, z_v the species valence, e the unit charge, and a the radius of ionic species. Transforming the concentration Eq. (7) by $z_1 = z - u_s t$ where z is the axial coordinate and $u_s = \mu_{eo,w} E_0 + \mu_{ep,w} E_0 (1+\omega)$ is the mean migration velocity of species, and then averaging the new equation over the cross-section lead to

$$\frac{\partial \bar{c}}{\partial t} = K \frac{\partial^2 \bar{c}}{\partial z_1^2} \quad (16)$$

where $\bar{c}$ is the mean species concentration, and K denotes the effective dispersion coefficient. In ideal circumstances, K is reduced to solely species diffusivity. However, the non-plug-like profiles of liquid electroosmosis and species electrophoresis both cause ▶hydrodynamic dispersion. If the contribution from liquid electroosmosis is neglected, the dispersion coefficient due to the parabolic profile of electrophoretic velocity and the radially non-uniform diffusion is given by

$$K = D_w(1+\gamma) + \frac{1}{48} \frac{\omega^2}{(1+\omega)^2} \frac{\left(1 - \frac{1}{5}\gamma\right)}{1+\gamma} \frac{R_1^2 u_s^2}{D_w} \quad (17)$$

where $D_w = k_B T_w / 6\pi\eta_w a$ is the diffusivity at the wall temperature T_w with k_B being the Boltzmann constant. Note that $\gamma = \omega/2 + \Delta T/2T_w$ characterizes the radial non-uniformity of diffusivity D. If a sample plug of uniform concentration c_0 and half width w_0 is initially injected to the capillary inlet, an analytical solution of $\bar{c}$ is available from Eq. (16),

$$\bar{c} = \frac{c_0}{2}\left[\operatorname{erf}\left(\frac{w_0 - z + u_s t}{2\sqrt{Kt}}\right) + \operatorname{erf}\left(\frac{w_0 + z - u_s t}{2\sqrt{Kt}}\right)\right] \quad (18)$$

where $\operatorname{erf}(x)$ denotes the error function and the true axial coordinate z has been recovered from z_1. Consequently, a larger value of K produces more dispersion in the species concentration field, indicating lower separation efficiency due to Joule heating effects.

With Thermal End Effects In practical electrokinetic flow, electroosmosis continuously pulls the cold liquid from the inlet reservoir while pushing the hot liquid into the outlet reservoir. Therefore, flow effect should be considered in the energy Eq. (1). Moreover, reservoir-based cooling effects, i. e., thermal end effects, produce a thermal developing region at each end of the capillary. Accordingly, there should also form a developing region for both electric field and flow field due to the temperature dependent liquid conductivity and viscosity [6].

Since the lateral temperature variation is typically very small in free air-cooled electrokinetic flow (while the temperature gradients may be very large), it is acceptable to replace the local liquid temperature T with its cross-sectional average, $\bar{T}$. Neglecting the effect of transverse liquid flow and averaging each term in Eq. (1) over the capillary cross-section yield

$$\frac{d^2\bar{T}}{dz^2} - \frac{\bar{u}}{\alpha_l}\frac{d\bar{T}}{dz} - \frac{2U}{k_l R_1}(\bar{T} - T_0) + \frac{\lambda_0[1 + \alpha(\bar{T} - T_0)]E^2}{k_l} = 0 \quad (19)$$

where $\alpha_l = k_l/\rho_l C_{p,l}$ is the thermal diffusivity of liquid, $E = -d\phi/dz$ the axial electric field strength, and $\bar{u}$ the mean liquid velocity that must be continuous through the capillary and will be specified later. Meanwhile, the electrical current density J should also be constant resulting in

$$\lambda_0\left[1 + \alpha(\bar{T} - T_0)\right]E = J. \quad (20)$$

Therefore, for small values of temperature rise, Eq. (19) may be rewritten as the following non-dimensional form (see [6] for the derivation)

$$\frac{\mathrm{d}^2\Theta}{\mathrm{d}Z^2} - \mathrm{Pe}\frac{\mathrm{d}\Theta}{\mathrm{d}Z} - \beta^2\Theta + 1 = 0 \tag{21}$$

where $\Theta = (\bar{T} - T_0)/q'$ is the non-dimensional temperature, $q' = J^2 R_1^2/\lambda_0 k_1$ the reference temperature, $Z = z/R_1$ the non-dimensional axial coordinate, $\mathrm{Pe} = \bar{u}R_1/\alpha_1$ the Péclet number (dimensionless), and $\beta = \sqrt{2\mathrm{Bi} + \alpha q'}$ (dimensionless). Considering the thermal end effects $\Theta(0) = \Theta(L) = 0$, one can derive from Eq. (21)

$$\Theta(Z) = \frac{1}{\beta^2}\left[1 - \frac{\left(\mathrm{e}^{A_1 L} - 1\right)\mathrm{e}^{A_2(L-Z)} + \left(\mathrm{e}^{A_2 L} - 1\right)\mathrm{e}^{A_1 Z}}{\mathrm{e}^{(A_2+A_2)L} - 1}\right] \tag{22a}$$

$$A_1 = \sqrt{\frac{\mathrm{Pe}^2}{4} + \beta^2} + \frac{\mathrm{Pe}}{2} \quad \text{and} \quad A_2 = \sqrt{\frac{\mathrm{Pe}^2}{4} + \beta^2} - \frac{\mathrm{Pe}}{2} \tag{22b}$$

where $L = L_0/R_1 \gg 1$ with L_0 being the capillary length. On assuming a positive $\bar{u}$ in Eq. (22), the thermal entrance length that corresponds to the temperature reaching 99% of the fully developed temperature is estimated as $4.605\,R_1/A_2$. Similarly, the length of thermal exit region, where the liquid temperature adjusts rapidly to that of the cold liquid in the outlet reservoir, is given by $4.605\,R_1/A_1$. Considering the fact $A_1 > A_2$, the axial temperature profile inclines to the direction of liquid flow. As to the fully developed liquid temperature, it has an approximate magnitude of $1/\beta^2$.

Turn to the unknown electrical current density J. For small values of temperature rise, Eq. (20) yields, to a good approximation,

$$E = \frac{-\mathrm{d}\phi}{\mathrm{d}z} \cong \frac{J\left[1 - \alpha(\bar{T} - T_0)\right]}{\lambda_0} \tag{23}$$

Incorporating the temperature distribution in Eq. (22) and then integrating Eq. (23) yields

$$\frac{\lambda_0 E_0 L_0}{J R_1} = L - \frac{\alpha q'}{\beta^2}\left[L - \frac{\left(\mathrm{e}^{A_1 L} - 1\right)\left(\mathrm{e}^{A_2 L} - 1\right)\left(\frac{1}{A_1} + \frac{1}{A_2}\right)}{\mathrm{e}^{(A_2+A_2)L} - 1}\right] \cong L\left(1 - \frac{\alpha q'}{\beta^2}\right) \tag{24}$$

where the approximation is valid only at $\exp(A_1 L) = \mathrm{O}\left[\exp(A_2 L)\right] \gg 1$. Thus, a compact formula for the electrical current density in the presence of Joule heating and thermal end effects is available from Eq. (24) after recovering q' and β,

$$J = \frac{U}{\alpha R_1 E_0}\left(1 - \sqrt{1 - 2J_0\frac{\alpha R_1 E_0}{U}}\right) \tag{25}$$

where $J_0 = \lambda_0 E_0$ is the electrical current density free of Joule heating. The terms within the square root imposes a limit to the applied electric field E_0, beyond which J becomes physically meaningless. This limit is mainly attributed to the linear approximation made in Eqs. (21) and (23), which differs from the limitation in Eq. (10) due to the aforementioned thermal runaway. Therefore, a new model with the linear approximation released is in need. In the range of $E_0 < \sqrt{U/2\alpha\lambda_0 R_1}$, J is always higher than J_0 and their difference grows larger at a higher E_0.

The mean liquid velocity $\bar{u}$ still remains unknown. Comparing the orders of magnitude in the flow equation tells that the pressure p only varies along the length direction and thus Eqs. (5) and (6) are reduced to

$$\frac{1}{y}\frac{\partial}{\partial y}\left(y\frac{\partial u_z}{\partial y}\right) = \frac{R_1}{\eta}\frac{\partial p}{\partial Z} \tag{26}$$

$$\frac{1}{y}\frac{\partial}{\partial y}(y u_r) + \frac{\partial u_z}{\partial Z} = 0\,. \tag{27}$$

As discussed previously, an electroosmotic slip condition $u_{\mathrm{slip}} = \mu_{\mathrm{eo}}E$, which varies along the length direction in the present circumstance, can be imposed on the capillary wall instead of the no-slip condition. Integrating Eq. (26) twice with respect to r gives

$$u_z(y, Z) = \mu_{\mathrm{eo}}E - \frac{R_1}{4\eta}\frac{\mathrm{d}p}{\mathrm{d}Z}(1 - y^2) \tag{28}$$

Referring back to Eq. (19), it is natural to average each term in Eq. (28) over the capillary cross-section,

$$\frac{\mathrm{d}p}{\mathrm{d}Z} = (\mu_{\mathrm{eo}}E - \bar{u})\frac{8\eta}{R_1}\,. \tag{29}$$

As the two reservoirs in ►capillary electrophoresis are both open to air, i. e., $p(0) = p(L) = 0$, integrating Eq. (29) along the capillary length yields

$$\bar{u} = \frac{-\int_0^L \varepsilon\zeta E \mathrm{d}Z}{\int_0^L \eta \mathrm{d}Z} \tag{30}$$

The final formula for the axial liquid velocity is written as

$$u_z(y,Z) = \mu_{eo}(z)E(z) - 2\left[\mu_{eo}(z)E(z) - \bar{u}\right]\left(1-y^2\right) \quad (31)$$

Therefore, Joule heating and thermal end effects not only alter the local electroosmotic velocity, but also induce axial-position dependent pressure-driven flows in electrokinetic flow.

It is certainly useful to have a compact formula for the mean liquid velocity $\bar{u}$ like that for the electrical current J in Eq. (25). Incorporating the temperature distribution in Eq. (22) and the electric field strength in Eq. (23), one can specify $\bar{u}$ in Eq. (30) as

$$\begin{aligned}\bar{u} &= \left\{1 - \frac{\omega'}{\beta^2}\right. \\ &\quad \times \left.\left[1 - \frac{1}{L}\frac{\left(e^{A_1 L}-1\right)\left(e^{A_2 L}-1\right)(1/A_1+1/A_2)}{e^{(A_2+A_2)L}-1}\right]\right\}^{-1} \\ &\quad \times \left[-\frac{\varepsilon\zeta E_0}{\eta_0}\right] \\ &\cong \frac{1}{1-\omega'/\beta^2}\left[-\frac{\varepsilon\zeta E_0}{\eta_0}\right]\end{aligned} \quad (32)$$

where $\omega' = Bq'/T_0^2$ has a similar definition to ω in Eq. (13). Obviously the square bracketed term on the most right side of Eq. (32) is the electroosmotic velocity without Joule heating effects, whose prefactor, always larger than 1, is reflective of the flow enhancement due to the rise of liquid temperature.

As the initially injected sample plug is normally a distance away from the capillary inlet in capillary electrophoresis, the entrance region should have negligible influence on the species transport. In the region of fully developed (denoted by the subscript fd) flow field, the thermally induced pressure-driven flow causes additional hydrodynamic dispersion to the species diffusion. Analogous to Eq. (17), the effective dispersion coefficient is given by

$$K = D_{fd} + \frac{\left(\bar{u}-u_{z,fd}\right)^2 R_1^2}{48 D_{fd}} \quad (33)$$

The electrokinetic transport of mean species concentration $\bar{c}$ is still described by Eq. (18).

Joule Heating in Electrokinetic Flow with Non-Uniform Cooling

In capillary electrophoresis with thermostating, a short length of the channel at each end must be left outside the thermostated cartridge for sample injection and detection. These two regions are exposed to free air (un-thermostated) so that the local liquid temperature is higher than that in the middle section subject to forced-air (or liquid) cooling. Therefore, axial temperature gradients are formed, which by analogy to thermal end effects will induce pressure-driven flows upon the electroosmotic flow field [7].

For simplicity, the transition regions in both temperature and flow fields near the channel entrance and at the junctions of un-thermostated and thermostated regions are assumed negligibly small and thus are not considered. This implies a discontinuity in the temperature and velocity at the above junctions. In each region itself, however, there are no axial variations. Given the fact that the radial profile of liquid temperature is essentially parabolic, one can obtain the cross-sectional average temperature $\bar{T}_i$ at each region of the capillary (denoted by the subscript index $i = 1, 2, 3$) from Eq. (11),

$$\bar{T}_i = T_{w,i} + \frac{\Delta T_i}{3} \quad (34)$$

Here, a new formula is derived for $T_{w,i}$ and ΔT_i in order to simplify the analytical modeling. Referring back to Eq. (8) and its boundary condition yields

$$E_i^2 \lambda_0 \left[1 + \alpha(\bar{T}_i - T_0)\right] R_1^2 = 4k_1 \Delta T_i \quad (35)$$

$$E_i^2 \lambda_0 \left[1 + \alpha(\bar{T}_i - T_0)\right] R_l = 2U_i(T_{w,i} - T_0) \quad (36)$$

where Eq. (35) is an approximate integration of Eq. (8). It is then straightforward to get

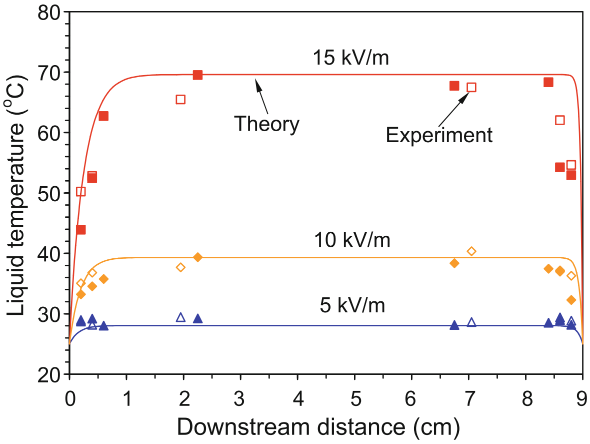
$$T_{w,i} = T_0 + \frac{1}{2U_i/E_i^2\lambda_0 R_1 - \alpha(1 + U_i R_1/4k_1)} \quad (37)$$

$$\Delta T_i = \frac{U_i(T_{w,i} - T_0)R_1}{2k_1} \quad (38)$$

Once again, Eq. (37) requires that the applied electric field strength E_0 be lower than $\sqrt{2U_i/\alpha\lambda_0 R_1(1 + U_i R_1/4k_1)}$ in order to avoid the thermal runaway.

Without loss of generality, the heat transfer conditions (reflected by U_i) in the injection ($i = 1$) and detection ($i = 3$) regions are assumed identical, resulting in $T_1 = T_3$ and thus $E_1 = E_3$. Then, the condition of current continuity gives rise to

$$\left[1 + \alpha\left(\bar{T}_1 - T_0\right)\right] E_1 = \left[1 + \alpha\left(\bar{T}_2 - T_0\right)\right] E_2 \quad (39)$$



Joule Heating in Electrokinetic Flow: Theoretical Models, Figure 1 Comparison of liquid temperature along the axis of a capillary in electrokinetic flow between numerical calculations (lines) and experimental measurements (symbols). Reprinted from [8]

In addition, the electric voltage across the whole capillary column should satisfy

$$E_1\,(L_1 + L_3) + E_2 L_2 = E_0\,(L_1 + L_2 + L_3) = E_0 L_0 \quad (40)$$

where E_0 is the average strength of the applied electric field, L_1, L_2 and L_3 are the lengths of the injection, forced air-cooling ($i = 2$) and detection regions, respectively, and L_0 is the total channel length. Referring to Eq. (34) for the average liquid temperature at each section, it is sufficient to determine the electric field strengths E_i from Eqs. (39) and (40). These results are omitted here for compactness. As for the mass continuity, we first integrate Eq. (12) with consideration of the electroosmotic slip condition leading to

$$u_i\,(y) = \mu_{\mathrm{eo,w},i} E_i - \left(\frac{\partial P}{\partial z}\right)_i \frac{R_1^2}{4\eta_{\mathrm{w},i}} \times \left[1 + \frac{1}{2}\omega_i - \left(1 + \omega_i - \frac{1}{2}\omega_i y^2\right) y^2\right] \quad (41)$$

The first term on the right hand side is the plug-like electroosmotic velocity, and the second term is the pressure-driven flow that is slightly different from a parabola due to the small quartic term caused by radial temperature gradients. Therefore, the cross-sectional average liquid velocity in each region $\bar{u}_i$ is easily derived as

$$\bar{u}_i = \mu_{\mathrm{eo,w},i} E_i - M_i \frac{\Delta P_i}{L_i} \quad (42)$$

where $M_i = (1 + \omega_i/3) R_1^2 / 8\eta_{\mathrm{w},i}$ can be understood as the hydrodynamic conductivity in the presence of radial temperature gradients, and ΔP_i is the pressure difference in region i. Then, the mass continuity requires

$$\mu_{\mathrm{eo,w},1} E_1 - M_1 \frac{P_1}{L_1} = \mu_{\mathrm{eo,w},2} E_2 - \frac{M_2 (P_2 - P_1)}{L_2} = \mu_{\mathrm{eo,w},1} E_1 + \frac{M_1 P_2}{L_3} \quad (43)$$

where P_1 and P_2 indicate the induced pressures at the two ends of the forced cooling region. Note that $\mu_{\mathrm{eo,w},1} = \mu_{\mathrm{eo,w},3}$ and $M_1 = M_3$ have been invoked in Eq. (43). Hence, P_1 and P_2 are easily determined from Eq. (43) as

$$P_1 = \frac{\mu_{\mathrm{eo,w},2} E_2 - \mu_{\mathrm{eo,w},1} E_1}{\frac{M_1}{L_1} + \frac{M_2 (1 + L_3/L_1)}{L_2}} \quad (44)$$

$$P_2 = -P_1 \frac{L_3}{L_1} \quad (45)$$

These axial temperature gradients induced pressure-driven flows can cause hydrodynamic dispersion (see Eq. (33)) and thus reduce the separation efficiency. The latter is usually evaluated in terms of the theoretical plate height H

$$H = \frac{2Kt}{L_0} = H_{\mathrm{dif}} + H_{\mathrm{axT}} \quad (46a)$$

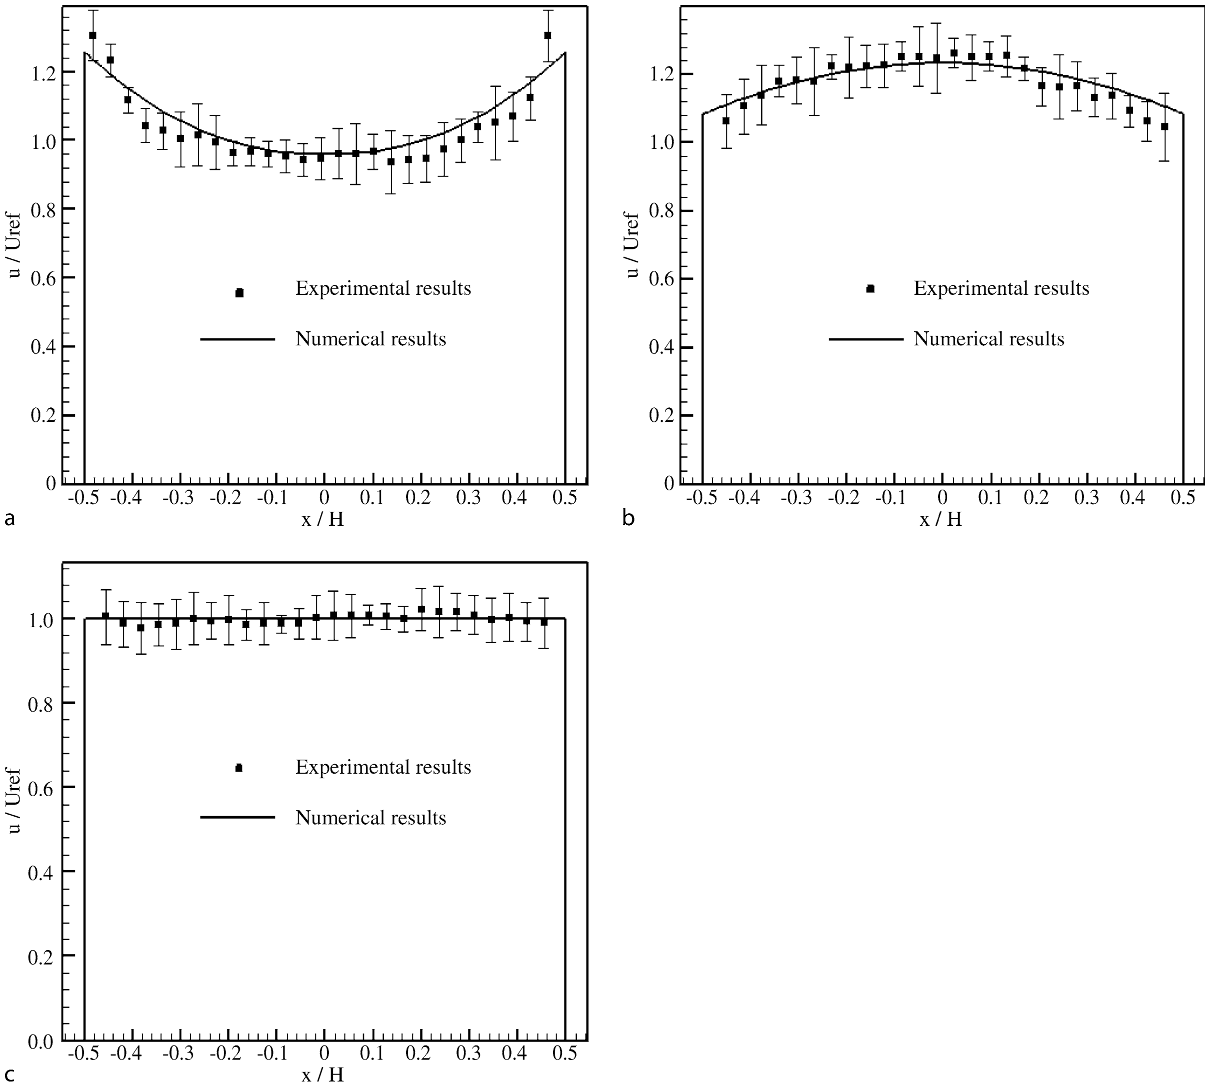
$$H_{\mathrm{dif}} = \frac{2}{L_0} \sum_{i=1}^{3} \frac{D_i L_i}{\bar{u}_i} \quad \text{and} \quad H_{\mathrm{axT}} = \frac{R_1^2}{24 L_0} \sum_{i=1}^{3} \frac{\bar{u}_{i,\mathrm{pd}}^2 L_i}{D_i \bar{u}_i} \quad (46b)$$

where H_{dif} and H_{axT} denote, respectively, the plate heights due to molecular diffusion and axial temperature gradients, and D_i is the diffusion coefficient at the average liquid temperature $\bar{T}_i$. Note that a higher value of H indicates lower separation efficiency.

Key Research Findings

As noted above, the direct consequence of Joule heating in electrokinetic flow lies in the variation of liquid temperature. The indirect consequences of Joule heating that originate from the temperature dependent liquid properties include the increased current load, enhanced flow rate, induced pressure-driven flows, and reduced separation efficiency. We provide here a brief overview of the key effects of Joule heating and as well the experimental verifications if available.

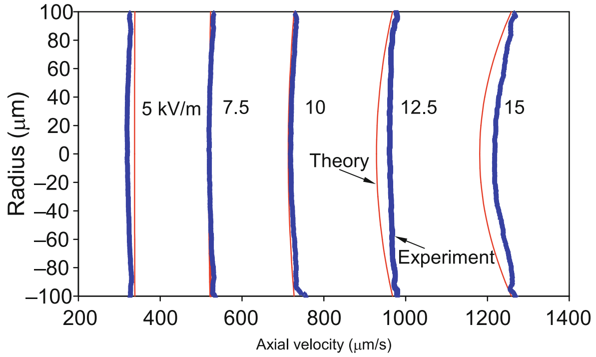
Fig. 1 shows the comparison of numerically calculated (lines) and experimentally measured (symbols) liquid temperatures in electroosmotic microchannel flow [8]. Overall, the numerical and experimental results are in good



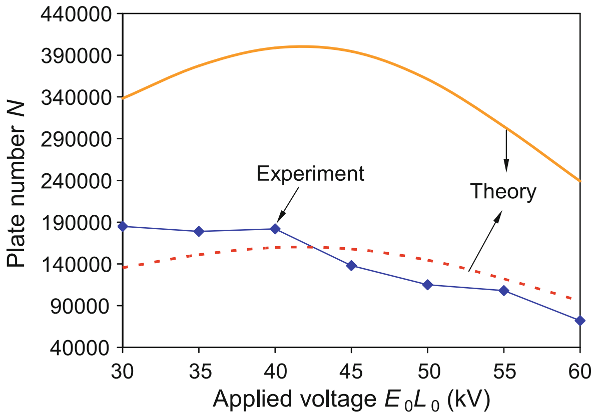
Joule Heating in Electrokinetic Flow: Theoretical Models, Figure 2 Comparison of transverse velocity profiles of electrokinetic flow in a poly(dimethylsiloxane) (PDMS) microchannel between the experiment (symbols with error bars) and simulation (lines): (**a**) entry region with significant Joule heating; (**b**) body region with significant Joule heating; (**c**) body region with negligible Joule heating. Reprinted from [9]

agreement. The numerical model was based on the finite element method, and the liquid temperature was extracted from the fluorescence images of rhodamine B dyes. Sharp temperature drops are observed close to the channel ends while in the middle there forms a high temperature plateau due to Joule heating and thermal end effects. In addition, the temperature profile is inclined to the downstream due to the advective effect of liquid electroosmosis. These phenomena are also predicted in the analytical solution, Eq. (22). Figure 2 compares the transverse velocity profiles of electrokinetic flow in a poly(dimethylsiloxane) (PDMS) microchannel between the microPIV (Particle Image Velocimetry) experiment (symbols with error bars) and 3D finite-volume simulation (lines) [9]. As a consequence of thermal end effects, the liquid velocity profile is concave in the entry region (Fig. 2a) while turns convex (Fig. 2b) in the body region if Joule heating is significant. This observation is consistent with the analytical solution, Eq. (31). In the circumstance of negligible Joule heating, however, the plug-like electroosmotic velocity profile (Fig. 2c) is resumed as expected [1].

Figure 3 plots the theoretical steady-state cross-stream velocity profiles (lines) with corresponding experimental results (symbols) for electrokinetic flow in a microchannel with non-uniform cooling [10]. The theoretical profiles were determined from Eq. (41) along with Eqs. (44) and (45). The experimental profiles were obtained from the images of uncaged fluorescent dye electrokinetic trans-



Joule Heating in Electrokinetic Flow: Theoretical Models, Figure 3 Comparison of steady-state cross-stream velocity profiles of electrokinetic flow within the cooled viewing window of a microchannel between experimental measurements (data points) and the analytical solution (line). Reprinted from [10]



Joule Heating in Electrokinetic Flow: Theoretical Models, Figure 4 Comparison of the theoretical plate numbers, $N = L_0/H$, between the analytical solution (lines) and the previous experiment (symbols). The solid line is determined from Eq. (46) while the dashed line accounts for 40% of the plate numbers in the solid line. Reprinted from [7]

port within the viewing window that was locally cooled by a drop of immersion oil. Although agreement between theory and experiment is not exact, the concave curvature of velocity profile is similar and apparent in both sets of results. Figure 4 shows the comparison of theoretical and experimental plate numbers, $N = L_0/H$, in capillary electrophoresis with thermostating [7]. The experimental plate numbers (symbols connected by lines) were adapted from previous measurements. The solid line displays the plate numbers calculated from Eq. (46) while the dashed line accounts for 40% of the values in the solid line. In the latter, all other sources of dispersion, for example, injection, detection and adsorption etc., are considered. Apparently the analytical model predicts properly the trend of the plate numbers with respect to the applied voltage.

Future Directions for Research

Regarding the future directions for theoretical research on Joule heating in electrokinetic flow, it may be interesting and important to clarify the true expression of Joule heating within electrical double layer, to determine the appropriate thermal boundary condition at the outlet of microchannels, to examine the role of Joule heating in electrokinetic instability with conductivity gradients, and to develop a numerical model for an efficient simulation of Joule heating in chip-based electrokinetic microfluidic devices.

Kelvin–Hemholtz Instability

Definition

Kelvin–Hemholtz instability arises because of shear along an interface between two different fluids. Related to turbulence and transition phenomena, it also describes the onset of ocean wave formation, jetting instabilities, and cloud formation. In microfluidics it is commonly seen in fluid-fluid interfaces. Not to be confused with Rayleigh–Taylor, or Rayleigh instabilities (► Rayleigh-Taylor instability).

Kernel Function

Synonyms

Nucleus; Smoothing function

Definition

The notion of kernel or smoothing function has its root in interpolation theory. In effect, the introduction of a localized kernel function works as a smoothing interpolation filter that generates a locally continuous field. In other words, kernels are used to localize the partial differential equations through a convoluted integration.
Considering a function A defined on a domain D, the integral representation of a this function can be written as

$$A(x) = \int_D A(\xi)\delta(x - \xi)\mathrm{d}\xi \,,$$

where x is a location vector and $\delta(x)$ is the Dirac delta function centred at the position x. Inspired by this form, the integral approximate of the function, $\langle A \rangle$, is written as

$$\langle A(x) \rangle = \int_D A(\xi) W(x - \xi, h)\mathrm{d}\xi$$

where W is a kernel function and h is a scaling variable with dimensions of length and is frequently known as the smoothing length of the kernel. The symbol $\langle \rangle$ denotes the approximated interpolation value.
In meshless methods, the choice of the interpolation kernel is the core of the method. Various types of kernel functions are used in the literature; the Gaussian kernel and spline-based kernels such as the cubic-spline, quartic or quintic kernels are among the most frequently used kernels.

Biosafety; Bioterrorism; Biosecurity; Biothreat

Definition

Biodefense is a method to protect a country from potential attack by deliberate release of agents such as viruses, bacteria or other germs used to cause illness or death in people, animals, or plants. These agents are typically found in nature, but could also be changed to increase their ability to cause diseases, to make them resistant to current medicines or to increase their ability to be spread into the environment. Biological agents can be spread through the air, water or in food.

Overview

Microfluidic and micro Lab-on-Chip technologies, which move microscopic and nanoscale drops of fluid, have great potential to be applied in the lucrative military market. The growing concern and lingering threat of possible unconventional warfare in the near future have generated tremendous demands for high technology and innovative devices for detecting this type of threat. Field portable devices that are faster, simpler and more reliable for use on the battlefield are much sought after by the military. The threat is not only concentrated on the battlefield, but also in homeland security, such as terrorist attacks. Real-time monitoring devices are urgently required to protect the well-being of military personnel and civilians, to ensure food safety and to avoid water contamination. This is especially useful when the detection of chemical or biological warfare agents is done in a rapid and sensitive manner which could provide an early warning of their possible impending catastrophic effects, thus minimizing or even eliminating any casualties by enabling preventive measures to be taken to contain the threat. With these devices, those who are exposed to the threat can be handled promptly by the medical providers to give appropriate treatments and to assure unexposed persons of their health status. These devices can also be used to detect noncombat threats such as diseases or infections when operating in hostile environments such as jungles and deserts.

Highly accurate and fast analytical devices are also urgently required for supporting various military and homeland security operations such as the investigation of bombing sites. Therefore, the device should offer high sensitivity and selectivity in detecting a threat, providing a fast detection and a high level of accuracy. Portability, rather than transportability, requires these devices to be portable, energy efficient, easy to operate and maintain, of low weight, have low power consumption and of low cost

to be deployed for field use such as a war zone. For effective sampling of biological agents, the device must have a portable sensor technology, which should be extremely sensitive, universal, reliable, fast and able to detect multiple threats simultaneously. Furthermore, the device must use fewer consumables, be of low maintenance and have a long shelf life. It should also be highly specific and sensitive to detect threats at threshold levels, process and deliver results within minutes and also able to store the data for later use. Figure 1 summarizes the basic requirements of a biodefense Lab-on-Chip device [1].

The devices that are currently available are either too bulky or slow to respond in detecting threats. Designing and manufacturing an appropriate device which is portable and easy to use by retaining the high sensitivity and selectivity is a major challenge.

Basic Methodology

Biological Warfare Agent

A biological agent is an infectious disease that can be used in biological warfare. There are more than 1200 different kinds of biological agents. Biological agents include prions, microorganisms (i. e. viruses, bacteria and fungi) and some unicellular and multicellular eukaryotes (e. g., parasites) and their associated toxins. Examples of biological agents are ►anthrax, avian influenza, botulism, foodborne illness, hantavirus, legionnaires' disease, molds and fungi, pneumonic plague, smallpox, tularemia and viral hemorrhagic fevers (VHFs) [2].

Lab-on-Chip-Based Immunoassays

Recent developments in ►immunoassays enable the detection of biological warfare agents. The principal measurement technique in immunoassays is the shape recognition of an antigen by the antibody to form an antibody-antigen complex binding. This type of assay allows the measurement of minute or trace amount of bindings in samples. The conventional measuring methods of immunoassays are slow and involve multiple processes which involve liquids handling. Sato et al. [3] developed an immunoassay microchip to detect cancer cells. The device was made of glass that integrated polystyrene beads, pre-coated with anti-CEA (carcinoembryonic antigen) antibody, with a microfluidic system using thermal lens microscopy as the detection method. The reaction time of this device was reduced to about 1% of that required for a conventional ELISA (enzyme linked immunosorbant assay). A novel cell analysis system consisting of a scanning TLM detection system and a cell culture microchip was also developed [4]. A microflask ($1 \times 10 \times 0.1$ mm; 1 μl) was fabricated in a glass microchip. The system could detect nonfluorescent biological substances with an extremely high sensitivity without labeling any materials and had a high spatial resolution of 1 μm. The microchip system is good for liquid control and simplifies troublesome procedures. This system was applied to monitor cytochrome c distribution in a neuroblastoma–glioma hybrid cell cultured in the microflask.

Lab-on-Chip Based on DNA Analysis

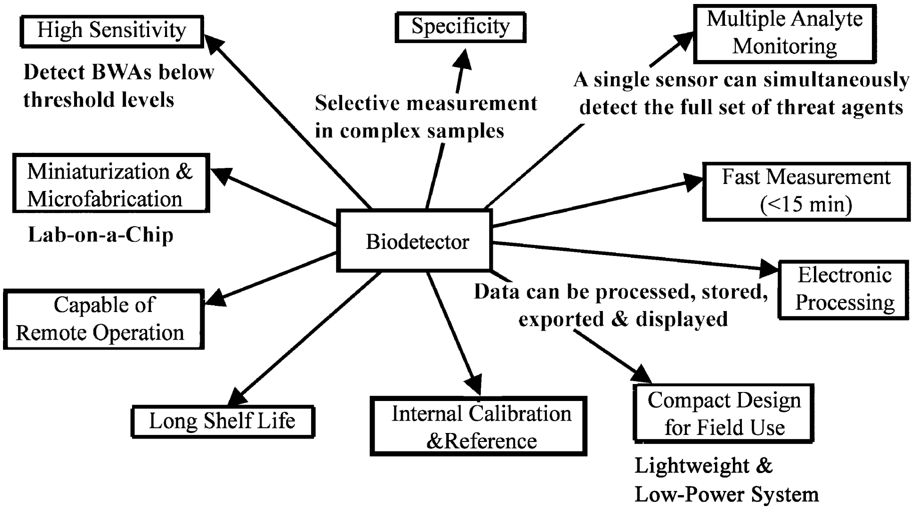
Rapid and accurate identification of bioagents are crucial in biodefense strategy. DNA recognition offers unique possibilities for identification of biological warfare agents and holds great promise for on-site detection. One of the key methods in DNA-based detection systems is the polymerase chain reaction (PCR) method. The PCR method enables detection of specific organisms of even a very low concentration. The PCR method also requires minimal amount of reagents and samples for detection and identification of harmful pathogens. Figure 2 shows a simple PCR chip fabricated from glass.

Delehanty and Ligler [5] used an antibody microarray system with continuous fluid flow to detect microbial toxins and simultaneously detected both cholera toxin and staphylococcal enterotoxin at a detection level as low as 8 and 4 ng/ml, respectively, within 15 min. Yang et al. [6] developed a device for detecting and genotyping influenza A viruses. Construction of the device utilizes solid-state electronics microfabricated in silicon and glass, deposition of resistive heaters for thermal cycling, a reaction chamber for restriction digestion and a miniature gel separation column, with DNA driven by an electric field produced by miniature microfabricated electrodes. The possible uses of this type of device are the tracking of influenza variants, including H1, H3, H5, H9 and other subtypes.

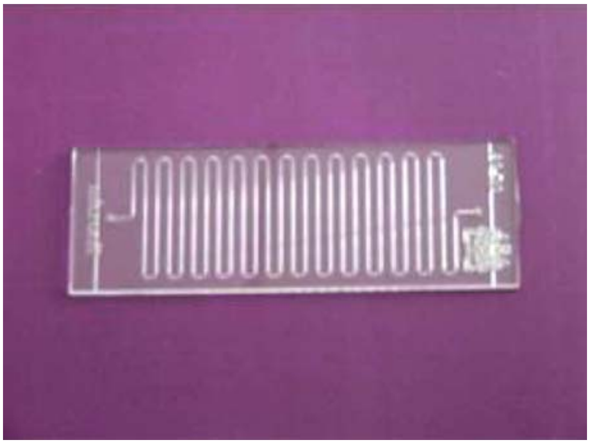
Related Biodefense Strategy

A threat to military personnel does not only come through the use of chemical and biological warfare agents, but also from hostile natural environments and the existing health status of the personnel concerned. Diseases inflicted by nature can be malaria, cholera, dengue fever and yellow fever. Military personnel in the field need a portable device that can detect diseases or contamination when they are far away from their base stations or camps where fast medical attention and analysis can be provided.

Rapid and sensitive detection of the presence of harmful pathogens in water, air or food is important for ensuring health safety. Timmer et al. [7] developed a micro-device to measure low concentration of ammonia levels in water.



Lab-on-Chip Devices for Biodefense Applications, Figure 1 Requirements for biodefense Lab-on-Chip device [1]



Lab-on-Chip Devices for Biodefense Applications, Figure 2 A simple PCR chip (Courtesy of Institute for Research in Molecular Medicine, Universiti Sains Malaysia)

The device can be used for fast diagnosis of patients with disturbed urea balance, either due to kidney disorder or *H. pylori* bacterial infection. From the experiments conducted, they showed that the system is sensitive to ammonia concentrations below 1 ppm.

A droplet-based microfluidic device for the measurement of glucose for clinical diagnostics was presented by Srinivasan et al. [8]. The device uses the electrowetting-based digital microfluidic platform for biochemical assay. The device is able to detect glucose concentrations in the range 25 – 300 mg/dl within 60 s for a dilution factor as low as 2 and 3. The device is also capable of detecting other human metabolites such as lactate, glutamate and pyruvate.

Key Research Findings

The success of Lab-on-Chip devices for biodefense is dependent on successful coupling of these devices with novel detection and diagnosis system. Lab-on-Chip devices must be able to provide fast, accurate, reliable and timely field identification and quantification of biothreat agents. Recent developments of Lab-on-Chip devices made possible integrated microfabricated devices for performing reagent and sample mixing, immunological reaction and affinity capillary reactions in a single chip. This chip is able to conduct the complete analysis within 60 s and is capable of nanomolar-scale detection accuracy. Several research organizations have started commercially developing rapid biodefense Lab-on-Chip devices. Cepheid (Sunnyvale, USA) has developed I-CORE® for performing fast PCR in large volumes. This device can perform PCR with a cycle time of less than 30 s for a sample volume as large as 100 µl. Other designs based on the I-CORE module are the MIDAS® (Microfluidic Integrated DNA Analysis System) and the Smart Cycler®.

The Lawrence Livermore National Laboratory (LLNL) has developed a handheld-type device named Handheld Advanced Nucleic Acid Analyzer (HANAA) (Fig. 3) which is capable of rapid detection of bioagents such as *B. anthracis* in the field. It uses the TaqMan-based PCR assay system. Due to its small footprint and low weight, it is ideal for field applications. Another development from them is the Nanowire Barcode System which speeds up detection of pathogens such as anthrax, small pox, ricin and botulinum. Antibodies of specific pathogens are attached to the nanowires which produce small, reliable and sensitive detection systems.

Lab-on-Chip Devices for Biodefense Applications, Figure 3 The Handheld Advanced Nucleic Acid Analyzer from Lawrence Livermore National Laboratory

Agilent's Bioanalyzer is another breakthrough system which enables real-time analysis of different bioagents. It combines a variety of approaches, including DNA microarrays, bioinformatics and Lab-on-Chip. This device integrates fluid handling, sample processing, separation and detection in miniature chip.

Future Directions for Research

The increasing threat of bioterrorism and continued emergence of new infectious diseases have driven a major resurgence in biomedical research efforts to develop improved treatments, diagnostics and vaccines, as well as to increase the fundamental understanding of the host immune response to infectious agents. As MEMS devices continue to merge sensing, actuation, control with computation, communication, power generation on microscale systems, so will Lab-on-Chip devices merge traditionally compartmentalized medical practices such as diagnostics (in vitro) and treatment (in vivo). For example, early detection of disease using transdermal sample acquisition devices can be integrated with drug synthesis and controlled drug delivery to monitor and control physiological parameters of choice. One of the challenges in applying Lab-on-Chip technology to biodefense screening is how to overcome the problem of low concentration of target pathogens. The US Biological Defense Research Program through Microfluidic Systems Inc. is creating microfluidic-based devices for a rapid detection system for pathogens that can concentrate and identify viruses, bacteria and other air- or waterborne toxins in less than 5 min. The system depends on the air or liquid flow across a series of deep etched pillars, 5 μm tall and 150 μm in diameter to capture DNA, proteins or cells and elute into 50 μl fractions.

Definition

A Lab-on-a-Chip for chemical analysis is a miniaturized device capable of analyzing chemical parameters in fluids. It comprises in a single chip the liquid-handling, the detection and the readout systems. Its reduced size and weight could improve the performance of an analysis and allow the device to be used in mobile chemical analysis equipment, such as medical diagnostics units.

Overview

The healthcare sector is nowadays one of the most dynamic and where novelty is a strategic and operational imperative. The possibility of increasing the quantity and quality of clinical analyses, performed with instantaneous results and outside clinical laboratories, contributes to a better quality in healthcare services and also a better efficiency in clinical and administrative processes. The healthcare sector is under pressure to provide better service at a lower price. Therefore, more cost-efficient practices are needed. One of the places to improve efficiency is at the physician's office.

When the physician is confronted with an ill patient he or she will start looking for symptoms. However, when these symptoms lead to a wrong diagnosis, there is a problem for the physician, the patient and society. A wrong diagnosis can lead to a wrong treatment that ultimately brings further harm to the patient and increases society expenses. The best way of increasing the quality of diagnosis is to give the physician more precise information about the state of the patient. Presently, this information is often based on the measurement of chemical parameters in biological fluids, such as blood and urine. Most diseases leave a molecular fingerprint in those fluids and by measuring that fingerprint in the right way, the precision of the diagnosis can be increased. Traditionally, this chemical parameter analysis is performed by mixing milliliters of samples and reagents in conventional test tubs or cuvettes and analyzing the product in an analytical instrument, e. g., a spectrophotometer. Moreover, the analysis is carried out in clinical laboratories and the results become available after several hours, sometimes days. As a consequence a reliable diagnosis cannot be performed within the consultation time. Mistakes in the logistics, such as lost samples and mislabeling, may further delay the diagnosis. The automated equipment used in a state-of-the-art laboratory reduces errors, but uses large sample and reagent volumes, making the analysis systems expensive and does not contribute to patient comfort. Outside the laboratory environment, reagent strips for colorimetric detection are commercially available. They provide a color when a fluid sample contacts the strip. However, such strips are intended for a limited set of compounds to be analyzed and provide a qualitative result in the form of a color readout (by visual inspection). The need for rapid and on-line measurements with low sample volumes has led to the development of miniaturized analyses devices with the fluidic, the detection and the readout (the data-processing) systems all integrated in a single chip. A system that encompasses those requirements is known as a "point-of-care" system, where "point-of-care" means that the analysis is performed where the physician meets the patient, or more generally, close to the place where the analysis needs to be performed. However, the physician is highly skilled in the art of medicine but has no routine or training in performing the advanced chemical analysis that is needed to decode the information of the biological fluids. Thus, to be of any value for the physician, the analysis system has to be highly automated, very robust, independent of a laboratory and laboratory personnel and the results must be processed so that it is easy for the physician or a regular user to interpret. A delicate combination of science and technology originating from microelectronic device fabrication, electrical engineering and analytical chemistry was essential in the development and optimization of these miniaturized analytical systems, which have been revolutionizing the field of chemical sensing. Moreover, microfabrication allows reproducing the same designed miniaturized analytical systems faithfully in very large numbers. The vision of those miniaturized devices was presented in 1990 [1] and has since then been the inspiration for an intense research effort geared towards miniaturization of macroscopic chemical analyses methods. Nowadays, they are called "Lab-on-a-Chip", which means an analytical laboratory of a microchip size. The great interest in Lab-on-a-Chip technology stems from the inherent performance gains that arise when most analytical systems are downsized to the micrometer scale. The advantages associated with shrinking clinical analyses systems include: reduced sample size, higher degree of integration and hence enhanced potential for automation, shortened response time, potential for improved analytical performance, reduced chemical storage and hence laboratory safety and a considerable reduction in samples handling, logistics and costs.

Chemical analysis systems, such as spectrophotometry, high-performance liquid chromatography, capillary electrophoresis and immunoassays, always consist of a combination of a reaction or separation and a detection system. In the following section, some generic features for chemical reactions and separations are addressed, and the major conventional detection techniques as well as the integration and miniaturization of optical components used in chemical analysis are briefly reviewed. In the "key

research findings" section, the latest Lab-on-a-Chip technologies for chemical analysis based on spectrophotometry are discussed.

Basic Methodology

Downscaling

Shrinking of clinical analysis systems is fundamentally limited by the amount of molecules available in the sample volume and thus by the concentration of the desired analyte. An analyte is the substance (element, ion, compound or molecule) being analyzed. The relation between the sample volume, V, and the analyte concentration, C_i, is given by [1]

$$V = \frac{1}{\eta_s N_A C_i}, \quad (1)$$

where η_s is the sensor efficiency ($0 \le \eta_s \le 1$) and $N_A = 6.02 \times 10^{23}$ is the Avogadro number. This equation demonstrates that the sample volume or the size of the microfluidic device is determined by the concentration of the desired analyte. Common clinical chemistry analyses of human biological fluids require the reproducible measurement of analyte concentrations between 10^5 and 10^{12} molecules per picoliter. Consequently, a picoliter sample volume is realistic only if the detection system can measure a detection limit of 10^5 molecules. For example, in human urine, albumin is the protein that has the lowest target molecules (on average 1 µmol in 1 l of urine) and also the lowest concentration (less than 15 mg/dl). For a low concentration of albumin in urine, for example 5 mg/dl, there are still 3.35×10^5 molecules per picoliter. Whether actual shrinking to the picoliter range is feasible depends not only on the sensitivity of the detection system, but also on practical aspects. For example, practical aspects for absorbance detection are the channel height (or optical pathlength) required to achieve measurable absorption (which depends on the analyte absorption coefficient (α), for example $\alpha = 0.27\,\mathrm{m}^{-1}$ for an albumin concentration of 5 mg/dl), as well as the minimum channel width and the photodetector area, which are both set by lithographic constraints. A typical minimum dimension for the optical pathlength in absorbance detection is 500 µm. The reduction of this optical pathlength makes solutes with poor absorption coefficients difficult to detect, even with a highly accurate optical detection system.

Chemical Analysis: Reaction and Separation

In a chemical analysis there needs to be a step that is specific for the analyte. For many applications the concentration of an analyte in a medium that contains mixtures of other compounds, often at much higher concentrations, must be detected. One way of obtaining specificity is to introduce a reagent with a chemical specificity and affinity for the analyte in the analysis (generally called affinity ►assay – assay means analysis). The term affinity in a chemical sense means a strong tendency for two entities to bind. Two molecules that bind with a high strength are said to have a high affinity for each other. For example, in colorimetric reactions, the shift produced in the spectrum of the mixture when the analyte is bound to the reagent is used; in immunoassays the high affinity between an antibody and its antigen is utilized; and in DNA hybridization one uses the high affinity of two single strands of DNA with complementary nucleotides. These techniques are well established with a multitude of reagents that are well characterized and commercially available.

It has been shown that a key component of a chemical analysis is the chemical reaction. Therefore, many analyte concentrations are measured by using a mixture of a reagent with a fluid sample. In addition, another essential requirement for any practical fully integrated Lab-on-a-Chip device in a single chip is the ability to mix two or more fluids thoroughly and efficiently, i. e., providing a homogeneous reaction in a reasonable amount of time. The microscale conditions have distinctive properties due to the small dimensions (of the order of 100 µm) and typically low volume flow rate. First, liquid flow is laminar (►laminar flow). Since velocities are of the order of 1 mm/s, the Reynolds number of microflows is usually less than 1. For these small Reynolds numbers the flow is dominated by viscous effects. Inertial effects are very small and turbulent mixing is impossible. Second, shrinking the dimensions of a Lab-on-a-Chip means that both molecular and thermal diffusion times are significantly reduced. As a result, ►diffusion can be used for mixing fluids, e. g., to bring reactants together across small channels. With a constant flux, the mass transport by diffusion is proportional to the contact surface of the two mixed species. The average diffusion time, t_D, over a relevant mixing path, d, is given by

$$t_D = \frac{d^2}{2D}, \quad (2)$$

where D is the diffusion coefficient of the analyte. This equation shows that the diffusion time changes with the square of the mixing path. Because of their small sizes, micromixers decrease the diffusion time significantly, so, while 17 min are required for diffusion across 1 mm, only 100 ms are required for a 10 µm distance. Therefore, fast mixing can be achieved with smaller mixing path and large contact surface. Furthermore, the small volumes involved

facilitate rapid dilution or injection of reactants into the system. Despite the fast mixing, some reactions need to wait for a reaction time determined by the ▶ kinetics inherent to the reaction.

This brief analysis shows that mixing only by diffusion is viable when small mixing paths are used. However, if the channel geometry is very small, the large fluid molecules must collide often with the channel wall and not with other molecules. Moreover, diffusion coefficients of solutions containing large molecules (e. g., enzymes and some proteins) are two orders of magnitude lower than those of most liquids. Therefore, if those large molecules with small diffusion coefficients must react, mixing only by diffusion may take long transit times (several minutes or even hours) and, consequently, long microchannels are necessary. This may be undesirable for some applications and alternative mixing methods must be developed.

The use of microelectromechanical systems (MEMS)-based devices as active mixers, such as microvalves and micropumps, is an alternative for accelerating the mixing, but their use increases the cost of the system, needs complex control systems and is difficult to integrate. To enable high-efficiency reactions overcoming the disadvantages of MEMS and the long transit times due to diffusion, acoustic waves are an interesting solution. They have been used both to promote mixing and to pump fluids [2]. Sound waves that propagate in the fluid generate pressure differences that induce so-called acoustic streaming. Two forms of acoustic streaming can be applied to microfluidic systems: quartz wind and Rayleigh flow. Quartz wind is generated when sound waves propagate along the fluid. Since some of the energy of the sound waves dissipates in the fluid due to viscous effects, a pressure drop is generated that induces fluid flow along the path of the sound waves. Rayleigh flow is generated by standing waves that create vortices. Secondary flows can be created in the plane perpendicular to the main flow in the channel [2]. These secondary flows promote mixing by convection between otherwise parallel currents. Therefore, acoustic microagitation could be a simple actuation source for mixing and promoting fluid reactions. In order to produce the ultrasounds, the fluidic die of the Lab-on-a-Chip must have an ultrasound transducer.

In applications where heating and cooling are necessary, such as the polymerase chain reaction (PCR), the miniaturization is an additional advantage. Conventional equipments need long cycles to perform PCR due to the large time constants associated with the heating and cooling. Once miniaturized systems allow the use of small volumes (nanoliters or even picoliters) as well as materials with high thermal conductivity, such as glass or silicon, the time needed for heating and cooling is drastically reduced.

In some chemical analyses it is necessary to separate the analytes present in a mixture, to identify the different analytes and to quantify their amount. Some of the common processes that perform this manipulation of analytes include extraction, precipitation, dialysis, ultrafiltration, distillation, centrifugation, chromatography and electrophoresis. The last two are the most frequently used separation techniques by those who do chemical analyses of biological fluids.

Chromatography performs separation according to the size, charge and affinity of the analyte, based on the different velocities that each compound is carried by a solvent in an appropriate porous medium. In electrophoresis, the separation is based on the ▶ electrokinetic mobility of particles under the influence of an electric field. More detailed information can be found in books such as [3].

A trend in Lab-on-a-Chip-based separations is to shorten the analysis time, increasing separation power and decreasing detection limits. The separation length is a crucial parameter in liquid chromatography (LC) and capillary electrophoresis (CE), determining analytical performance. These two techniques are highly suitable for implementation in a Lab-on-a-Chip format. Using CE as an example, the analysis time, t, is determined by the migration time of the slowest detectable analyte, i, and can be calculated from [4]

$$t = \frac{L^2}{\mu_i V_{\text{sep}}} \,, \tag{3}$$

where L denotes the distance between injection and detection, μ_i the vector sum of the electroosmotic and the electrophoretic mobility of the analyte i and V_{sep} the potential drop across L. Equation (3) shows that to shorten the analysis time, decreasing the separation length or increasing the applied voltage can be considered. Often, the voltage is limited by material restrictions (dielectric breakdown of chip materials) or increased Joule heating. The separation efficiency is only limited by diffusion and is proportional to the strength of the electric field, which means that it is relatively independent of the separation pathlength and is, therefore, compatible with miniaturization.

The dominance of electrophoresis over chromatography has been a trend in separations with Lab-on-a-Chip devices. The reason is that from an engineering point of view it is easier to apply a voltage across the terminals of microchannels than the application of a pressure difference. In CE, electrokinetic control of fluid transport eliminates the need for external components such as pumps and valves. Furthermore, miniaturization of chromatography systems involves technical challenges that are usually not necessary in CE. However, LC is the most used separa-

tion technique in conventional systems. Therefore, investigation for implementing this technique in Lab-on-a-Chip devices is an active trend.

Chemical Analysis Based on Spectrophotometry

In clinical diagnostics, one of the most commonly used analytical techniques for chemical analysis of body fluid samples is ▶spectrophotometric analysis (the study of the interaction of electromagnetic radiation with chemical compounds). Biological molecules interact in some way with many different parts of the electromagnetic spectrum. Spectrophotometry is a very popular technique and can be used to determine the concentration and/or amount of a particular analyte, determine the structure of a new compound, identify a specific compound and determine the activity of a specific enzyme, among others. The spectrophotometric detection methods are briefly reviewed in the following paragraphs. More detailed information can be found in books such as [3].

Chemical Analysis Based on UV/Visible Absorbance Detection

The UV/visible region of the electromagnetic spectrum is the most commonly used region for quantitative chemical measurements of biological fluids. In absorbance detection, the sample is excited by a light source of intensity I_0. The light intensity that passes through the sample is measured, I. The ratio of these two quantities is denominated as the absorbance, A, and is linked to the concentration of the analytes according to the Lambert–Beer law [3]

$$A = -\log \frac{I}{I_0} = \alpha c d\,, \tag{4}$$

where d is the pathlength, c is the concentration of the analyte in the sample and α its corresponding molar absorption coefficient. The Lambert–Beer law, as written above, is not directly applicable to circular microchannels. Diffraction and reflection effects strongly modify the pathlength, and therefore a correction factor must be applied.

In microchip format, the reduction of the optical pathlength has a severe impact on the detection sensitivity and it makes solutes with poor absorptivity difficult to detect. The shorter the optical pathlength, the fewer the molecules affected and the difference between I_0 and I is smaller. This reduces the I_0/I ratio and consequently the sensitivity of the measurement. Nevertheless, it has been shown that sensitivity can be improved by increasing the optical pathlength while detection volume is maintained small (further referred to in the "key research findings" section).

Chemical Analysis Based on Fluorescence Detection

Fluorescence detection is not only a very sensitive detection technique but also very selective and has been used most widely for detection using Lab-on-a-Chip devices. The detection is applied to compounds that contain fluorophores. An excitation source (of intensity I_0) is directed toward the sample and, consequently, fluorescent light is emitted. The intensity of the emitted light, F, is measured and is linked to the concentration of the analyte present in the sample [3]

$$F = I_0 \varphi \left(1 - 10^{-\alpha c d}\right)\,, \tag{5}$$

where φ is the ▶fluorescence yield. The wavelength of the excitation source and of the fluorescent emitted light differs. Therefore, one is no longer dependent on the ratio of two signals at a single wavelength, but is rather looking for one signal in the presence of light at other wavelengths, resulting in a very low measured background signal and consequently in a low detection limit. Because spectral filtering alone is not sufficient to guarantee this, fluorescence detection is generally carried out by placing the detector at some angle with respect to the incident light beam. Less excitation light collected by the detector improves the signal-to-noise ratio (SNR). In conventional fluorimeters, this angle is usually 90°.

Laser-induced fluorescence (LIF) detection uses a laser as the excitation light source, which increases the sensitivity because of its high intensity allowing detection limits reaching the attomolar range. A drawback of using a laser is that a continuous variation of the wavelength is not possible. Moreover, working at a fixed wavelength restrains one to only few analytes. The use of chemistry with some type of fluorophores allows the extension of fluorescence detection to many analytes. Furthermore, the use of a fluorescent carrier electrolyte combined with indirect detection also extends the type of detectable analytes with LIF. For indirect detection a fluorescent substance with a charge of the same sign as that of the analyte is added to the background buffer and its displacement (in order to maintain electroneutrality) is measured in the form of negative-going peaks. Nevertheless, in CE, indirect LIF should be considered as a last resort, because small changes in a background signal are monitored and the methods are thus limited by the noise on the baseline. Moreover, poor (when compared to direct LIF) detection limits have been reported (0.1 μmol). This is partly due to the fact that existing laser sources are unstable, yielding a noisy background signal. Conventional lasers are Ar^+, He – Ne and He – Cd lasers. Semiconductor or diode lasers are promising because they are more robust (longer life time), com-

pact and stable than the conventional lasers. This is important for indirect detection, which as such has a potential to become a useful on-chip technique. The miniaturization of the photodetector and the use of CMOS-compatible interference filters are also important. By making channels in silicon, the integration of photodetectors is possible, resulting in a very compact system.

Low-volume sample (less than a picoliter) fluorescence detection requires to date relatively bulky optical systems using lenses, mirrors and filters, and having excitation light directly to a tiny detector volume. Alignment of these optical elements is critical and the number of detector configurations limited. However, a number of research groups are investigating the miniaturization of these elements for integrating them into Lab-on-a-Chip devices, and consequently increasing both flexibility and performance of fluorescence detection.

Chemical Analysis Based on Chemiluminescence Detection

Chemiluminescence offers high sensitivity, low background noise, high specificity and reduced instrumental complexity due to the absence of an optical source for excitation, but it is limited in its applicability. This technique has a reduced spatial resolution when compared to fluorescence techniques. Since the light-emitting species are normally not surface-associated, they may diffuse across surfaces and cause emission from different parts.

Chemical Analysis Based on Electrochemistry

In electrochemical detection, changes in solution current, potential or conductivity as a function of the analyte concentration are measured. The chemical signal is directly converted into an electronic signal using simple electrodes. Since electrode deposition is a well-established process in microfabrication, the implementation of detection techniques using integrated electrodes has become an attractive approach for Lab-on-a-Chip devices. In electrochemical detection the output signal is dependent on electrode surface area. As a result, limits of detection (in concentration terms) do not degrade as rapidly as they would for optical techniques where the output signal is dependent on available detection volumes. Moreover, devices incorporating detection electrodes do not require a large amount of peripheral equipment for the acquisition of the detector signal. This makes the development of portable Lab-on-a-Chip devices a realistic possibility. However, electrochemical detection is not applicable to all situations where portable devices are required, and will never compete with fluorescence in terms of sensitivity. The electrochemical detection methods are briefly reviewed in the following paragraphs. More detailed information can be found in books such as [3].

Chemical Analysis Based on Amperometric Detection

Amperometric detection makes use of three electrodes: the auxiliary, the reference and the working electrode. The first two mentioned are used to monitor the potential in the solution, and the working electrode is the detection electrode. A constant potential is kept between the solution in the cell and the working electrode. Redox reactions of the analyte at the working electrode produce the detection signal. The generated current, I, is proportional to the amount of redox reactions, and thus to the concentration of the analytes [3]

$$I = z\mathrm{F}(c_i - c_0)\,, \qquad (6)$$

where z is the number of electrons transferred in the reaction, F is the Faraday constant, c_i is the concentration of the analytes that enter the detection cell and c_0 is the concentration of analytes that exit the detection cell. The coulombic efficiency is defined as the percentage of an electroactive analyte undergoing an electrode reaction inside the cell, and is linked to c_i and c_0. The detection sensitivity is strongly linked to the coulombic efficiency.

The reference electrode is in most applications a silver/silver chloride (Ag/AgCl) electrode. However, the material for the working electrode differs according to the analyte ions that have to be detected. The materials employed are gold, platinum, palladium, copper and carbon.

Amperometric detection is comparable to LIF detection: it is selective (only electroactive analytes are detected) and it has a low detection limit (femtomolar).

The electrochemical reactions that take place at the electrodes may result in a modification of their surface. These effects are prevented by pulse amperometric detection, where the polarization voltage is applied for only a short time and is followed by a reverse polarization in order to clean the electrodes.

Chemical Analysis Based on Potentiometric Detection

Potentiometric detection is similar to amperometric detection in the sense that both involve electrochemistry at the surface of a chemically active electrode. In the case of amperometry, a known electrode potential is applied, and the current resulting from redox activity is measured. This implies that the electrode has a low impedance in order to allow the flow of the redox current. The case of potentiometry is the opposite. A high electrode impedance keeps

the current negligible and the redox activity at the electrode leads to accumulation of charge at the surface. The resulting potential drop, denominated as the Nernst potential, is measured. In Lab-on-a-Chip devices ion-selective potentiometry has become a routine analytical technique for both in vivo and in vitro chemical analysis [5]. Special membranes have to be used for this purpose in order to achieve detection of a range of ions rather than the usually desired selectivity to just a single ion.

Chemical Analysis Based on Conductivity Detection

In conductivity detection, the concentration of an analyte is determined by measurement of the liquid conductivity. Two electrodes are placed in the channels. An alternating voltage, v_{in}, is applied between the electrodes and the resulting current, i_o, is measured. The value of the current is proportional to the liquid conductivity, κ (Sm^{-1})

$$i_o = \frac{v_{\text{in}}}{\text{K}}\kappa \,, \tag{7}$$

where K is the cell constant (m^{-1}).

Conductivity detection has also been investigated for chip-based separation and is a good technique in particular for small (inorganic) ions which are otherwise not readily detected [6].

The primary advantage of amperometric and potentiometric detection over conductivity detection is the high sensitivity induced by the electrochemical reactions that take place at the electrode surface. Only electrochemically active compounds can be detected using these methods, thereby eliminating interference from other compounds present in the sample. This selectivity can also turn into a disadvantage, since it strongly limits the applicability of the detection system. Additionally, the interference between the electrical separation field and the detection electrodes and associated electronics can be a problem.

Chemical Analysis Based on Mass Spectroscopy Detection

Mass spectroscopy offers a powerful tool for the detection and identification of compounds. The method is highly sensitive to small changes in mass, it needs minimal sample preparation and it allows structure elucidation and accurate molecular weight determination. It is the natural figure of merit when detecting single small entities such as bacteria, viruses, nanoparticles or individual molecules [7]. Furthermore, DNA-based assays are easy to perform [4]. Interfacing of microfluidic systems with mass spectrometers represents a special challenge. However, as miniaturization of this detection offers no meaningful advantages in terms of sensitivity or selectivity, mainly conventional-size detectors have been used in combination with chip-based separation systems.

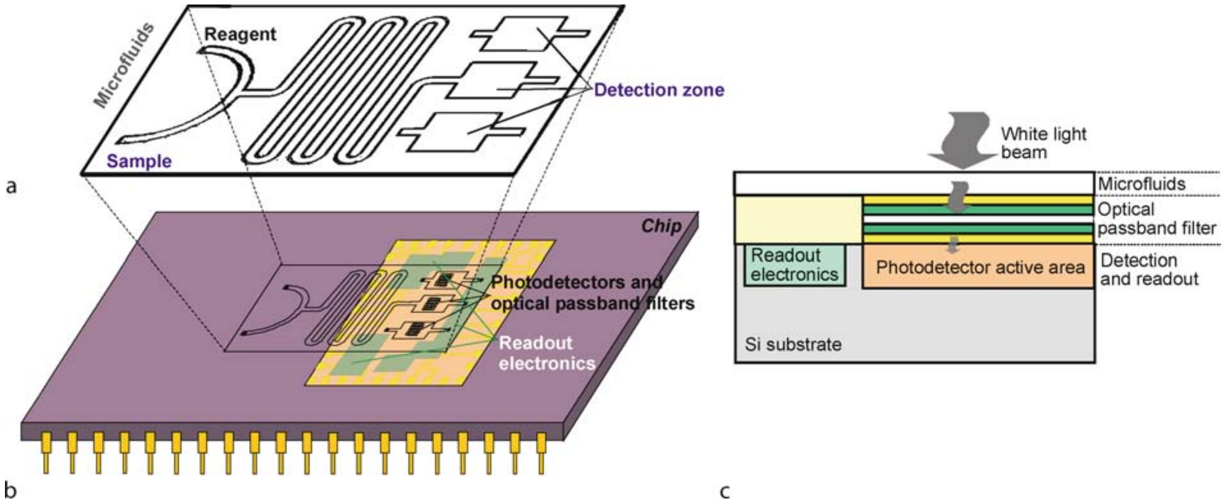
Integration of Optical Detection Systems

If a Lab-on-a-Chip is defined to be a unit that should be able to perform all chemical functions and detection in a monolithic device that fits in the palm of one's hand (or smaller), then existing Lab-on-a-Chip units are generally still quite underdeveloped. This miniaturization will require increased integration not only of fluidic elements, but also of electrical, optical or other types of elements. The major criteria that lead the choice of a detection scheme are the properties of the analyte (optical, electrical, electrochemical and physical), the composition of the sample (do the analytes have similar properties and/or similar concentrations?) and the required detection limit. Other specific criteria can be the price, ease of use and implementation and, as far as Lab-on-a-Chip devices are concerned, the ease of fabrication and the possibility for miniaturization. In applications where the Lab-on-a-Chip is discarded after a single use, the cost of the device is very important and can even limit the choice of detection scheme.

As said before, a Lab-on-a-Chip device is composed basically of two elements: the fluidic and detection elements. These elements can be totally integrated in the same substrate, can be bonded and thus integrated or, when total integration is not possible, they can have a multi-chip-module (MCM) configuration. Figure 1 shows a schematic of a device using absorption spectrophotometry as the optical detection scheme. In a chip format device, distances between elements are reduced, resulting in better coupling of light from one element to the next. Moreover, the number of optical interfaces has also been reduced by directly contacting the various components one to the other, thereby reducing interfaces at which optical losses can take place.

Integrated Light Sources

Many semiconductors and their combinations form the basis of light-emitting diodes (LEDs) and laser diodes, a class of devices producing light in different wavelength regions from the blue to the near infrared. LEDs have been employed as external light sources for on-chip absorbance and fluorescence detection [8], and also as integrated arrays for sensing applications. Laser diodes have mainly been employed for LIF detection in on-chip CE. However, portable Lab-on-a-Chip units for in-field or point-of-care applications clearly should avoid external light sources.



Lab-on-a-Chip Devices for Chemical Analysis, Figure 1 Schematic of a Lab-on-a-Chip structure: (**a**) microfluidic die; (**b**) optical detection die; (**c**) cross-section of the structure for a single optical channel

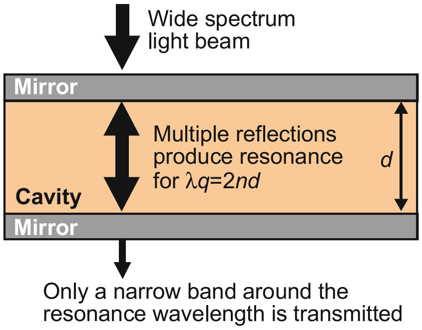
The integration of organic light-emitting diodes (OLEDs) as an excitation source is a promising alternative. The use of solution-processable semiconducting polymers or vacuum-deposited small-molecule organic semiconductors offers simple routes to device fabrication and tunable optical properties. These characteristics have been extensively demonstrated for thin-film polymer light-emitting diodes (pLED) which have entered the market place for simple display applications [9].

A typical OLED comprises one or more organic layers sandwiched between two electrodes, of which at least one must be transparent. The organic layer emits light under electrical excitation (via radioactive recombination of injected electrons and holes) and the devices may therefore be used as light sources. The emission color is determined by the chemical structure of the organic material and it may therefore be controlled using standard synthetic chemistry [10]. Therefore, an array of OLEDs producing light in the visible spectrum from blue to red may be fabricated. Many of the organic materials are soluble allowing for low-cost deposition from solution. Once OLEDs are fully compatible with polymeric substrates, and also the organic layers can be fabricated using simple layer-by-layer deposition procedures, they may be easily integrated into existing microchip structures at marginal additional cost. The tunable optical properties, simple fabrication, small size and low cost of OLEDs have already attracted considerable interest for employing them as integrated light sources for on-chip spectrophotometric measurements.

If the same device is needed to analyze more than one analyte an integrated light source such as a LED or semiconductor laser is not enough, since they cannot output a continuous variation of the wavelength. Macroscopic equipments for chemical analysis based on spectrophotometry include a wavelength-dependent light source illuminator, such as a monochromator, for illuminating the sample at the wavelength at which the analyte has its absorption or fluorescence maximum. However, Lab-on-a-Chip devices for portable point-of-care chemical analysis should avoid those external, complex and expensive macroscopic optical systems. This means that the monochromator must be integrated on-chip with the optical detector and the readout electronics devices. For that purpose, a regular white light source and an on-chip monochromator, as well as on-chip optical detectors with high spectral selectivity over a relatively wide wavelength range are required. However, on-chip integration of a monochromator, based on a grating as dispersive element, is expensive and difficult, due to the limited optical pathlength available.

Integrated Optical Filters

A Fabry–Perot (FP) interferometer can be used in an optical sensing system to pass a specific part of the spectrum, functioning like a monochromator. A FP structure is the most suitable for passband optical filters. A ►Fabry–Perot optical filter consists of two parallel mirrors with a resonance cavity in the middle (Fig. 2). The equation $\lambda q = 2nd$ shows its operation principle, where n is the refractive index of the cavity medium, d the cavity length, λ the incident wavelength and q the interference order ($q = 1, 2, 3, \ldots$). Therefore, in a FP optical filter the thickness of the resonance cavity, n, determines the tuned wave-



Lab-on-a-Chip Devices for Chemical Analysis, Figure 2 FP structure

length, λ [11]. The most important parts of the FP devices are the mirrors. Two types of highly reflective coatings are used for the mirrors: metallic and dielectric. Metallic mirrors have high absorption losses, but they can be attractive in certain applications due to the simplicity of their fabrication: only three layers are deposited and wavelength selection is performed by changing only the thickness of the cavity layer. The layout design for the etching/deposition process of the several cavities is crucial to minimize the number of masks and etching/deposition steps. Moreover, if the filters can be co-fabricated in a CMOS process and post-processed on top of the silicon optical detectors, the resulting Lab-on-a-Chip will be a low-cost disposable device and can be used for point-of-care diagnosis. A structure that comprises an array of 16 FP optical filters with metallic mirrors has been demonstrated [11]. It uses silver and aluminum as the top and bottom mirrors, respectively, and SiO_2 as the cavity layer. The aluminum bottom layer was evaporated on top of the photodetectors. Then a SiO_2 layer was deposited by chemical vapor deposition. In subsequent plasma etching steps, for which a mask is used, the 16 resonance cavities were realized in the SiO_2 layer. The evaporation of the silver layer on top of the resonance cavities ends the array fabrication. However, FP filters using metallic mirrors cannot provide both high ►transmittance and low ►full-width at half-maximum (FWHM) due to the optical absorption in the metal layers. The price of such simple a fabrication process was the 10% of transmittance for achieving a FWHM = 7 nm.

These drawbacks can be avoided using a FP structure with dielectric mirrors. Dielectric mirrors, when properly designed and fabricated, offer high-performance characteristics (high reflectivity with low absorption losses). When using dielectric layers, at least two different materials with high and low refractive index and alternately deposited are needed to obtain narrow passband optical filters. A structure that comprises an array of 16 FP optical filters with dielectric mirrors has been demonstrated [12] and is shown in Fig. 3. The fabrication process is similar to that described above. Each optical channel is sensitive in a single wavelength with a FWHM of 6 nm and with a peak intensity higher than 86%. The 16 optical channel array fabrication requires only four masks, used with different deposition times. It uses TiO_2 and SiO_2 (with refractive indexes of about 3.0 and 1.5 in the visible spectrum, respectively) for the fabrication of the dielectric mirrors. These films are hard materials, and thus it is extremely difficult, or even almost impossible, to remove them from the substrate. SiO_2 has been selected because the wavelength dependence of its refractive index for the spectral band between 480 and 700 nm is almost constant (1.465 and 1.457, respectively). TiO_2 has been selected due to fabrication constraints (the deposition process is well characterized).

Instead of an array of fixed sized FP optical filters, a tunable scheme would be an alternative. A conventional tunable filter comprises, usually, an air-gap cavity and one movable mirror using, for example, electrostatic actuation. Comparing both schemes, the array of fixed-sized FP optical filters has the following disadvantages:

- it requires a large area (proportional to the number of different sized cavities);
- several layers have to be deposited/etched for the several cavity widths; and
- the spectral range covered is smaller.

However, it is relatively simple to operate. The tunable approach has three disadvantages:

- fabrication requires complex micromachining, which is difficult to be merged with a standard process;
- large voltages are required for actuation; and
- operation is difficult, mainly for achieving parallelism between the mirrors during the tuning of the filter.

An alternative to solve the problem of maintaining parallel mirrors in tunable FP optical filters is using a polymer such as poly(vinylidene fluoride) (PVDF) in its β-phase as the resonance cavity, instead of an air-gap cavity. The filter is tuned through an electric voltage inducing dipolar orientation in the β-PVDF film. Since the thickness changes of the β-PVDF film are due to variations at a molecular level, the changes are rather homogeneous within the samples. This is reflected in the ability to maintain parallel mirrors. Furthermore, the fabrication process is simpler and of lower cost, when compared with the conventional tunable FP optical filter. This kind of filter can be fully integrated with the polymeric substrate of the microfluidic element, allowing a Lab-on-a-Chip suitable for low-cost disposable point-of-care diagnosis. This idea leads to integrated monolithic optical filters that can be attached to the substrate of the microfluidic chip or even to the photode-

L

tectors, when organic photodetectors are used. For example, a structured dye-doped polydimethylsiloxane (PDMS) layer can serve concurrently as a microfluidic network and optical filter.

Integrated Detectors

Generally, silicon and other semiconductor materials exhibit active optical properties, such as the ability to absorb and emit light. In a standard *n-well* CMOS process, three photosensitive structures are possible as vertical junction photodiodes: *n-well/p-epilayer*, *p+/n-well* and *n+/p-epilayer*, formed by doping the silicon substrate (see Fig. 4). These structures operate by converting absorbed photons directly into electronic carriers which are ultimately detected. At a particular wavelength, their ▶ quantum efficiency varies according to their junction depth. The quantum efficiency of a photodiode reveals how well it collects the incident light. In the visible spectrum, blue light (of about 450 nm) is more efficiently collected by a shallower junction (*p+/n-well* and *n+/p-epilayer*) and red light (of about 650 nm) by a deeper junction (*n-well/p-epilayer*). Moreover, despite the shallower junction of the *n+/p-epilayer* photodiode, it has the higher quantum efficiency at wavelengths of about 500 nm, due to the different doping concentration between the n- and the p-side, which extends the p-side depletion area more deeply. Since technology rules from the CMOS process should be met, the design of the optical path is restricted to combinations of the three dielectric layers available on top of the pn junction. The second oxide layer and the silicon nitride layer were removed (without affecting the CMOS process) to eliminate the wavelength dependence of the transmission through these layers. The first oxide layer should remain to protect the photodiode active area. In addition, removal of the first oxide layer would introduce random surface roughness, which introduces wavelength dependence that would adversely affect the optical performance. CMOS photodetectors have the advantage of being generic, favoring the integration of multiple electronics functions with a high yield and the CMOS process is, currently, the cheapest of the competing technologies.

An alternative approach to silicon photodiodes is the use of organic photodiodes [10]. They can be realized on different substrate materials, such as glass, plastic foil, ceramics silicon or even paper. However, plastic-based organic photodiodes are mechanically flexible, very thin, of low weight and may be fabricated at low temperature using simple layer-by-layer deposition procedures. Unlike silicon-based photodiodes, their size is not limited by the size of a silicon wafer. Organic photodiodes comprise one or more layer of organic semiconducting material sandwiched between two electrodes (the same structure as for OLEDs). They generate a measurable current under illumination. The photovoltaic effect in organic photodiodes is based on the formation of electron–hole pairs (excitation) and subsequent dissociation and charge collection at the electrodes. While photoinduced charge generation is enhanced by large interfaces between electron donor and acceptor materials, good connectivity to

The CMOS chip includes FP optical filters, photodetectors and readout electronics. Each detection chambers is 2 mm wide, 3 mm long and 500 μm deep (this depth is crucial for optical absorption measurements). The main channel is 500 μm wide, 70 mm long and 500 μm deep, with a liquid volume quantity of 20 μl. This volume is fitted for any untrained person to inject with an appropriate syringe

the collection electrodes must also be ensured [10]. Once organic photodiodes are fully compatible with plastic substrates, they can be easily integrated on the microchannel substrate resulting in a fully integrated Lab-on-a-Chip device. Nowadays plastic-based fluidic microchannels are the most used. For example PDMS has good biocompatibility and optical transparency over the visible range and allows for rapid molding-based prototyping and scalable manufacturing at low cost and with high reliability. The combination of PDMS microfluidic chips with organic photodiodes offers an attractive route to fabricating low-cost diagnostic devices, which incorporate the fluidic channels, the detectors and even OLEDs into a single monolithic package. Such devices, when used in combination with integrated filters reported above, may offer a means of creating completely monolithic ultra-low-cost microfluidic devices suitable for use in disposable point-of-care diagnostics [13].

Waveguides

Fundamental premises for the use of fiber optic technology are the possibility of confining and propagating the light along specific pathways for transporting it from one location to another with as little loss as possible. The integration of waveguiding structures in planar chips has attracted interest for achieving optical components of greater robustness and minimal cost. Waveguiding structures have been previously fabricated in silicon substrates by oxide deposition, ion-exchange and anisotropic etching. However, their fabrication using polymers such as SU-8 and PDMS have grown in popularity, due to the low cost of these materials and the rapid fabrication processes based upon them. Combination of such structures with liquid guiding microchannels has been reported [14, 15]. For example, waveguiding channels can be integrated into the walls of a channel in order to launch light across it for being collected on the other side [14].

Key Research Findings

Lab-on-a-Chip Devices for Chemical Analysis Based on Absorbance Detection

A Lab-on-a-Chip for point-of-care routine analysis of urine is presented in Fig. 5. It measures the concentration of 16 different chemical parameters in urine by optical absorption. Usually, urine analyses in conventional clinical laboratories are performed by absorbance.

It includes an array of highly selective optical filters, based on FP thin-film optical resonators that are integrated on top of silicon CMOS photodetectors. Integrated CMOS readout electronics are also included for data acquisition. This scheme avoids the use of a dedicated light source allowing a regular white light illumination for the absorbance measurements. The microfluidic channels and detection chambers are fabricated using a layer of ►photoresist SU-8 deposited on a glass substrate. This epoxy-based material provides low sidewall roughness and a deep rectangular vertical profile of the microchannels, which is suitable for optical absorption measurements (the Lambert–Beer law can be directly applied). Moreover, it also provides a low-cost fabrication process, UV lithography semiconductor compatibility and does not require expensive masks. Therefore, the microfluidic die can be a disposable die avoiding contaminations between analyses, a requirement that should be fulfilled in point-of-care systems for

use by any untrained person. The chosen structure of the channels, in conjunction with the sample and reagent fluid properties, allows a complete and homogeneous mixing of the reagent with the sample, driven only by diffusion (no external devices for pumping are needed). The combination of the integrated optical detection scheme and the low cost fabrication of the SU-8 microfluidic structure offers unique opportunities for spectrophotometric analysis in clinical diagnostics, in addition to the general advantages of Lab-on-a-Chip units concerning small sample volume. Moreover, the device can be broadly applicable and a powerful tool in hospitals, operating rooms, doctors' offices, clinical laboratories as well as in patient homes, e. g., a point-of-care device. The results obtained using this Lab-on-a-Chip (see Table 1) agree with macroscopic measurements performed with well-known standards and using state-of-the-art laboratory equipment. The features such as performance, precision, reliability and sensibility of the analysis were the same from the ones obtained in clinical analysis laboratories.

Increasing the Optical Pathlength

In applications where the liquid volume is very small, such as CE, absorbance detection is difficult because of the reduced optical pathlength. Using micromachining techniques, an easy route to small-volume, long-pathlength detector cells can be offered. Liang et al. [16] showed how to increase the optical pathlength without increasing the sample volume. They included optical fibers fit-

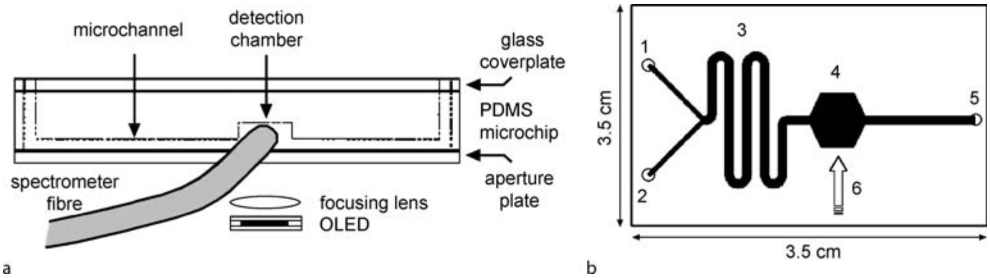
ted into two etched channels and placed at the end of the detection channel (Fig. 6). However, the finite dimensions of the optical fibers (usually > 100 μm in diameter) limit their use for detection at multiple, closely spaced points along a channel. Additional freedom can be provided in many cases by the integration of waveguide structures directly into the microfluidic devices. For example, deep grooves can be fabricated in the microfluidic device into which fused silica capillary can be placed, forming buried waveguides. Light could be coupled to the waveguides via optical fibers, which were in turn fixed in the chip by connectors formed in its substrate. Mogensen et al. [14] extended this concept further to integration of waveguiding and microfluidic channels together in the same device (Fig. 7).

That example demonstrates the benefits of using MEMS technologies for absorbance detection in microfluidic devices, especially in terms of improving sensitivity by increasing the optical pathlength. However, Mogensen et al. [17] and Liang et al. [16] point out that this sensitivity is often achieved at the cost of lower transmitted optical power, which at some point will begin to reduce the SNR. Mogensen et al. [17] proposed the inclusion of focusing and reflecting elements in its device that could alleviate this problem somewhat. The use of the longitudinal direction of a flow channel, in which mirrors above and bellow of the channel have been patterned, is another possibility for increasing the optical pathlength. Light can be introduced in such a way that it will encounter the channel walls several times and will be reflected as it propagates



Lab-on-a-Chip Devices for Chemical Analysis, Figure 9 (**a**) Schematic of experimental setup and (**b**) microchip layout. The device comprises two inlets, a meandering mixing channel, a detection chamber and an outlet. The inlets are 400 μm wide, 800 μm deep and 10 mm long, while the mixing channel is 800 μm wide, 800 μm deep and 520 mm long. The extended detection chamber is 5 mm long, 5 mm wide and 1.6 mm deep, with a volume of 27 μl. (Reprinted with permission from [9])

down the channel. This can be still more advantageous, as the effective optical pathlength of the channel is increased beyond the actual length of the channel. In this scheme, source and detection will be positioned on opposite sides of the flow channel and absorbance can thus be measured in the direction of the flow.

Lab-on-a-Chip Devices for Chemical Analysis Based on Fluorescence Detection

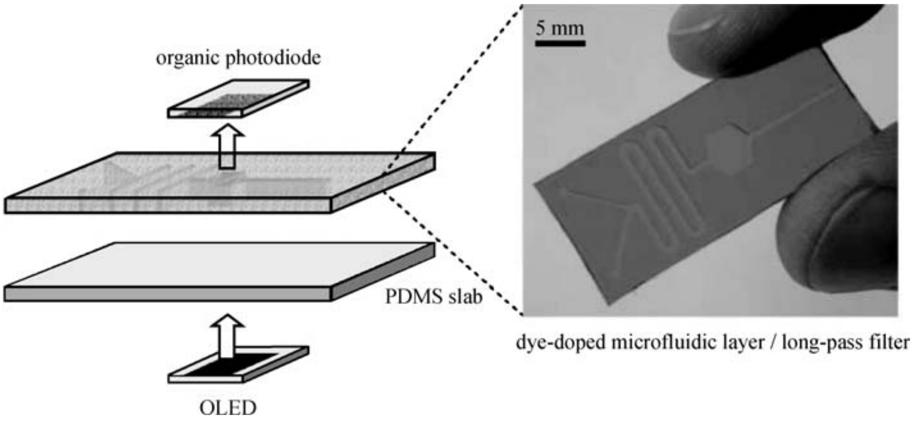
LIF is, at present, the most widely used detection technique for fluorescence detection in CE Lab-on-a-Chip devices, because of its high sensitivity. Kamei et al. [18] proposed a hydrogenated amorphous silicon (a-Si : H) pin photodiode used as the fluorescence sensor for detecting fluorescein in a CE device for DNA analysis. The a-Si : H is a suitable material for fabricating integrated fluorescence sensors on glass and plastic because of its compatibility, low dark current and low manufacturing cost. More important, the enhanced optical absorption of a-Si : H in the visible range matches perfectly with the fluorescence bands of most practical labeling dyes used in molecular biochemistry (except green fluorescence). The hybrid integrated sensor comprises a fluorescence collecting lens, a multilayer optical interference filter with a pinhole and a ring-shaped a-Si:H pin photodiode. The fluorescence measurements are performed using vertical laser excitation. Using this integrated device, the limit of detection achieved for fluorescein in a 50 μm deep channel was 17 nM with a SNR = 3. From the viewpoint of laser integration, an important aspect of this device is vertical laser excitation through the detector. When combined with vertical cavity surface emitting laser diodes, this integrated a-Si:H sensor should facilitate the construction of a coaxial excitation–detection module for low-cost portable microfluidic bioanalyzers.

Another example of a monolithic CE device with integrated on-chip fluorescence detection has been reported by Webster et al. [8]. The device incorporates a silicon photodiode, an optical interference filter that prevents excitation light from inhibiting the fluorescence detection and a thin-film plastic (parylene) electrophoresis channel above (Fig. 8). Chemical isolation to prevent ions in the separation solution from reaching the ion-sensitive silicon detectors below is provided by a 5 μm thick lower wall of the electrophoresis channel. A transparent aluminum zinc oxide conducting ground plane is also used to prevent the high electric fields, needed for the separation, from interfering with the photodiode response. The performance of the device was demonstrated in the separations of DNA restriction fragments. The achieved detection limits were of the order of femtograms.

Waveguides have also been integrated into microchannel devices for fluorescence detection. Silica on silicon chip technology was commonly used to form the heart of a fiber for fluorescence measurements.

Human microalbuminuria typically relies on fluorescence detection due to the very low concentrations that must be detected. Hofmann et al. [9] reported the use of a thin-film OLED as an excitation source for microscale fluorescence detection. The OLED has a peak emission wavelength of 540 nm with a FWHM that overlaps with the absorbance spectrum of the microalbuminuria complex reagent assay. Fluorescent at 620 nm is emitted by the reaction when excited by the OLED. Concentrations down to 10 mg/l were measured with a linear range from 10 to 100 mg/l and without the need of a filter between the excitation light and the generated fluorescent light. Orthogonal detection geometry, implemented using a microfluidic layer with optical grade side surface, avoided the use of such a filter (Fig. 9). The concentration range measured and its sensitivity comprise the required range for human microalbuminuria detection.

In this approach the detection architecture was not fully integrated on-chip. However, recently the same group reported a monolithically integrated optical longpass filter for use in microchip fluorescence detection [13]. The inte-



Lab-on-a-Chip Devices for Chemical Analysis, Figure 10 Schematic of a monolithically integrated optical longpass filter. The structured dye-doped PDMS layer is able to serve concurrently as the microchannel medium and optical filter, negating the need for an additional filter layer, and allowing for improved collection of the fluorescence signal, since the detector can be placed in closer proximity to the channel. The enclosed microchannels are obtained by sealing the doped layer against a second nondoped PDMS slab. For a collinear detection geometry the excitation source and detector are positioned below and above the assembled microchip. The photograph shows a Sudan II-doped PDMS filter with 800 μm wide and 800 μm deep microchannels. (Reprinted with permission from [13])

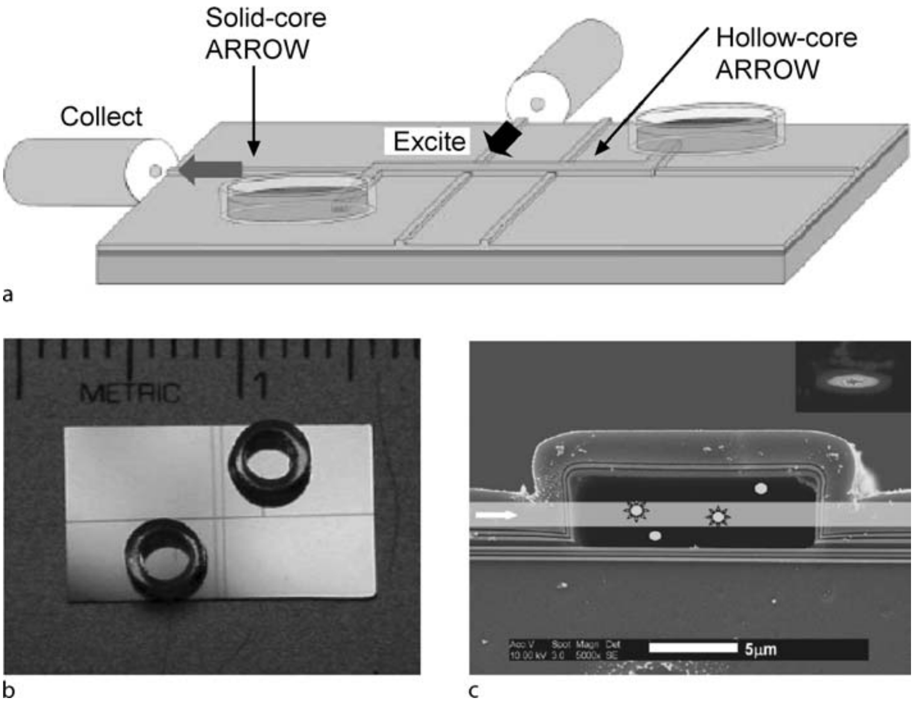
grated filters are monolithically attached to the substrate of the microfluidic chip. They were prepared by incorporating dye molecules into a PDMS microfluidic chip substrate, allowing for the fabrication of colored substrates that serve concurrently as channel medium and optical filter (see Fig. 10). The filter features 0.01% transmittance below 500 nm, more than 80% transmittance above 570 nm and negligible autofluorescence. These kinds of filters integrated with OLEDs and organic photodiodes offer a means of creating a completely integrated monolithic Lab-on-a-Chip fabricated at low cost, compared to fully integrated filters for silicon based devices, which is suitable for disposable point-of-care diagnosis.

Yin et al. [15] described a fully integrated SU-8 microfluidic chip for detection, manipulation and analysis of bioparticles (Fig. 11). It integrates liquid-core optical waveguides with fluidic reservoirs and solid-core antiresonant reflecting optical waveguides to define sub-picoliter excitation volumes and transport and collect light on the chip, resulting in fully planar beam geometries. The liquid-core optical waveguides guide both light and fluids in the same volume. The photograph of Fig. 11c visualizes the propagation of a light beam across a SU-8 microfluidic channel filled with solution containing a fluorescent die [15].

Lab-on-a-Chip Devices for Chemical Analysis Based on Chemiluminescence Detection

A fully integrated Lab-on-a-Chip device for chemiluminescence was proposed by Jorgensen et al. [19]. This device takes advantage of both semiconductor properties and the advanced micromachining possibilities of silicon. It integrates a backside silicon photodiode with a microfluidic channel network on the front side of the same silicon substrate wafer. The Lab-on-a-Chip has all fluidic and electrical connections on one side of the chip. The channel networks were sealed using anodic bonding (glass to silicon) on the front side of the silicon wafer. The chip size is 10 mm wide and 20 mm long. The sample and reagent channels have a meandering layout and they meet in a laminar mixer. The device performance was demonstrated in chemiluminescence-based detection of hydrogen peroxidase and luminol.

Thin-film organic photodiodes as integrated photodetectors for microscale chemiluminescence assays were reported by Hofmann et al. [10]. The organic photodiodes are based on vacuum-deposited bilayers of copper phthlocyanine (CuPc) and fullrene (C_{60}) to detect the emission signal from peroxyoxalate chemiluminescence reactions. The organic photodiodes have an external quantum efficiency of approximately 30%, an active area of 16 mm^2 (large when compared with the 2 mm^2 area of the detection zone) and a total thickness around 2 mm. For applied flow rates of 25 μl/min a chemiluminescence signal of 8.8 nA within 11 min was obtained as well as a background signal of 1 nA (high value due to the mismatch between the photodiode area and the detection zone area). Preliminary quantization of hydrogen yielded a detection limit of approximately 1 mM, which is high compared to the 10 μM reported by Jorgensen et al. with inorganic devices [19].

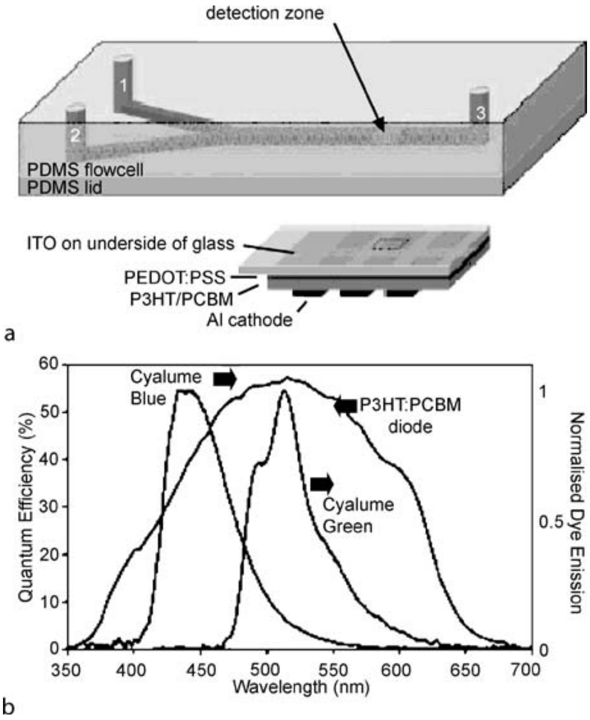


Lab-on-a-Chip Devices for Chemical Analysis, Figure 11 Planar optofluidic chip: (**a**) schematic of integrated optofluidic chip showing hollow- and solid-core waveguides; (**b**) photograph of the finished chip; (**c**) photograph showing schematically the excitation beam traversing the microchannel (as indicated by the arrow) and fluorescing particles that may diffuse in and out of the excitation volume. (Reprinted with permission from [15])

That detection limit was recently improved by Wang et al. [20]. The authors replaced the 16 mm^2 vacuum-deposited CuPc-C_{60} bilayer devices by 1 mm^2 solution-processed polymer devices based on a 1 : 1 blend by weight of the conjugated polymer poly(3-hexylthiophene) (P3HT) and 6,6-phenyl-C_{61}-butyric acid methyl ester (PCBM), a soluble derivative of C_{60}. The device has an active area of 1 mm^2 and an external quantum efficiency of more than 50% between 450 and 550 nm (Fig. 12). The device area is well matched with the detection zone area of the microfluidic chip, which results in a minimized background signal (225 pA). The achieved detection limit for detecting the emission signal from peroxyoxalate chemiluminescence reactions was 10 μM. The photodiodes have a simple layered structure that permits easy integration with planar chip-based systems. The authors are investigating the use of integrated electronics for readout and display of the photodiode current, in order to obtain a completely integrated Lab-on-a-Chip for disposable point-of-care diagnosis.

Future Directions for Research

Much of the investigation performed of Lab-on-a-Chip devices for chemical analysis is driven by the promise of cheap and disposable devices. The fact that many of the devices presented above require additional processing in a cleanroom makes them unattractive for applications requiring inexpensive solutions, once the cost reduction in silicon micromachining is not possible (no potential in downscaling of the footprint). That is why many Lab-on-a-Chip approaches have lost focus on the total analysis in favor of single operations, such as separation and detection. However, the growing knowledge based on the replication of devices in plastics will help to change this. Microfabrication technologies for polymers like injection molding or hot embossing are probably the most promising alternatives, as it becomes possible to form both microoptical and microfluidic elements in single devices by these processes. For more demanding applications in which the optical signal is weak, some increase in complexity is inevitable. The challenge for the next generation of cheap and disposable Lab-on-a-Chip devices for chemical analysis by spectrophotometry is improving the sensitivity, so that these devices can accomplish low-light tasks. This implies that there still needs to be substantial improvement in filter performance and in the efficiency of detectors in collecting the light for the promise of having truly implemented Lab-on-a-Chip platforms for chemical analysis by spectrophotometry that can outperform the



Lab-on-a-Chip Devices for Chemical Analysis, Figure 12 (**a**) Microchip layout. The inlets are 400 μm wide, 800 μm deep and 10 mm long. The mixing channel is 800 μm wide, 800 μm deep and 520 mm long. The active area of the photodiode used for chemiluminescence detection is 1×1 mm^2. The photodiode is located at a position 10 mm downstream from the point of confluence of the two inlet streams. The emission spectra of both dyes overlap the spectral response of the photodiode. (Reprinted with permission from [20])

standard macroscale technologies. Maybe it will not be too long until we will all be able to have our own Lab-on-a-Chip at home: you feel sick one day and maybe you can know what is wrong by simply loading urine or saliva into a Lab-on-a-Chip device.

Definition

An immunoassay is a biochemical test that measures the level of a substance in a biological liquid, using the reaction of an ►antibody or antibodies to its ►antigen. The assay takes advantage of the specific binding of an antibody to its antigen. ►Monoclonal antibodies are often used as they only usually bind to one site of a particular molecule, and therefore provide a more specific and accurate test, which is less easily confused by the presence of other molecules. The antibodies picked must have a high affinity for the antigen.

Overview

Microfluidic devices have been one of the earliest success stories in the commercialization of microelectromechanical systems (MEMS). Efforts to dispense minute amounts of liquid at high precision date back to the early 1950s and constitute the basics of modern inkjet technology. When MEMS were still chiefly an academic topic in the 1980s, microfluidic research outside the inkjet world focused on the miniaturization of conventional components like pumps and valves. Later, design paradigms began to shift. Novel operating principles based on genuine microfluidic effects emerged which could not be realized by simply downscaling traditional solutions.

The heart of a microfluidic device is often a microchannel, in which reaction, separation or detection takes place. The flow of liquids in microchannels is laminar, and therefore mixing at the micrometer scale is difficult to achieve. The large surface to volume ratio of microchannels can make interfacial reactions efficient. Microfluidic devices sometimes comprise a complex mix of elements and functionalities, making them efficient for tasks as elementary as metering liquids as well as for processing and analyzing complex biological samples. It can be as simple as glass capillary tubes or as complex as microchips having micropumps, sensors and electronic circuitry to move liquids.

Immunoassays are analytical experiments in which identification and quantification of target molecules are done by using highly specific antibodies. Antibody-based immunoassays are the most commonly used technique to identify different types of analytes such as proteins, peptides and low molecular weight molecules. This technique has been used in hospitals, laboratories and industries for the last few decades to detect antibody–antigen in samples.

Basic Methodology

Immunoassays are analytical experiments in which antibodies are used for detection and quantification of target molecules. Immunoassays have been used in the medical field, life sciences, prognostics and diagnostics, environmental control and pharmaceutical and biotechnology industries for the past 40 years. The method has been reliable in detecting the presence and the amount of antibody and antigen in a sample. Conventional immunoassays are a time-consuming process which requires several steps such as reagent addition and washing. Some of the common immunoassay methods include radio immunoassays, enzyme linked immunosorbent assays (ELISA), enzyme immunoassays (EIA) and fluorescent immunoassays (FIA).

Antibodies are the key element in an immunoassay method. Typically, there are two types of antibodies: monoclonal and ►polyclonal. Monoclonal antibodies are completely homogeneous with respect to antigen while polyclonal antibodies are heterogeneous and always a mixture of various antibodies.

Antibodies are proteins developed by animals to counteract the invasion of foreign molecules (antigens) into the body. Antibodies can be found in body fluid such as blood and tissue. The main function of antibodies is to bind to antigens to render them harmless to the body function. There are five main classes of antibodies: IgM, IgG, IgA, IgD and IgE. All antibodies have at least two antigen binding sites. IgM has ten potential binding sites, IgA has four binding sites while IgG has only two binding sites. Even though all antibodies are antigen specific, they do, however, cross react with other antigens that look similar to the one to which they are specific.

The binding of antibodies to antigen assays can be classified into three different categories: direct, competitive

and sandwich [1]. Direct assays are a simple procedure whereby excessive antibody is incubated with antigens. The sensitivity of this method is proportional to the amount of antibody present in the assay. The antibody is fixed to a substrate and a fixed amount of labeled antigen and varying amount of unlabeled antigen are introduced to the sample. Then the amount of bindings or antibody–antigen is measured [2]. In a *competitive* immunoassay, the antigen in the sample competes with the labeled antigen for a limited number of antibody binding sites. The bound antigen is separated from the excess antigen not bound to the antibody. The amount of antigen in the unknown sample is inversely proportional to the amount of labeled antigen, as measured in a gamma counter or spectrophotometer. Examples of competitive immunoassays are double antibody radioimmunoassays (RIAs), coated tube RIAs and coated well enzyme immunoassays (EIAs).

In non-competitive immunoassays, the antigen is a *sandwich* between two antibodies, the capture antibody and the detection antibody. Typically, the capture antibody is coated to a solid phase, such as a tube or a well, and the detection antibodies are labeled with either an isotope or an enzyme. The amount of antigen in an unknown sample of these immunoassays is directly proportional to the amount of labeled detection antibody measured by the detection system. Examples of non-competitive assays are IRMA and ELISA. Figure 1 illustrates different types of binding.

A number of methods are used for the detection of antibody–antigen bindings. The most common methods used are radioisotopes, fluorophores, color changing enzymes and metallic and magnetic beads. The advanced detection methods make use of ► chemiluminescent chemicals, and immunoblotting and signal amplification.

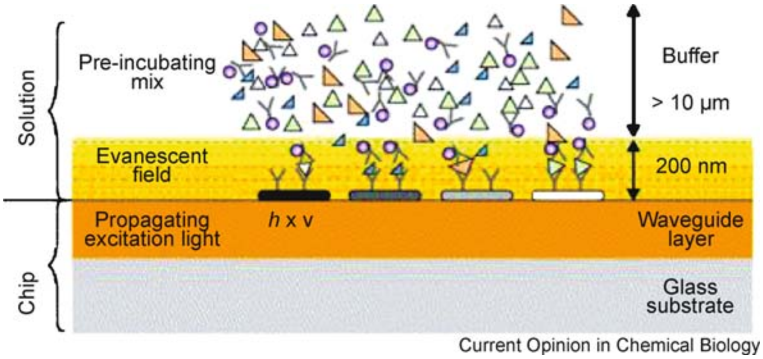
Key Research Findings

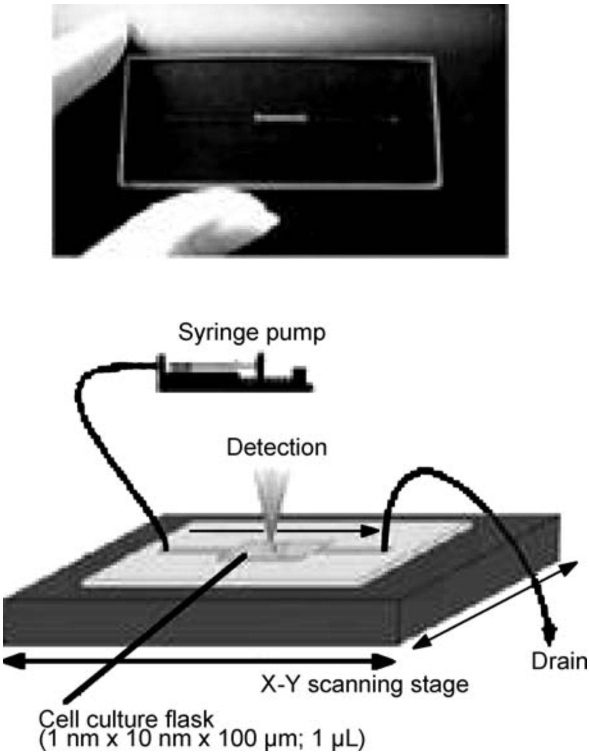
Fairly comprehensive research on immunoassays based on microfluidic technology has been made recently. Antibody microarrays are still in their infancy but rapidly growing. Microarrays are used in the detection of diseases, cancer research and drug discovery. Immunoassay microarrays consist of antibodies immobilized on a solid substrate. Immunoassay microarrays are fabricated by using antibody microspots on a solid substrate. Samples containing antigen are incubated on the microspots coated with capture antibodies. Unbound molecules are then washed away and labeled conjugate or detection antibodies are allowed to bind to the captured antigens on the microspots. The signals from the labeled conjugate antibodies which are bound to the captured antigens are then detected using scanners. Signal intensities are commensurate with the amount of captured analytes present in the sample. A significant amount of research has been conducted towards integrating microfluidic technologies with protein microarrays.

An important aspect of microarrays is the capability of detecting multiple analytes in a single sample for rapid analysis of sample fluids. A simultaneous detection of 24 cytokines with a very high sensitivity was reported by Huang et al. [3]. This method is comparable to the ELISA method in terms of specificity, detection limit and sensitivity using enhanced chemiluminescence (ECL). An improved fluorescence-based detection microarray system has also been developed using planar optical waveguide technology [4]. The capture antibodies are immobilized on the planar waveguide in a microarray format (Fig. 2). This method does not require the washing steps to remove the unbound antibodies. The antibody binding is detected using laser light to excite the surface-bound fluorophores.

Recent developments in bead-based immunoassays mean they have an edge over the normal fluidic systems. There are several main advantages of using microbeads [5]. The surface to volume ratio (SVR) is increased even in a microfluidic system. As a result, the sensitivity of the assays increases due to higher efficiency of interactions between the samples and reagents. Another advantage is that the beads can be easily transported in a fluidic system using pressure-driven or electric fields. The beads can also be modified by altering the surface properties which can provide multiple functionalities to a single microflu-



Lab-on-Chip Devices for Immunoassays, Figure 2 Immunoassay based on planar waveguide [4]



Lab-on-Chip Devices for Immunoassays, Figure 3 (**a**) Cell culture chip; (**b**) Single-cell imaging using thermal scanning lens [6]

idic device. A glass-based immunoassay microchip has been reported involving the integration of polystyrene beads with pre-coated anti-CEA antibody. This microfluidic system uses thermal lens microscopy as the detection method [6]. By using this device, reaction time was reduced to about 1% of that required for ELISA. The system has inlet holes and a reaction zone with a reservoir for the microbeads to be detected. A sensitivity of 1 ng/ml was achieved for the detection of peptide hormone concentration. Figure 3 shows the experimental setup for this method. The incorporation of luminescence-based tags into proteins as well as bead-based surface chemistries has resulted in new types of immunoassay systems. Bead-based detection systems use synthetic beads pre-coated with antibody to detect antigens in analytes. Bead-based immunoassays contain an immunosorptive area much larger than that of microarrays. Since the beads are exposed to the entire sample, reaction takes place in entire volume. Beads are easily manipulated, collected from the sample and immobilized for readout purposes. In multi-analyte-based reading, each bead is coated with a specific antibody or antigen. Colored beads are the most common method for this purpose. Choi et al. [7] reported a bead-based device consisting of an integrated bio-filter, an electrochemical immunosensor and a series of custom designed microvalves. The bio-filter is comprised of a planar electromagnet to capture magnetic beads carrying the target antigen.

More recently, multiple immunoassays in microfluidic chips have been developed. A compact disc-shaped microfluidic immunoassay device based on centrifugal force was explored [8]. The study examined the imprecision of assays carried out with 200 nl of samples. The study concluded that the day-to-day total imprecision of the immunoassays on the compact disc-shaped device is less than 20%. Another group successfully developed a method for a high-throughput multi-antigen microfluidic immunoassay system [9]. The system was able to perform up to five tests for each of ten samples with each sample consisting of 100 nl. A theoretical model was developed to understand the relative importance of various parameters affecting the immunoassay in a microfluidic device [10]. In this study, the effect of analyte transport, binding kinetics between analyte in a solution and a surface-immobilized antibody and the footprint of a capture antibody on the substrate for the assay was examined

theoretically. The model shows that assays can be greatly optimized by varying the flow velocity of the solution. The model also shows the degree of influence of the analyte–antibody binding constant and the surface density of the capture antibodies on the performance of the assay.

Future Directions for Research

The new Lab-on-Chip immunoassay devices form the basis of new and smaller analyzers and may ultimately be used in even smaller devices useful in decentralized testing. In contrast to previous analytical technologies, Lab-on-Chip devices offer an enlarged and unified menu of tests, which will have far-reaching effects on the future of central laboratories. The impact of Lab-on-Chip devices on life sciences could be significant via timely intervention and monitoring, combined with improved treatments. Empowerment of health consumers to perform self-testing is limited, but Lab-on-Chip devices could accelerate this process and so produce a level of self-awareness of biochemical and genetic information hitherto unimaginable. The next level of miniaturization is nanometer-sized features, and the technological foundation for these futuristic devices will be built on nanofluidics and self-assembled molecular structures.

Definition

Lab-on-a-Chip Devices for Particle and Cell Separation are used to either remove particles of interest, sort a mixed population of particles into subpopulations of like particles or concentrate (enrich) particles for downstream processing within microdevices. Methods for particle or cell separations exploit specific physical properties which include: fluorescence-based, magnetic-based, affinity-based, and cell density gradient-based separations depending on the properties of the particles of interest. Particle separation devices are often geared towards biomedical research and diagnostics particularly in blood cell separation and blood diagnostics.

Overview

The separation of a specific biological cell from an original mixed biological sample is an essential step for a variety of applications in biological research, biomedical diagnostics and treatment. In most cases, one specific cell type must be examined to quantify the population, obtain genetic material or assay for gene expression and protein synthesis. However, raw biological samples obtained from various sources, (e. g., blood, tissue, or primary cell culture), generally contain many different types of cells mixed together. To use these samples in diagnostics, a purified sample containing only the desired material must be separated before specific analysis assays can be conducted. Furthermore, the desired biological sample population must often be concentrated from the initial raw sample concentration to acquire a sufficient quantity of material for anal-

ysis. For instance, typically in clinical blood tests, several milliliters of whole blood are sampled from patients and then centrifuged in a density gradient in order to separate the appropriate blood components based on their density. Also, in order to conduct detailed investigations on blood related diseases, separation of a specific blood cell type is required such as the separation of lymphocytes from the mixture of erythrocytes, other leukocytes, and platelets in whole blood. In addition, rare cell separation from mixed cell populations is very important in biological research activities including stem cell biology studies. Currently, the conventional methods for particle or cell separations exploit specific cell properties and include fluorescence-based, magnetic-based, affinity-based, and cell density gradient-based separations depending on the properties of the cells of interest. In the *basic methodology* section, the conventional methods for particle or cell separation are briefly introduced. In the *key research findings* section, the latest Lab-on-a-Chip technologies for particle or cell separations are discussed.

Basic Methodology

Fluorescence-Based Cell Separation

Fluorescence-activated cell sorting (FACS) is a type of flow cytometer and one of the most common techniques used in investigation of cell populations because of its effective performance in discrimination and sorting of cells into their subpopulations. In general, a concentrated cell suspension is allowed to bind with a fluorescent antibody or fluorescent dye that reacts with a specific particle or molecule existing on or inside the target cells. The cell suspension is then mixed with a buffer (sheath) fluid and the cells are transported through the FACS system in a single-file format where they pass through the path of a laser and the fluorescent light emitted by each cell is measured. The light scattered by each cell is also measured at the same time which can be correlated with cell size and sphericity. Once properties of the cells are determined based on both fluorescence and light scattering, the fluid stream containing the cells is broken into single droplets containing only a single cell. During droplet formation, each droplet is given an electrical charge, which is proportional to the amount of fluorescence of the cell within the droplet. Each droplet is then separated in an electric field and collected. Ideally, after this separation step the dyed cells are collected in a single purified population. FACS scanners are also used to determine the relative population of different cells within a mixed population based upon multiple fluorescent labels with different emission spectra (e. g., green emission versus red emission) or scattering properties such as individual white blood cell populations (e. g., lymphocytes versus granulocytes versus monocytes) which can aid in the understanding of blood disorders such as leukemia.

Magnetic-Based Cell Separation

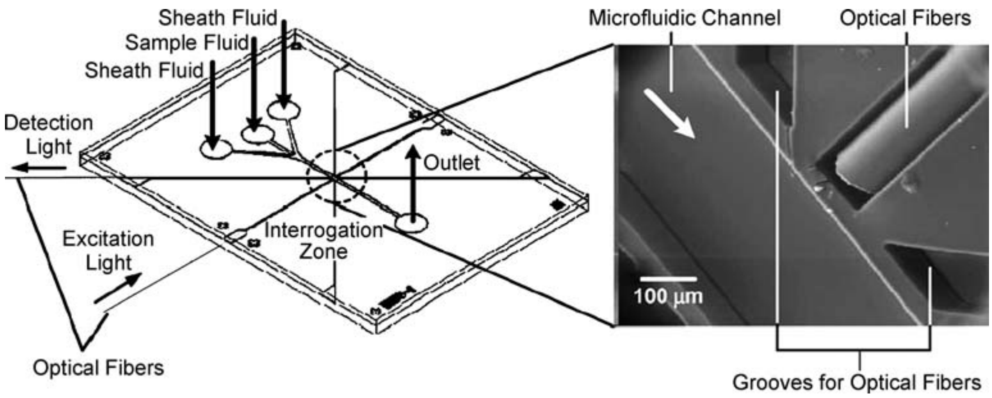
Magnetic-activated cell sorting (MACS) is an attractive method because the magnetic force can decouple the movement of the cell of interest from the rest of a cell population allowing them to be separated within a magnetic field. In many cases, micron or nanometer sized magnetic particles are used in MACS. These particles are usually conjugated with the appropriate antibodies to physically bind with antigens on the target cells. Once the magnetic particles bind with the target cells, they are attracted by a magnetic field gradient towards designated regions for downstream analysis, while the unwanted cells pass to a waste container. Magnetic separation is applicable to cells which can be separated by selective binding of the antibody bound magnetic particle to specific surface antigens.

Affinity-Based Cell Separation

The most conventionally used macroscale affinity-based cell separation system is cell affinity chromatography (CAC). These systems can provide relatively high purity ($> 95\%$) and high throughput ($10^8 - 10^9$ cells/h). CAC procedures can be divided into three consecutive steps: loading, washing, and elution. Affinity-based cell separation technologies are generally based on the immobilization of either antibodies or antigens on a substrate with selective binding and immobilization of the target cells, while unwanted cells pass through the device. After the target cells are captured, they are released and eluted by changing the buffer medium with the appropriate solutions.

Centrifugation-Based Cell Separation

The most common method for particle or cell separations is centrifugation-based separation. In biological or medical research labs, these particles are usually cells, organelles, or large molecules. When two particles in suspension differ in either mass or density, they will settle to the bottom of a centrifugation tube at different rates under centrifugation. There are two types of centrifugation: preparative and analytical centrifugation. In preparative centrifugation, the main purpose is to separate specific particles. In analytical centrifugation, the main purpose is to measure the physical properties of particles by measuring the sedimentation properties of the particles. In most cases, the centrifugation-based separation means the



Lab-on-a-Chip Devices for Particle and Cell Separation, Figure 1 PDMS-based optofluidic micro flow cytometer with two-color, multi-angle fluorescence detection capability using PIN photodiodes. Optical fibers are manually embedded close to a microfluidic channel to excite particles and detect emitted light from particles. Reprinted from [1], with permission from Elsevier

preparative centrifugation. Cells of varying density may also be separated using density gradient centrifugation. In this case a density gradient may be developed either by layering sucrose solutions of decreasing density and centrifuging or using specialized media which naturally develops a density gradient under centrifugation. Again, density gradient centrifugation is often used for white cell separation as erythrocytes will collect at the bottom of a gradient and the individual white cell populations will migrate and collect in bands based on their density which can be removed using a micropipette.

Key Research Findings

Lab-on-a-Chip Devices for Particle or Cell Separations Based on FACS

Recently, there have been several Lab-on-a-Chip devices based on FACS reported. For instance, Tung et al. [1] reported a PDMS-based optofluidic micro flow cytometer with two-color, multiangle fluorescence detection capability using PIN photodiodes. They integrated laser excitation with silicon-based PIN photodiode detectors on a microchannel in conjunction with optical fiber waveguides (Fig. 1). By using multiple angles for the fluorescence excitation of particles and detection of emitted light through the optical fibers, they demonstrated multicolor excitation of single particles at a single interrogation point within the microfluidic channel and examined the ability of using lock-in amplification techniques to increase the signal-to-noise ratio of the PIN-based photodetector. Experimentally, they demonstrated the detection of weak fluorescence signals from fluorescently labeled nucleic acids in yeast (*S. cerevisiae*) at a counting rate of 500 particles/s.

Another example of a particle or cell separation device based on FACS was reported by Quake and colleagues [2]. In this system, the fluid flow is controlled by pneumatically actuated pumps and microvalves which can control fluid flow direction. The flow direction is changed as fluorescence from a target particle population is detected with a forward-sorting algorithm so that target particles are sent directly to the collection channel. The reverse-sorting algorithm allows rare-event capture at a rate independent of the switching speed of the device. A high fluid flow rate is established from the input well to the waste channel. After each fluorescence event detection, the fluid flow is halted and reversed until the bead is detected a second time. It is then directed at a slower speed to the collection channel (Fig. 2). A mixed population of *E. coli* bacteria with one strain expressing green fluorescence protein (GFP) and the other expressing p-nitrobenzyl (pNB) esterase were sorted using this reverse sorting algorithm based on the fluorescence of the GFP expressing cells. The recoveries from multiple devices, with varying input cell concentrations and input GFP fraction ranged from 16 to 50% and enrichment of the GFP population varied from 6.9 to 89 times over the input sample fraction. The authors noted several advantages of this system over conventional FACS systems including: minimal background fluorescence noise from the cell media and channel materials, higher detection sensitivity, being mass producible and having a self-contained cell sorting system on a chip.

Lab-on-a-Chip Devices for Particle or Cell Separations Based on MACS

Magnetic sorting of particles is of particular interest since it can be miniaturized easily and utilized in applications where a small sample volume is required. One of the chal-

lenges in designing MACS based Lab-on-a-Chip devices is to achieve an efficient separation in a continuous manner. Thus, it is essential to understand the fundamental physics underlying the behavior of the magnetic particles when they are exposed to various forces including an external magnetic field, hydrodynamic drag and gravity.

The behavior of magnetic particles within a magnetic field strongly depends on their magnetic properties and the magnetic force on the particles can be derived from Maxwell's equations. Magnetic micro- and nanoparticles used in most biotechnology applications are paramagnetic so the magnetic force exerted on magnetic particles vanishes once the external magnetic field is turned off. If ferromagnetic particles are used, then the particles could aggregate and may be difficult to disperse in a carrier fluid. For paramagnetic particles, the magnetic force exerted on a particle is

$$\boldsymbol{F} = \frac{1}{2}\mu_0 v_\mathrm{p}(\chi_\mathrm{p} - \chi_\mathrm{f})\nabla\,|\boldsymbol{H}|^2 \tag{1}$$

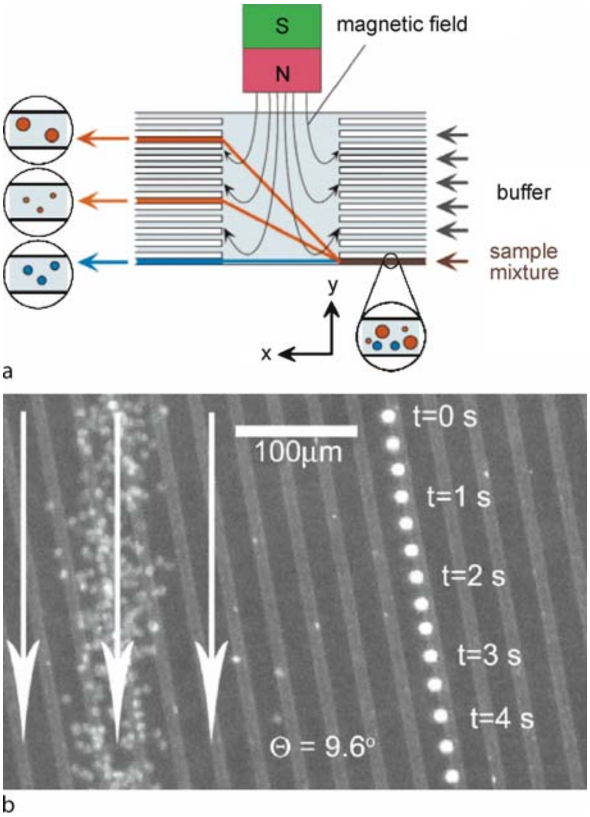
where $\mu_0 = 4\pi \times 10^{-7}$ H/m is the magnetic permeability of vacuum, v_p is the volume of a particle, χ_p and χ_f are the magnetic susceptibility of the particle (p) and the carrier fluid (f), and $\boldsymbol{H}$ is the applied magnetic field. For Lab-on-a-Chip systems using magnetic particles, three types of forces affect the trajectory of a magnetic particle: gravity, hydrodynamic drag, and magnetic forces. In this case, Newton's equation acting on a spherical particle can be written as

$$\begin{aligned}\frac{4\pi R_\mathrm{p}^3}{3}\left(\rho_\mathrm{p} + \frac{\rho_\mathrm{f}}{2}\right)\frac{d\boldsymbol{V}_\mathrm{p}}{dt} &= \frac{1}{2}\mu_0 v_\mathrm{p}(\chi_\mathrm{p} - \chi_\mathrm{f})\nabla\,|\boldsymbol{H}|^2 \\ &\quad - 6\pi\eta R_\mathrm{p}(\boldsymbol{V}_\mathrm{p} - \boldsymbol{V}_\mathrm{f}) \\ &\quad - g v_\mathrm{p}(\rho_\mathrm{p} - \rho_\mathrm{f})\hat{y}\end{aligned} \tag{2}$$

where $\boldsymbol{V}_\mathrm{p}$ and $\boldsymbol{V}_\mathrm{f}$ are the velocities of the particle (p) and fluid (f) respectively, η is the dynamic viscosity of the carrier fluid, R_p is the particle radius, ρ_p and ρ_f are densities of particle (p) and fluid (f), g is the gravitational acceleration, and $\hat{y}$ is the unit vector in the vertical direction. Therefore, the movement of the particle under the influence of magnetic forces, hydrodynamic drag, and gravity can be determined by solving Eq. 2. The left hand side of Eq. 2 accounts for both the particle and fluid inertial force. However, under most conditions, a creeping flow limit is assumed so the left hand side of Eq. 2 is set to zero and the right hand side determines the steady state velocity of the particles.

A simple demonstration of magnetic particle separation on-a-chip was demonstrated by Pamme and Manz [3]. They showed that on-chip free-flow magnetophoresis could continuously separate a heterogeneous particle population using a combination of flow and magnetic forces (Fig. 3). The particle separation was demonstrated by infusing two types of magnetic (2 and 4.5 μm in diameter, with magnetic mass susceptibilities of 1.12×10^{-4} and 1.6×10^{-4} $\mathrm{m^3/kg}$ respectively) and nonmagnetic (∼ 6 μm in diameter) particles into the device at the same time. A permanent magnet is placed along the flow path of the device. Since the magnetic particles are deflected under the external magnetic field and the nonmagnetic particles are not, a separation of the magnetic particles from the nonmagnetic particles was achieved. The deflected magnetic particles were further separated according to their size because the larger particles (∼ 4.5 μm) have larger magnetic susceptibility than the smaller particles (2 μm) and therefore a larger magnetic force is exerted on them causing a larger deflection than the smaller particles.

Magnetic cell separation was also be demonstrated in microfluidic structures, as described by Inglis et al. [4]. They demonstrated a continuous-flow microfluidic device that enables cell separation of leukocytes from erythrocytes in whole blood using a CD45 sensitive magnetic bead to selectively bind with the CD45 antigen expressed on the surface of the target leukocytes. In their demonstration, they allowed both unlabeled erythrocytes and the labeled leukocytes to flow over an array of microfabricated magnetic strips which are aligned at a constant angle of 9.6° from the flow direction. Since a series of large magnitude magnetic field gradients are created by the parallel magnetic strips, the magnetically labeled leukocytes are deflected along the direction of the strips while the erythrocytes flow straight through the device (Fig. 3b). After some time the leukocytes have been deflected by a large enough amount that they are separated from the rest of the blood cell population.



Lab-on-a-Chip Devices for Particle and Cell Separation, Figure 3 (**a**) Conceptual drawing of free-flow magnetophoresis. A mixture of magnetic and nonmagnetic particles are infused into a device. The magnetic particles are deflected into the upper microfluidic channel due to the presence of the magnetic field perpendicular to the flow direction. However, nonmagnetic particles are not affected by the magnetic field and continue to flow in the same direction. Magnetic particles can be further separated according to their size and magnetic susceptibility. Reprinted with permission from [3]. The red blood cells on the left are from a single image. All cells entered the chip at the same point approximately 1.5 mm above the field of view. Reprinted with permission from [4]

Lab-on-a-Chip Affinity Based Devices for Particle or Cell Separations

Affinity based systems typically rely on the immobilization of antibodies or antigens onto which a cell of interest will bind to. For example, Revzin et al. [5] have described a microfabricated cytometry platform for creating high-density leukocyte arrays and demonstrated the retrieval of single cells from the array. To create their devices they used a combination of surface patterning and immobilization of cell adhesive ligands. Briefly, in order to modify surfaces through avidin-biotin conjugation, a glass substrate with lithographically micropatterned poly(ethylene

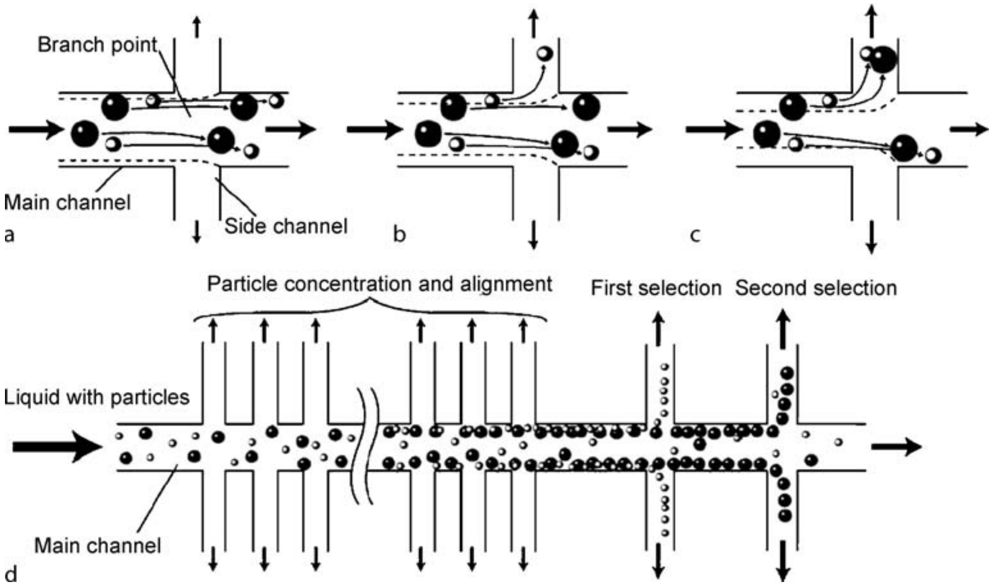
glycol) (PEG) wells were placed in avidin solution for 1 h. After obtaining avidin adsorption at the bottom of the well, the substrate was rinsed with DI water to remove unbound avidin. Next, the substrate was placed in a solution of biotinylated antibody for 2 h to immobilize the antibody within the wells through an avidin-biotin conjugate followed by washing of unbound antibody with DI water. As a final step, they seeded leukocytes and incubated the cells for 30 min (Fig. 4a). By applying this principle using an anti CD5 antibody as a cell adhesive binding they found that 95% of the micropatterned PEG wells were occupied by CD5+ T-lymphocytes. They further described the removal of cells using laser capture microdissection (LCM) which involves capping the PEG wells with an adhesive thermoplastic which is selectively melted to envelop the cells of interest using an IR laser. The thermoplastic is then removed from the array with the captured cells of interest.

Chang et al. [6] have described a microfluidic device for separating leukocytes by mimicking the physiological process of leukocyte recruitment to blood vessel walls: adhesive cell rolling and transient tethering. To accomplish their separation, they first coated the surface of silicon pillars with E-selectin IgG chimera protein and investigated cell capture using HL-60 promyelocytic leukemia and U-937 histiocytic lymphoma myeloid cell lines, both of which produce ligands for the immobilized E-selectin. They studied two types of micropillar arrays: a square structure where the pillars are placed in a linear array and an offset structure where the pillars are staggered between each other (Fig. 4b). In the offset array device, the cells initially roll slowly tangential to the flow direction due to viscous shear on cells. Once the cells reach the trailing edge of the micropillars, the cells experience viscous shear loading which causes them to move perpendicularly away from the pillar. As a result, the cells are detached from the pillar surface and leave to the free stream and are not captured by the next post (Fig. 4b part a). However, in the square array device, the cells that move into the free stream are always recaptured by the next micropillar due to the sluggish flows behind the micropillars (Fig. 4b part b). Cell density enrichment up to 400 fold over the initial cell density was demonstrated with the HL-60 cells due to the accumulation of the cells on the surface of the pillar array. For the two different cell types tested in the square array device, transit velocities of 1.4 ± 0.8 mm/s and 2.7 ± 1.4 mm/s were obtained for the HL-60 and U-937 cell lines, respectively. This difference in transit velocities was suggested as a mechanism to separate the different cell populations from each other.

Lab-on-a-Chip Devices for Particle or Cell Separations Based on Dielectrophoresis

Dielectrophoresis (DEP) refers to the motion of polarizable particles or cells suspended in an electrolyte subjected to a nonuniform electric field. Dielectric particles, including cells, can be categorized into two types depending on their behavior within the nonuniform electric field, i. e., positive and negative DEP. Positive DEP occurs when the particle is more polarizable then the surrounding media so the particles or cells are attracted toward areas of high elec-



Lab-on-a-Chip Devices for Particle and Cell Separation, Figure 6 Principle of hydrodynamic filtration. (**a**) When the flow rate ratios between the side and main channels are low, (**b**) medium, and (**c**) high. Broken lines show the virtual boundaries (critical streamline) of the flows distributed into the side and main channels. (**d**) Schematic diagram showing particle concentration and classification in a microchannel having multiple branch points and side channels. Reprinted with permisiion from [8]

tric field strength. On the contrary, in negative DEP, the particles or cells are less polarizable than the surrounding media and move towards areas of low electric field strength.

Quantitatively, a force ($\boldsymbol{F}$) acting on a spherical particle, whose radius is a and polarization $\boldsymbol{P} = \alpha\boldsymbol{E}$ where α is the polarizability and $\boldsymbol{E}$ is the electric field, is given by

$$\boldsymbol{F} = \boldsymbol{P}v_{\mathrm{p}} \cdot \nabla\boldsymbol{E} = \frac{2}{3}\pi a^3 \alpha \nabla |\boldsymbol{E}|^2 \quad (3)$$

When a steady state sinusoidal electric field is applied, the polarizability of the particle and solvent becomes complex and the force in Eq. 3 can be generalized as

$$\langle\boldsymbol{F}\rangle = 2\pi a^3 \varepsilon_0 \varepsilon_{\mathrm{r,solvent}} \mathrm{Re}(f_{\mathrm{CM}}) \nabla |\boldsymbol{E}_{\mathrm{RMS}}|^2 \quad (4)$$

where $\varepsilon_0 \approx 8.854 \times 10^{-12}$ F/m is the vacuum permittivity, $\varepsilon_{\mathrm{r,solvent}}$ is the relative permittivity of the solvent, $\boldsymbol{E}_{\mathrm{RMS}}$ is the root mean squared applied electric field and $\mathrm{Re}(f_{\mathrm{CM}})$ is the real part of the Clausius–Mossoti factor. The Clausius–Mossoti factor depends on the complex permittivity of both the particle and medium. For a spherical particle surrounded by an infinite fluid

$$f_{\mathrm{CM}} = \frac{\varepsilon_{\mathrm{p}} - \varepsilon_{\mathrm{f}}}{\varepsilon_{\mathrm{p}} + 2\varepsilon_{\mathrm{f}}} \quad (5)$$

where ε_{p} and ε_{f} is the complex permittivity of the particle and fluid respectively. It should also be noted that the Clausius–Mossoti factor varies for different particle types and is also frequency dependent due to the dielectric relaxation of both the particle and surrounding media. The direction of the force directly depends on the sign of $\mathrm{Re}(f_{\mathrm{CM}})$. Thus it is possible to change from positive to negative DEP simply by changing the excitation frequency using AC excitation. If the $\mathrm{Re}(f_{\mathrm{CM}})$ is positive, then the particle will be attracted toward the electrode where the magnitude of the electric field is maximum. This is called positive DEP as mentioned above. In the opposite situation, if the $\mathrm{Re}(f_{\mathrm{CM}})$ is negative, then the particle will be repelled from where the electric field magnitude is largest, negative DEP. Another important consequence of DEP is that the force acting on the particle is proportional to the gradient of the external electric field intensity squared. Thus, the larger $\nabla|\boldsymbol{E}|^2$; the larger the force acting on the particle. The gradient of the electrical field intensity can be increased either by increasing voltage across electrodes, decreasing distance between electrodes, and/or by increasing the nonuniformity of the electric field. In macroscopic DEP devices, there is usually a technical limitation to how far the distance between electrodes can be decreased, and electrical breakdown limits the maximum voltage and smallest electrode spacing. In microscale DEP devices, these strategies can be applied to maximize the force acting on a particle. This is the main reason that Lab-on-a-Chip devices based on DEP are very efficient for particle separation. Since the force depends on the elec-

tric field gradient squared the external electric field used for DEP may be either a DC (as represented by Eq. 3) or AC (as represented by Eq. 4) field. However, it is usually undesirable to use a DC electric field because it can cause particle electrophoresis, which counteracts the DEP force in the motion of the particles. Thus, for most DEP based particle or cell separations, an AC electric field is applied. Voldman et al. [7] have developed a microfabrication-based dynamic array cytometer (μDAC) for use in a parallel luminescent single-cell assay that can separate small cell populations. They designed quadrupole DEP trap arrays to trap cells. Figure 5a shows a schematic representation of a quadrupole DEP trap. If a negative-DEP is used, then an effective dipole moment in the cell is antiparallel to the electric field. Thus the cell is repelled from each electrode and the cell is stably trapped at the quadrupole's field minimum, at the center of the quadrupole. Figure 5b shows how a cell can be ejected from the DEP trap. By switching the potential on one of the controlling electrodes from positive to negative, the symmetry of the electric fields within the quadrupole is disrupted so that the cell can be ejected. To demonstrate selective cell sorting, the cells (HL-60 cell line) were fed into the chip via a reservoir and then exposed to calcein to fluorescently stain each cell. Then they were individually loaded into each trap and optically interrogated over time for their fluorescence response to the calcein (Fig. 5c). First, three cells designated by red arrows were released by changing the potential of the controlling electrode from +3 V to −3 V. Next, three cells designated by blue arrows were released by following the same principle. Only one cell designated by the large green arrow in the bottom panel was left in a single activated trap.

Lab-on-a-Chip Devices for Particle or Cell Separations Based on Hydrodynamics

Hydrodynamic particle or cell separation is also an attractive and ideal way to separate particles or cells because it requires only well controlled flow structures. Usually, this method utilizes a cell's physical properties to distinguish them from other cell types. Cell size, density, and stiffness can be used as criteria for separating the cells of interest from the rest of a population.

Continuous particle separation in microfluidic channels based on particle size was extensively studied by Yamada et al. [8]. In their report, they proposed a concept called *hydrodynamic filtration*. Figure 6 shows the principle of hydrodynamic filtration. When side channels are designed to have sufficiently lower flow rate than the downstream of the main channel (Fig. 6a), only a small portion of fluid near the wall will be skimmed into a side channel, while the majority of fluid flow is through the main channel. The streamline which separates the fluid skimmed into the side channel and the fluid which remains in the main channel is known as the critical streamline. Thus, there is a lower probability that particles will flow into the side channel. On the contrary, as the flow rate in the side channel increases, there is a larger possibility that the particles will flow into the side channel because more fluid can flow into the side channel so a larger percentage of the main channel width is skimmed into the side channel capturing particles further from the walls beyond the critical streamline (Fig. 6a through Fig. 6c). This leads to a separation of particles based on size because the centroid of a particle cannot be within one particle radius from the channel wall so larger particles will not flow into the side channels until the critical streamline placement corresponds to the particle's centroid. Based on this principle, they have demonstrated leukocyte enrichment and/or removal of erythrocytes. The initial particle counts reported of erythrocytes and leukocytes were 27,400 and 35 respectively. After conducting the hydrodynamic filtration twice, they obtained particle counts of 3180 and 118. This result corresponds to a 29-fold increase in leukocyte concentration.

Based on a similar principle, Yang et al. [9] have developed a microfluidic device for continuous, real time blood plasma separation from whole blood. The device is composed of a blood inlet, a bifurcating region which leads to a purified plasma outlet, and a concentrated blood cell outlet. They have precisely designed flow rate ratios at each bifurcation so that no blood cells (erythrocytes, leukocytes, or platelets) flow into the side channels, while blood plasma is skimmed into the purified plasma collection channels. The experimentally determined plasma selectivity with respect to blood hematocrit level was almost 100% regardless of the inlet hematocrit (Fig. 7a). The total plasma separation volume percent varied from 15% to 25% with increasing inlet hematocrit (Fig. 7b).

Shevkoplyas et al. [10] reported a platform for the autoseparation of leukocytes within a microfluidic device. Their device is composed of a series of bifurcating rectangular microfluidic channels. They imitate leukocyte flow behavior in vivo to obtain a leukocyte rich sample at the device outlet. It is well known that blood exhibits unique flow characteristics within the microcirculation. Erythrocytes tend to flow in the center of blood vessels, leaving a plasma-rich zone near the vessel wall. The red blood cells also flow faster than leukocytes which causes mechanical collisions between leukocytes and erythrocytes within a vessel, yielding an uneven distribution of leukocytes across the blood vessel. Thus, leukocytes usually have a larger population near the blood vessel wall than the center of the vessel. Thus, by mimicking this

property, Shevkoplyas et al., designed a flow structure which diverted the leukocyte-rich plasma layer through several bifurcations (Fig. 8), to obtain a 34-fold increase in the leukocyte-to-erythrocyte concentration ratio compared with the inlet concentration. This device is particularly useful in applications where high concentrations of leukocytes are required.

Lab-on-a-Chip Devices for Particle or Cell Separations Based on Ultrasound

It is well known that the ultrasonic standing wave can exert forces on particles and have been used in many fields including chemical and materials engineering to separate or enrich suspended particles in a medium at well defined positions. The force produced by ultrasonic standing waves move particles to either the pressure node or antinodes of the standing wave depending on the density and compressibility of the particles and the medium.

The primary acoustic force ($F(z)$), which acts on a spherical particle in a one-dimensional standing wave propagation direction, is [11]

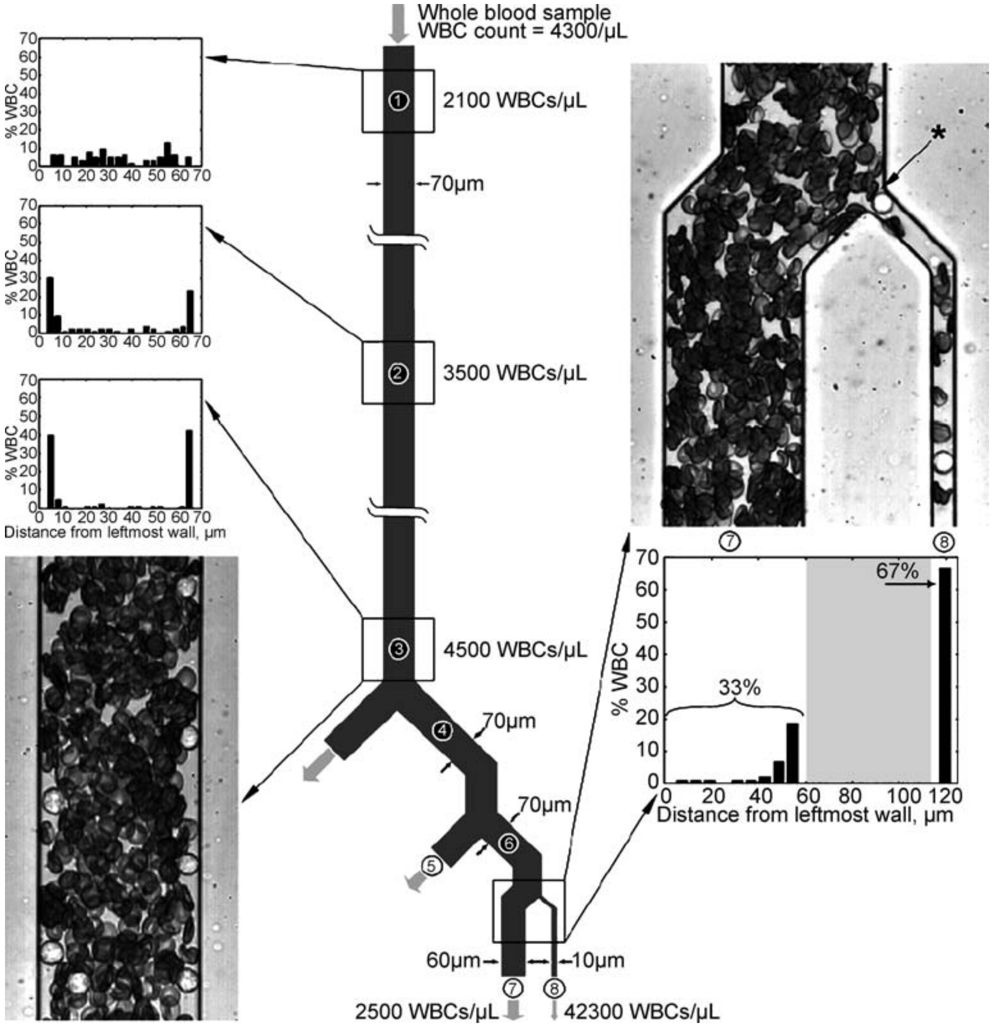
$$\langle F(z) \rangle = 4\pi\rho\Phi^2(ka)^3 K_s(\lambda,\sigma)\sin 2kz \quad (6)$$

where a is the particle radius, $k = \omega/c_f$, the wave number in the fluid, ρ is the density of the fluid, Φ is the amplitude of the velocity potential of a standing wave, and c_f is the speed of sound in the fluid. The acoustic contrast factor K_s is described by

$$K_s(\lambda,\sigma) = \frac{1}{3}\left(\frac{5\lambda - 2}{2\lambda + 1} - \frac{1}{\lambda\sigma^2}\right) \quad (7)$$

where $\lambda = \rho_P/\rho_F$ is the density ratio between the particle and fluid and $\sigma = c_p/c_f$ is the sound speed ratio between the particle and fluid. Aside from the primary acoustic force on the particle, there are also secondary forces which act on particles. These secondary forces are mainly caused by the interaction between two particles within the acoustic field. When these secondary forces are generated, the two particles are attracted to each other and move together. However, these secondary forces are negligibly small when compared with the primary acoustic force.

Recently, Petersson et al. [12] have developed a Lab-on-a-Chip device for particle separation based on this ultrasonic principle. In order to demonstrate the separation of particles with different physical properties in a continuous laminar flow, they have prepared a microfluidic device with a 750 μm wide and 250 μm deep channel. As a test material, a mixture of milk and blood was used. The ultrasound half standing wave at 2 MHz was produced by a piezoelectric ceramic, which was glued directly on the bottom of the microfluidic device. Milk was used as an initial test medium (Fig. 9a and 9b) to confirm that the lipid particles within the milkfat were attracted toward the pressure anti-nodes of the half standing wave, which exist along the microfluidic channel wall. In addition, when they infused a mixture of milk and blood, they found efficient separation of blood cells from the mixture (Fig. 9c). This demonstration showed that a mixture of heterogeneous components can be effectively separated by utilizing ultrasonic standing waves, combined with the laminar flow in microfluidic channels. The separation efficiency of erythrocytes from the mixture was about 70%, while more than 80% of the milkfat lipid particles were



Lab-on-a-Chip Devices for Particle and Cell Separation, Figure 8 Leukocyte autoseparation device. By imitating leukocytes' behavior in vivo, the leukocyte-to-erythrocyte ratio is significantly increased (29-fold compared with the inlet ratio). Reprinted with permission from [10]

removed. Based on these demonstrations, they proposed that this technique might be useful for intraoperative blood wash applications, where shed blood can be collected and returned to the patient during or after surgery.

Future Directions for Research

Although a variety of technologies related with the Lab-on-a-Chip devices for particle or cell separations are introduced here, there are still many challenges to producing efficient Lab-on-a-Chip based particle separation technologies over the conventional particle separation methods. For instance, although they have relatively high separation efficiency some of the microsystem technologies such as FACS-based, DEP-based and affinity-based separations still have lower throughput when compared with the conventional macroscale method. In addition, MACS-based and hydrodynamics-based separation technologies show significantly lower separation efficiency. This implies that there still needs to be substantial improvement in the further development of these particle and cell based separation microsystems for truly realizing the promise of Lab-on-a-Chip separation platforms which can outperform the standard macroscale technologies.

Definition

Devices that have the capability of performing one or more analytical laboratory functions on a single platform of a small area (a few square millimeters to a few square centimeters) and are capable of handling extremely small fluid volumes (down to less than pico liters), which (among other applications) can be used for protein analysis.

Overview

Proteins are encoded by DNA and translated from RNA in the cell and are the *effector molecules* that play essential roles in carrying out cellular function. In disease state, various molecular changes occur in an individual at the DNA, RNA and protein level. Disease, therapy and drugs alter the structure, metabolism and functions of proteins. Understanding the expression and function of proteins in normal and pathophysiological conditions is critical for developing effective therapeutic strategies.

Protein analysis in general refers to sequencing, identification, and characterization of the structure, metabolism and function of proteins. The new and developing field of proteomics focuses on protein profiling, which is the identifi-

cation and ideally the quantification of proteins on a large scale at the cell and tissue level.

Conventional Techniques for Protein Analysis

Conventional bench/lab methods of protein separation and identification include one dimensional (1D) and two dimensional (2D) gel-electrophoresis (GE), mass-spectrometry (MS), immuno assays and affinity chromatography. 1 and 2D electrophoresis techniques separate proteins based on their charge and/or mass in an electric field within a matrix, while MS is widely used to detect mass of biomolecules with very high accuracy. Immunoassays take advantage of specific binding of antibodies to peptide ligands or antigens making it highly specific in identifying proteins. X-ray diffraction (XRD) of protein crystals and nuclear magnetic resonance (NMR) are some of the techniques that have been traditionally used for the characterization and structural/functional analysis of proteins. These techniques offer the capability for detailed measurement of spatial arrangement of atoms within the protein molecules and thus provide insights on protein structure and function. Protein analysis methods for functional characterization include immuno–precipitation, confocal and electron microscopy of tagged/labeled proteins, which have been widely used to study protein–protein interaction and the spatial and temporal arrangement of proteins within the cell and cellular compartments. Functional assays that provide a snapshot of what the protein actually does in the living cell have been carried out using techniques like spectroscopy, colorimetric and chemical detection assays.

Limitations of Conventional Techniques

Limitations of conventional methods include poor detection limits, large sample volumes, long processing times, cumbersome sample preparation, complex instrumentation and requirement of specific expertise. For example, conventional gel-based methods require a great deal of expertise and hands-on time. The process is slow, difficult to automate leading to lack of reproducibility across different personnel, laboratories and samples. While methods like liquid chromatography (LC)/MS perform well when used by skilled operators, even these techniques are limited by their difficulty to set up. Also, protein analysis using conventional methods are largely confined to research/diagnostics laboratories, and still have many logistical hurdles for adoption in clinics or other point-of-care facilities. Thus, there is an urgent need for new portable technologies specifically designed for use in clinics, for example, in health diagnostics. Also, with the advent of systems biology and 'omics' approaches, there is a need for large-scale experimentation and analysis using small amount of reagents/samples, and the information needs to be available accurately, quickly and cheaply. These requirements are not met by the conventional methods which in turn spurred interest in other innovative technologies for protein analysis. Various studies including one by Bill and Melinda Gates foundation and NIH to identify the "Grand Challenges for Global Health", have highlighted the need for *modified molecular technologies* that allow assessment of individuals for multiple disease conditions or pathogens at the point-of-care as well as quantitative assessment of population health status.

Miniaturized Systems or Lab-on-Chips

Miniaturization enabled by micro- and nano-technologies have given a new thrust to the field by introducing rapid low cost analytical systems and methods with better sensitivity that can also be multiplexed to allow large-scale analysis of multiple proteins. Other advantages of these miniaturized systems or Lab-on-Chips (LOC) include lower sample volumes and thus lower potential sample loss, better reproducibility of experiments, reduction in possible contamination and carry-overs, simpler infrastructure requirements, automation allowing for unattended operation, portability enabling on-site analysis, reduced waste generation, more efficient reactions through enhanced heat and mass transfer and no reactor dead volumes, and lower operating costs.

Micro-Total Analysis Systems

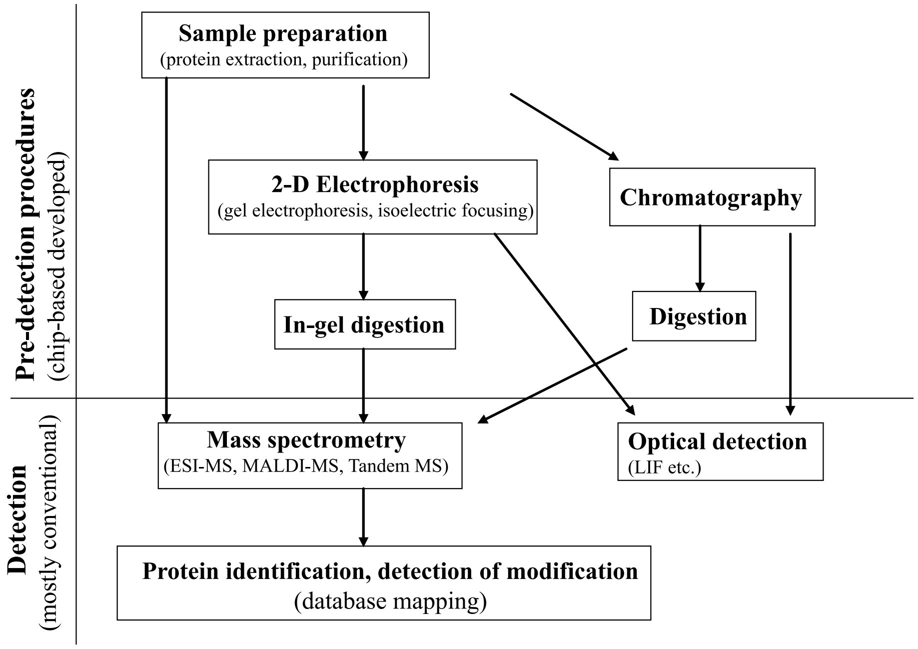
Another advantage of LOC devices is the possibility of integration of different steps of the entire analytical procedure on to a single device, resulting in a micro-Total Analysis Systems (μ-TAS). Only a limited number of LOC device developments have reached the status of a complete laboratory, where all the stages of conventional laboratory systems are integrated on a chip. Most of the currently available systems are semi-integrated.

Classification of Lab-on-Chips for Protein Analysis

LOC systems can be broadly classified into

- microfluidic based and
- spotted microarray based systems.

LOC systems can also be variously classified based on sample preparation/separation methods (e. g. gelfilteration, chromatography), detection methods used (e. g. MS, optical systems, immuno-detection) and application (research vs. diagnostics, multiuse vs. single use).



Lab-on-Chip Devices for Protein Analysis, Figure 1 Typical flow scheme of microfluidic protein separation and detection

Basic Methodology

Microfluidic Based Technologies

In microfluidic based systems, material is transported within microstructures (of typical dimensions of 10 – 500 μm) where separations, reactions and other processes occur. Focus has been on the realization of the traditional separation techniques (electrophoresis, chromatography, isoelectric focusing etc.) and reactions in the microchip format. The principles of separation, as in the conventional formats, are based on differences in mass and charge (thus mobility) and partitioning between phases. However, advantages associated with the small dimensions provide superior performance. For example, the higher surface to volume ratio arising from the smaller dimensions, results in lower heat and mass transfer resistances, and thus an improved performance.

A majority of the separation-based approaches in the microfluidic chip format for protein analysis have focused on single or multidimensional separations with detection by conventional MS or optical methods (e. g. laser induced fluorescence (LIF)). Microfluidic separation chips have also been adapted for use in immunoassays. They have also been utilized for the pre-MS sample preparation followed by conventional detection by MS. A typical flow scheme of microfluidic protein separation and detection is shown in Fig. 1.

Glass, and to some extent silicon, have been the main material for fabrication of the microfluidic devices. Microstructures for these systems are fabricated by traditional techniques employed in the microelectronics industry. For example, the structures are made by depositing photoresist on surfaces, applying lithographic techniques to expose the desired pattern followed by etching (wet or dry). Wafer pieces are then fused together to form enclosed systems by bonding. The schematic of a typical process flow is shown in Fig. 2. There has been recent interest in the use of polymeric materials for fabricating chips. These polymeric materials include polymethyldisiloxane (PDMS), polymethylmethacrylate (PMMA), polycarbonate (PC), etc. Some important advantages of polymeric materials include inert surface characteristics, low temperature fabrication methods, relative ease and lower cost of fabrication and disposability of devices. The microstructures on polymers fabricated using techniques of soft lithography, injection molding, hot embossing etc.

Microarray Based Technologies

DNA microarrays have been successfully used to measure mutations and/or gross changes in genomic DNA and levels of messenger RNA (mRNA). Measuring DNA or mRNA does not provide a direct measure of the levels, activation state or function of proteins. Hence, protein

Lab-on-Chip Devices for Protein Analysis, Figure 3 A general schematic for microarray printing where the pin head carrying the printing device (pins) is mounted on a robot arm that carries the sample from the reservoir to the plate (substrate) where it is deposited in an array format (adapted from [2])

microarrays were developed to study the protein–protein, protein–ligand (like DNA, lipid, small molecule drugs etc.) interaction, and protein profiling. Though similar in concept and principles to DNA microarray, the physicochemical differences lack of amplification methods and the requirement to maintain native 3D molecular structure of proteins for function necessitates development of different handling procedures for protein microarrays. Apart from DNA and protein there are cell and tissue microarrays that have been developed [1].

Fabrication of microarrays involve deposition of nanoliter quantities of biological fluids (proteins) in a desirable arrangement of discrete spots on a substrate (e. g. glass or plastic) surface. All microarray techniques target efficient deposition of dense but uniform, homogeneous spots. There are two main types of spot formation techniques – contact printing and non-contact printing. The contact printing is a serial deposition method that forms array of spots by direct contact between the printing device (pin or tip) and substrate. Pin printing, microstamping and nanotip printing are some of the other technologies that have been developed. These methods are useful with reproducibility, but suffer from low-throughput fabrication. The non-contact printing involves techniques based on photochemistry, electro-printing, droplet dispensing and laser writing [2]. These later technologies have the advantage over the contact printing methods in being able to reduce contamination and having higher fabrication throughput. Figure 3 shows a general schematic for microarray printing where the pin head carrying the printing device (pins) is mounted on a robot arm that carries the sample from the reservoir to the plate (substrate) where it is deposited in an array format (adapted from [2]).

Separation in the second dimension (by GE) occurs in the channels between Reservoir 3 and Reservoir 4. Appropriate voltages are applied across the reservoirs (adapted from [4])

Key Research Findings

Technology

Microfluidic Based Technologies

1D Separation of Proteins There has been considerable research devoted to the development of microfluidic platforms capable of performing small-scale protein separations. In addition to diffusion based methods [3], nearly every type of electrokinetically driven separation has been demonstrated in a chip-based platform, including free-flow electrophoresis, capillary electrophoresis, capillary gel electrophoresis, isoelectric focusing (IEF), micellar electrokinetic chromatography and capillary electrochemical chromatography.

2D Separation and Combination Methods 1D separation methods are frequently limited in providing the resolution required for the analysis of complex biological samples. 2D separations, where separation occurs in orthogonal directions, however, greatly increase resolving power. Several such 2D methods and combinations of 1D methods have been implemented on microchip format for protein separations, such as free-flow electrophoresis coupled with isoelectric focusing, gel electrophoresis coupled with isoelectric focusing, open channel electrophoresis with micellar electrokinetic chromatography, open channel electrochromatography and capillary electrophoresis, and parallel capillary zone electrophoresis and capillary electrochemical chromatography separations. A schematic of a microfluidic chip protein separation by 2D gel electrophoresis is shown in Fig. 4. The separation in the first dimension (by isoelectric focusing) occurs in the channel between reservoir 1 and reservoir 2, and separation in the second dimension (by gel electrophoresis) occurs in the channels between reservoir 1 and reservoir 2, with appropriate voltages applied across the reservoirs (adapted from [4]).

Interface with MS Systems for Detection MS is one of the most popular methods for peptide sequencing. However, the long (up to 24 h) incubation times and extensive manual sequences employed in conventional sample preparation procedures are bottlenecks for process improvement. A number of papers on coupling microfluidic chips, where the pre-MS sample preparation steps are performed, to mass spectrometers have been reported [5] and references 1–33 there in. Advantages of miniaturization of sample preparation steps include small sample volume, reduction in processing time and improved MS efficiency. For example, in an application of temperature-controlled silicon based microreactors, comprising microchannels and reaction chambers [6], the sample preparation time was reduced from the conventional time of about 24 h (chemical denaturation) and 3.5 h (thermal denaturation) to 11 min (thermal denaturation for 1 min and trypsin digestion for 10 min). This study also demonstrated that enhanced digestion efficiency was achieved by miniaturization of the reaction system. In another study, an integrated microfluidic chip of glass substrates with electrowetting-on-dielectric actuation for multiplexed proteomic sample preparation and analysis by MALDI-MS was described [7]. The integrated device was demonstrated for processing four angiotensin peptide/urea samples in parallel through a sequence of seven actuation steps. While a considerable amount of work has been done to realize protein separations on microfluidic platforms, interfacing with MS has been a bottleneck. An example of progress in this area has been the integration of a microfabricated IEF chip with an electrospray ionization (ESI) tip [8]. More recently, a microfluidic chip, that integrated all the fluidic components of a gradient liquid chromatography system and an electrospray nozzle has been reported [9]. The device was used to perform a liquid chromatography-tandem mass spectrometry (LC-MS/MS) analysis of a mixture of peptides from the trypsin digestion of bovine serum albumen (BSA). Compared to the analysis of the same sample using a commercial nanoflow LC system, the chromatographic resolution was nearly as

good, and the total cycle time was significantly reduced because of the minimal volume between the pumps and the column. Agilent (Santa Clara, CA) reported a polymeric microfluidic chip that integrated an enrichment column, separation column, and electrospray source on a single chip [10]. Overall system performance was demonstrated through reversed-phase gradient separations of tryptic protein digests at flow rates between 100 and 400 nL/min.

Integrated Optical Systems for Detection Detection of labeled proteins by means of laser-induced fluorescence (LIF) is a popular technique associated with separation based processes. The limitations (of mobility) due to the bulkiness of the conventional detection system spurred an interest in optical detection systems integrated to chip based separations of biomolecules For example, Viellard et al. [11], reported a glass/PDMS hybrid microfluidic chip for electrophoretic separations (capillary zone electrophoresis and capillary gel electrophoresis) of proteins with integrated optical waveguides for fluorimetric detection. Also, Mizukami et al. [12], fabricated an integrated micro-electrophoretic chip by implementing an acrylic microfluidic channel directly on top of a photosensor array. Capillary gel electrophoresis was performed for the separation of a mixture of two labeled proteins and the separation process was visualized as a sequence of two-dimensional images. Calliper Technologies (Mountain View, CA) has described a microfabricated analytical device on a glass chip that performed a protein-sizing assay, by integrating the required separation, staining/destaining, and detection steps.

Immunoassay Microfluidic networks have high resolution and contrast capabilities for simultaneously patterning lines of proteins onto a surface. This has been utilized, for example, by Bernard et al. [13], to create a miniaturized mosaic of imminoassays by patterning lines of antigens on PDMS surfaces by a microfluidic network and delivering the analytes by another set of microfluidic channels at right angles to the direction of the first set. Microfluidic separations have also been combined with immunoassay based detection. For example, Lonnberg et al. [14], reported fabrication and performance of a porous monolith chip where ion-exchange chromatographic separation of protein isoforms was integrated with immunoassay detection. Sensitivity was demonstrated with transferrin isoforms which differed only by a pH of 0.1 in their pI.

Microarray Based Technologies

Proteins can be identified by antibodies, enzymes, or aptamers. Microarray technology has proven successful in detection and quantitation of proteins and studying protein–protein interactions. The basic technique involves immobilization of a set of proteins on a solid surface preserving their native folded confirmations in an array format using high precision robotics and then allowing them to interact with another set of proteins [15]. Each spot on the array can contain a homogeneous or heterogeneous set of "bait" molecules. A spot on the array may display an immobilized antibody, a cell or phage lysate, a recombinant protein or peptide, a drug, or a nucleic acid. The array can then be queried with

1. a probe (labeled antibody or ligand), or
2. an unknown biological sample (e. g., cell/tissue lysates or serum sample) containing analytes of interest.

The querying molecules are tagged with a signal-generating moiety, such that for each spot, the intensity of signal is proportional to the quantity of applied query molecules bound to the bait molecules. An image of the generated positive and negative pattern of spots is captured using various detection methods, analyzed, and interpreted. Protein microarrays are broadly classified into

1. Forward Phase Arrays (FPA) that immobizes the bait and captures analyte from solution, allowing assay of multiple analytes from a single sample, and
2. Reverse Phase Arrays (RPA) where the test sample is immobilized and query molecule in applied in solution phase allowing for analysis of a single analyte across multiple samples.

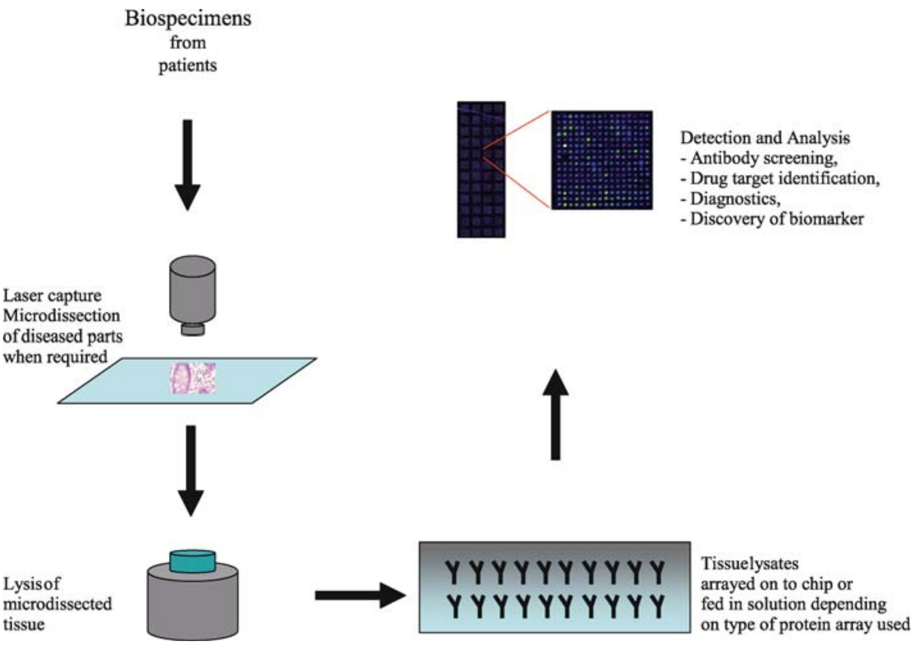
Shown in Fig. 5 is a general scheme for the use of protein microarray to analyze patient tissue for various applications.

Applications

Unlike LOC technologies associated with DNA and RNA, the protein analysis platforms for these technologies are not fully mature. Nevertheless, useful implementation of protein analysis technologies in LOC formats are beginning to be developed and field tested.

Some of the successful applications have been in Antibody screening, drug discovery, drug target identification, patch-clamp assay for cell membrane ion channels function and electric signals in neuron. Besides these basic applications many diagnostic tools have also been developed to detect pathogens and disease agents like HIV/AIDS, malaria, tuberculosis, pertussis, meningitis, lymphatic filariasis, gonorrhea, leishmaniasis, trypanosomiasis, liver cirrhosis, osteoarthritis, rheumatoid arthritis, to name a few [16].

LOC devices are being demonstrated to be superior than conventional methods in many applications. LOC



Lab-on-Chip Devices for Protein Analysis, Figure 5 Biomedical applications of Protein microarray. A general schema for analyzing disease tissue samples from patients using protein microarray technology

immunoassay to detect C-reactive protein in saliva using porous beads to capture probes on solid phase is 1000 fold more sensitive than traditional ELISA [17]. Use of micron scale paramagnetic beads and complimentary metal oxide conductor (CMOS) chip has been demonstrated to have application as an immunosensing devise [18]. A self-contained point-of-care device that can detect enterotoxin B in urine, milk etc. with considerable sensitivity has recently been developed [19].

Zyomyx (Hayward, CA) has developed the Zyomyx human cytokine Biochip that uses microfluidics to measure 30 different human cytokines simultaneously. Biosite (San Diego, CA) markets commercial microfluidics chip based immunoassay for clinical applications. Multiplexed assays using fluorescent microspheres/beads in Lab-on-Chip format manufactured by Becton-Dickinson (Franklin, NJ), Diasorin (Stillwater, MN) and Luminex Corp. (Austin, TX) are also available for use in clinics.

Protein arrays have been employed for studying biomolecular interactions including antibody specificity, mechanism of gene regulation and protein phosphorylation. Ciphergen Biosystems Inc. (Fremont, California) makes ProteinChip, the first commercial tool available for profiling serum biomarkers in disease – pancreatic cancer. For clinical diagnostics, Caliper Life Sciences (Hopkinton, MA) has developed LabChip – a capillary electrophoresis chip that can assay 500 different protein kinases and can analyze 12 different biomolecules per minute. Tecan Group Ltd. (Mannedorf, Switzerland) has developed LabCD, a CD format microfluidics and reaction chambers. These compact disc shaped microfluidic device can perform 48 drug screening assays simultaneously with centrifugation.

Future Directions for Research

The field of biology in general and biomedicine in particular is turning to a *systems approach* where all genes (DNA), translational products/messenger (RNA), and proteins and their relationship to each other in response to perturbations are studied in tandem. This current thrust will lead to more of a predictive science and as a result, to individualized preventative medicine. Advancement in technology that allows for sampling, manipulation and measurement of individual molecules with high spatial signal resolution has allowed the packaging of these technologies onto a Lab-on-Chip format with some success. DNA and RNA based technologies have made rapid strides in the last decade, while the protein technology has generally lagged behind. In the coming decades the field needs to bring to fruition the promises of LOC technologies in protein analysis to achieve success of the *systems approach*.

The general challenges of protein analysis (and thus applicable to LOC-based analysis) include those related to the composition of the proteome and the analytical meth-

ods. No ideal protocols exists, for example, to selectively, reproducibly and non-intrusively isolate the full complement of proteins from tissue samples. The vast diversity in protein expressions, charged states, molecular sizes and configurations etc. make sample preparation a challenging task. Also, extreme range of concentration of proteins in any given sample with a large number of proteins of interest for drug targets and biomarkers occurring in low abundances necessitates enrichment techniques which again have drawbacks [20]. These, in conjunction with lack of any amplification methods for proteins pose challenges for protein analysis. More specifically for microfluidic systems, the small analyte volumes put a high demand on the detection system. The requirement of high affinity antibodies/ligands and unique affinity constants for each antibody–ligand interactions etc. are some of the other challenges of microarray technology that needs to be addressed. Another challenge is to lower the manufacturing costs of the devices and increase their range of applications. The ultimate goal of the Lab-on-Chip technology would be the integration and automation of multiple diagnostic processes (and thus the total sequence of the laboratory processes) on the same miniaturized platform and research needs to focus in this direction.

The impact of rapid and reliable protein analysis technology using LOC devices will not be limited to the development of diagnostic tools like detection of pathogens, disease biomarkers or target identification. Rather, this technology in combination with other developing technologies will become essential tools in rational drug design and personalized medicine. Inexpensive LOC technology will also play a very critical part in global healthcare assessment and influence future healthcare policies.

Definition

Sample extraction involves purifying a single component from a complex mixture. It usually is based on exploiting a unique property of the component of interest such as solubility or charge which allows it to be separated from other components in solution. Sample extraction is often referred to in the context of nucleic acid purification from a complex biological mixture such as a cell lysate.

Overview

A major research thrust in microfluidic science and technology is the development of autonomous platforms for the extraction and purification of biological material from cells. Batch fabricated diagnostic and medical treatment units hold great potential to enable both research and healthcare advances. This article presents research focused on sample extraction and purification with an emphasis on steps taken towards miniaturizing one of the fundamental preparative techniques used in molecular biology: DNA extraction and purification from a complex biological sample. After the extraction procedure, the DNA can be processed downstream for Polymerase Chain Reaction (PCR) amplification, restriction enzyme digest and capillary electrophoresis. Two approaches to sample extraction techniques will be discussed: solid phase extraction and liquid phase extraction techniques. The fabrication methods for creating the extraction modules should also be compatible with downstream sample analysis technologies. These approaches form some of the basic requirements towards the development of highly integrated biological and genomic analysis systems by allowing efficient DNA purification.

Basic Methodology

Standard Macroscale Extraction Techniques

Genomic or plasmid DNA purification from a cell sample using extraction techniques is one of many standard techniques routinely performed in biology laboratories [1]. These extraction techniques can be classified as either liquid phase extraction or solid phase extraction techniques and involve extracting DNA or RNA from a biological sample while removing other biological molecules such as lipids and proteins. Historically, liquid phase extraction techniques were developed first. However, solid phase DNA extraction preparative kits have recently become more popular because of their ease of use and the avoidance of organic solvents used in liquid extraction techniques. Briefly, the liquid extraction procedure termed 'phenol extraction' consists of lysing cells in a basic lysis buffer (10 mM Tris pH 8.0, 0.1 M EDTA, 20 μg/ml Pancreatic RNAase, 0.5% Sodium dodecyl sulphate (SDS), and 100 μg/ml proteinase K) and adding an equal volume of phenol:chloroform:isoamyl alcohol (25 : 24 : 1 parts by volume) mixture to the aqueous solution. The organic (phenol) phase is immiscible with the aqueous phase and so the two phases separate by gravity or centrifugation. A vortexing step 'mixes' the two phases and allows the different cellular components to partition into either the aqueous or organic phases. With effective mixing, the cell components naturally distribute themselves into the two phases in order to minimize interaction energies of the biological components with the surrounding solvents. The membrane components and protein will partition to the organic–aqueous interface while the DNA remains in solution within the aqueous phase. Thus, effective mixing maximizes the surface area over which this partitioning occurs. Therefore, the smaller the discrete phase domains, the more effective the DNA extraction procedure is. After the mixing step, the two immiscible phases are allowed to separate by centrifugation at 10,000 RPM for 10 min. The lower density aqueous phase which contains the DNA separates above the phenol phase and is carefully pipetted into a new tube. The centrifugation can be repeated up to three times to completely separate the aqueous phase from the organic phase. The DNA is then concentrated by precipitation in ethanol and resuspended in an aqueous Tris-EDTA pH 8.0 (TE) buffer. Two to two and a half times the aqueous sample volume of ice cold 100% ethanol is added to the aqueous solution and gently mixed. The mixture is then spun for 20 min in a fixed-angle microcentrifuge to precipitate the DNA and 'pellet' it at the bottom of the sample tube. After centrifugation the supernatant is removed leaving only the DNA pellet at the bottom of the tube. A 1 ml 70% ethanol wash is added to the tube, gently mixed and

spun at 10,000 RPM for 1 min in the centrifuge. The supernatant is again removed and the DNA pellet is resuspended in 20 – 50 μL of TE buffer.

Recently, the use of DNA extraction centrifugation compatible columns such as those offered by Qiagen Corporation has become more commonplace. These extraction procedures are based on the alkaline lysis of cells followed by a chaotropic salt induced adsorption of DNA onto a silica surface within a silica gel matrix in a high ionic strength salt solution which shields the coulombic interactions between the DNA and silica surface. Cells are lysed in an alkaline solution, and the lysate is neutralized and adjusted to a high-salt concentration for optimal DNA binding. Following the alkaline lysis of the cells, the crude lysate is loaded directly onto a filter where the denatured and precipitated cellular components are removed by filtration through an integrated filter membrane. The dissolved components flow through the filter directly into the silica matrix where selective adsorption of the DNA in the high salt buffer occurs. The column is centrifuged at 10,000 RPM for 10 min. The buffers in these preparative kits are optimized for the cell lysis procedure and the silica gel binding to ensure that only DNA remains in the gel matrix, while RNA, cellular proteins, and metabolites are not retained in the matrix but are found in the flow-through. Free trace nucleases are removed by a short wash-centrifugation step. The DNA is then eluted from the column with 50 – 100 μl of a low ionic strength salt elution buffer followed by 1 min of centrifugation. During this step, the DNA and silica negative charges are no longer shielded so the DNA elutes from the silica surface.

After extraction by either procedure, the purified DNA concentration is usually about 1 mg/ml and can be quantified either by using a spectrophotometer monitoring the solution absorbance at 260 and 280 nm or by gel electrophoresis against known concentration standards. The purified DNA is free of other cellular components such as free nucleases which can interfere with other DNA processing techniques required in biological research such as restriction endonuclease cutting, PCR amplification, or gel electrophoresis.

The ability to miniaturize DNA extraction and analysis devices will benefit many research areas which require portable and rapid analysis of biological samples. Some of these areas are those where only a small DNA sample such as samples from only a few cells must be efficiently detected such as is commonly encountered in forensic analysis at crime scenes or is necessary for biological warfare monitoring. Miniaturized DNA analysis can also be adapted to replace conventional DNA extraction techniques. There is a huge reduction in the quantity of reagents which are used and the small size naturally lends itself to mass production and automation that will reduce the cost per device and analysis time. Approaches toward miniaturizing both solid phase and liquid phase extraction techniques are discussed in the next section.

Key Research Findings

Current Research on Solid Phase Extraction Techniques

The basic approach towards developing devices allowing solid phase DNA extraction has been to try to miniaturize the basic components of the solid phase DNA preparative kits. Most microdevices for solid phase DNA extraction still depend on selective DNA binding to a silica surface followed by a DNA elution step. One of the first reports of DNA purification in a solid phase extraction technique was by Cepheid Corporation [2]. In their research, the extraction of DNA was accomplished by creating high aspect ratio silicon pillar microstructures through Deep Reactive Ion Etching (DRIE) which have a high binding surface area to fluid volume ratio. The device is housed within a cartridge with reagent containment reservoirs, areas for solution mixing and the DNA extraction module. A raw cell sample containing the DNA of interest is lysed and introduced into the cartridge. The cartridge with the crude lysate is then inserted into an instrument that drives the sample through the DNA extraction module containing the silicon pillars (Fig. 1a). The DNA binds to the native silicon dioxide (silica) surface which forms on the surface of the silicon pillars. The device is designed to ensure that the silicon pillars have a sufficient binding capacity and adequate capture rate to allow quick flowthrough of the sample volume with enough time for DNA binding. A DNA washing step is then performed by flowing a buffer through the extraction module to remove any PCR inhibitors such as heavy metals (iron in hemoglobin), enzymes, proteins and nucleases. At this point the DNA is still bound to the silicon pillars. The bound DNA is then eluted using a low salt elution buffer. The eluted DNA is then amplified by an on chip rapid multichannel PCR thermal cycling module that has been integrated into the device (Fig. 1b). The PCR amplification unit has resistive heaters in the form of thick-films that perform rapid thermal cycling. When fluorescent molecules are incorporated into the DNA, the DNA fluorescence increases with each amplification cycle and is detected by an optical module. The reaction is stopped when a fluorescence threshold is reached. DNA extraction using this technology has been demonstrated using both high and low concentration DNA test samples.

Landers and colleagues have demonstrated [3, 4] a microchip-based DNA purification technique where DNA from biological samples such as blood has been isolated. The approach taken here was to maximize the surface area of

interaction for DNA adsorption to the silica. Hence, silica beads of $\sim 10\,\mu m$ diameter were packed into a microfabricated channel (Fig. 2) as a means to increase the silica-DNA interaction surface area. To pack the column, the silica beads are first introduced into the microfluidic channel and then the beads are immobilized within a sol–gel. In the silica particle/sol–gel hybrid approach employed here, the sol–gel acts as filler material as well as an interparticle glue which immobilizes the silica particles. It was found that by immobilizing the silica particles within the sol–gel there was a significant improvement in both DNA extraction reproducibility and the number of times the devices could be used over simply using a column packed with the silica beads. The improved recovery rate using the sol–gel/silica particle hybrid as compared to just using silica particles is attributed to the presence of the sol–gel preventing tight and dynamic packing of the silica particles during column pressurization. In order to extract the DNA, the devices were first conditioned with methanol (MeOH) for 30 min and washed with TE elution buffer for

30 min. The extraction procedure consisted of a sample loading, washing and elution step. In the load step 20 μl of load buffer (6 M guanidine hydrochloride, 1% Triton X-100 in TE buffer) containing the DNA is passed through the device. Trace proteins and other PCR inhibitors that may also be adsorbed onto the silica during this step are removed by flowing a wash buffer (2-propanol/water 80/20 (v/v)) through the device. The DNA is then eluted in a low ionic strength TE buffer. Ten DNA extractions per device have been demonstrated with a λ-phage DNA. An average recovery of 76% (10% Standard Deviation) with a chip to chip reproducibility average of 68% (6% Standard Deviation) has been demonstrated.

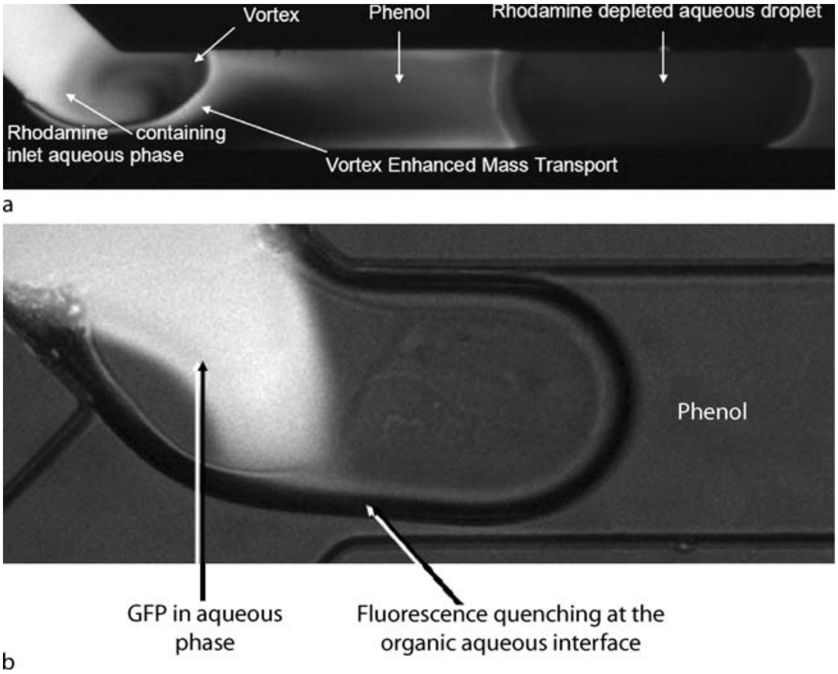
Finally, an integrated sample lysis and DNA extraction device has been demonstrated by Quake and colleagues [5]. The unique feature of this design is that all steps required for DNA extraction are carried out on the chip without any cell sample pretreatment. The device is fabricated using soft lithography techniques and consists of a series of chambers (Fig. 3) with integrated pumping and valving functions operated by external hydraulic activation (Fig. 3f). The integrated pumping and valving functions allows the sequential operation of the steps required for DNA isolation from a bacterial cell sample and the ability to pump the fluid through the different reaction chambers. Each reagent solution and silica

beads with DNA binding capacity are loaded into their appropriate chamber prior to device use. Each chamber allows the sequential introduction of the different reagents which are necessary for DNA extraction. The main chambers include the lysis buffer chamber, followed by a dilution buffer chamber and the cell chamber. These respective chambers are first filled with the lysis buffer, dilution buffer and bacterial cells. In device operation, the hydraulic valves that initially separated the chambers are opened (Fig. 3a) and the contents of the three chambers are pumped into a circular chamber (Fig. 3b). Here, the contents are mixed by pumping the solution around the circular chamber (Fig. 3c). During the mixing process, the cells are lysed by the lysis buffer in the solution. The mixture is then pumped further downstream into a chamber filled with the DNA adsorption beads (Fig. 3d). The DNA binds to the beads while the remaining solution flows through the chamber and is directed through a waste outlet. The DNA is then eluted off the beads through the introduction of a elution buffer (Fig. 3e) and collected at the device outlet. Extraction of DNA from single cells has been demonstrated using this device. The microfluidic structure has also been parallelized (Fig. 3f) to increase throughput and also to increase the level of automation in analyzing different cell populations simultaneously.

Current Research on Liquid Phase Extraction Techniques

Liquid phase extraction techniques, though less developed than solid phase extraction for biological sample preparation, have nonetheless seen an increase in interest in recent years. One of the reasons liquid phase extraction techniques have not developed as rapidly as solid phase techniques is due to the need for a fluid–fluid interface through which material may partition and therefore a need for a fuller understanding of multiphase microflows. Two-phase flow is the simultaneous flow of two immiscible fluid phases and is the simplest case of multiphase flow. Within the microfluidic device, the mass transfer rate is determined, to a large extent, by the fluid flow pattern. In previous studies, factors that affect the flow pattern of co-infused organic–aqueous flows were investigated. Two phase flow most often involves an interface between the two phases and this interface has various degrees of influence on the flow characteristics. The presence of the interfacial forces influences the microflow profiles which can be exploited to realize certain types of flows. The tendency of immiscible liquids to form dynamic droplet emulsion patterns as a function of capillary number and flow velocity ratios between a continuous and noncontinuous phase has been exploited from a T-section microfluidic channel [6] to obtain a tight control of the emulsion droplet size distribution. A number of techniques have been used to improve the interfacial stability or the overall stability of two phase flow in microfluidic systems. Some of the techniques include patterning the base of the micro-channel with ridges that guide the flow [7], and the incorporation of surfactant [8, 9]. Stable and unstable stratified flow profiles have been studied using immiscible organic/aqueous solvent mixtures [8, 9]. Kitomori and colleagues have demonstrated stable two phase systems for continuous liquid extraction techniques of molecules from one phase into another [7]. Here, a methyl red dye was extracted across a stratified three layer multiphase system where the dye was extracted from an aqueous donor phase across an organic cyclohexane membrane and finally into a acceptor aqueous phase. In this case, all of the dye transport is due to diffusion from the donor phase to the acceptor phase as the fluid moves through the microchannels.

Zahn and colleagues has begun to explore approaches towards developing a miniaturized phenol extraction module using a two or three inlet converging microchannel geometry. Here, two phases are coinfused through a microfluidic network where one of the components is Phenol : Chloroform : Isoamyl alcohol (25 : 24 : 1) and the other is a 0.5% SDS aqueous solution. Here, biological interactions at the organic aqueous interface were studied. A fluorescent rhodamine dye labeled Bovine Serum Albumin (BSA) protein was added to the aqueous phase containing surfactant and coinfused with the phenol phase through a microchannel in a stable stratified flow. As the protein solution flowed through the device, the BSA was seen precipitating at the organic–aqueous interface to create a line of protein precipitate which appeared bright under epifluorescent microscopy demonstrating the ability to remove protein from an aqueous solution at the organic–aqueous interface. Complete removal was not possible due to the limited surface area of the interface and because the protein transport to the interface was diffusion limited. More recently, an electrohydrodynamic approach for destabilizing the stratified phenol-aqueous flow to increase the interfacial area between the two phases to improve extraction efficiency has been investigated [10]. Additionally, it has been recognized that a droplet flow profile between the phenol and water phases improves extraction efficiency because of a convective enhancement to the mass transport due to internal fluid circulation within a droplet as it moves through the microchannel [11]. To demonstrate this effect, a sulphorhodamine dye is added to the aqueous phase. The rhodamine dye was observed to naturally partition from the aqueous phase into the organic phase so it was utilized as a fluorescent marker to visualize the component extraction from the aqueous phase into the organic phase. A large increase in dye extraction efficiency



Lab-on-a-Chip Devices for Sample Extractions, Figure 4 (**a**) Experiment results of two phase extraction using rhodamine dye. Internal circulation of the fluorescent dye helps the mass transfer from the aqueous to the phenol phase. At the same time, the fluorescent dye in the previous aqueous droplet moving through the channel has almost been depleted. (**b**) Image of a cell lysate droplet containing Green Fluorescent Protein (GFP) near the inlet intersection. The GFP is quenched at the two phase interface due to protein denaturation at the organic-aqueous interface. (Reprinted with permission from [11])

has been shown when droplet flow is used as opposed to a stable stratified flow due to this convective enhancement. Figure 4a shows a fluorescent microscopy image of an aqueous droplet forming within the microchannel. By initially labeling the aqueous phase with rhodamine, the fluid–fluid interface as well as the extraction between two phases can be tracked. It is clearly shown that the circulating flow pattern is developing within the forming droplet. A significant amount of fluorescent dye has been transferred into the organic phase even before the droplet formation process is complete. The ‘flare’ of the fluorescent trace extending from the interface toward the organic phase indicates that the fluorescent dye is quickly being transported across the organic/aqueous interface. Downstream of the forming droplet, the previous droplet which has broken off has been almost completely depleted of fluorescent dye. In order to demonstrate the feasibility of using a droplet flow pattern to remove protein from a DNA containing biological sample, an aqueous cell lysate solution containing a green fluorescent protein (GFP), DNA, and other cell components was tested. The sample was co-infused into the channel with phenol and an epifluorescence image was obtained as shown in Fig. 4b. The image shows the lysate solution droplet is being generated near the inlet intersection. The GFP within the droplet emits fluorescence while it still maintains its folded 3 dimensional structure and biological function. However, when the GFP is transported to the organic/aqueous interface the fluorescence of GFP was rapidly quenched, due to protein denaturization at the organic aqueous interface. When the protein denatures, the GFP fluorochrome unfolds resulting in a loss of fluorescence. This result implies that the protein is rapidly transported to the organic aqueous interface and removed from the aqueous phase. This is similar to results seen in [9] where the rhodamine labeled BSA was visualized denaturing and precipitating along the organic aqueous interface in a stratified flow.

Future Directions for Research

The development of Lab-on-a-Chip devices for sample extraction is important to allow further advances in genomics, proteomics and bioinformatics. The further development and commercialization of both solid phase extraction and liquid phase extraction technologies will be fundamental to providing the next generation of integrated microfluidic systems for high throughput genomic analysis. In addition, the next generation devices should also be developed to allow protein extraction and purification for proteomic analysis.

Lab on chip; Lab-on-a-chip; Lab on a chip; Micro total analysis system (μTAS)

Definition

Lab-on-Chip devices refer to devices that integrate one or several biochemical analysis functions on a chip of small size using semiconductor manufacturing processes, and are capable of handling extremely small volume of fluid. They usually have the size of only square millimeters to a few square centimeters and are able to handle fluid volumes down to picoliter levels.

Lab-on-Chip devices for separation-based detection refer to Lab-on-Chip devices that are capable of performing detection based on the result of separation. Both separation and detection functionalities should be integrated in a single chip.

Overview

The history of Lab-on-Chip devices can be dated back to 1975, when the first Lab-on-Chip device, a gas chromatograph used to separate a mixture of various gases, was invented [1]. However, the real boost and serious growth in Lab-on-Chip devices were not seen until 1990 when the term "μ-TAS" was first proposed by Manz et al. [2] who demonstrated a microchip incorporating sample separation and detection. For the past few years, research activities and investment have been growing continuously in this rapidly emerging field. Microfabrication technology has allowed the realization of Lab-on-Chip devices. Miniaturizing a conventional biochemistry laboratory down to the size of a silicon microchip is the driving concept behind Lab-on-Chip technology. Ideally, each Lab-on-Chip device may have one or more sample injection reservoirs, sample mixing chambers, sample separation channels, chemical reaction chambers and a monitor and measuring system. Lab-on-Chip devices offer many benefits. Due to their small sizes, they consume very tiny amounts of biochemical reagents. This is very desirable since many reagents are very expensive. Moreover, using small amounts of chemicals will result in a reduction of analysis time and a faster response as chemicals can mix and react more quickly. Furthermore, since some reagents and reaction products can be very harmful to humans, Lab-on-Chip devices minimize human interaction with chemicals and reaction products by consuming and producing small amount of chemicals. High-throughput analysis is enabled by massive parallelization due to compactness of the system. Small size also enables portability of Lab-on-Chip devices. Because fabrication of Lab-on-Chip devices

is based on highly developed semiconductor processing techniques, it is fairly easy to manufacture Lab-on-Chip devices in large quantities, and thereby reducing cost per chip.

Detection in biochemical experiments refers to the extraction of information, such as concentration of ions in a solution, from a signal such as induced electric current. It plays an essential role in Lab-on-Chip devices. No biological experiments or chemical analysis is considered complete until the signals collected during the process have been detected. Separation is another routine task in biochemical experiments. It refers to the process of separating a type of substance from other types or separating different types of biochemical reagents from each other. Separation-based detection combines the two tasks. A very common example is the blood test performed in hospital. The process separates different cells from the blood plasma followed by a series of other steps including detection and characterization. Compared to conventional separation-based detection analysis, which requires long analysis time, expensive cumbersome equipments and provides limited throughput, Lab-on-Chip devices for separation-based detection offer shorter analysis time, low reagent consumption, low fabrication costs, small size and better fluidic control.

Basic Methodology

The working principle for separation-based detection can be divided into two parts: separation and detection. In this section, a variety of mainstream separation and detection techniques suitable for Lab-on-Chip devices including electrophoresis separation, dielectrophoresis separation, ultraviolet (UV)-visible absorbance detection, fluorescence detection and electrochemical detection will be discussed in detail.

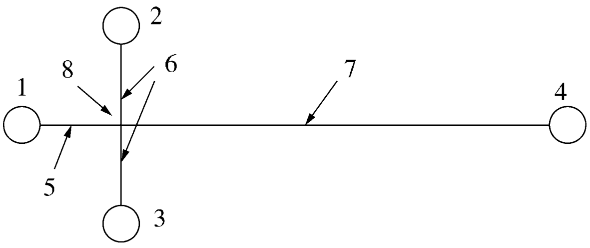
Separation Techniques

Electrophoresis (EP)

Electrophoresis (EP) is the movement of an electrically charged particle within a solution medium under the influence of an applied electric field. The movement is due to the EP force acting on the particle. The EP force is a type of Coulomb force in its origin and is simply given by

$$F = qE \tag{1}$$

where q is the number of net charges on the particle and E is the applied electric field intensity. In fact, the viscous or frictional force experienced by the particle within the solution medium tends to balance the EP force such that the particle velocity of migration is constant in a constant and homogeneous electric field. The electrophoretic mobility



Lab-on-Chip Devices for Separation-Based Detection, Figure 1 A typical microcapillary electrophoresis system with straight capillary separation channel: (1) buffer reservoir, (2) sample reservoir, (3) sample waste reservoir, (4) end waste reservoir, (5) buffer injection channel, (6) sample injection channel, (7) capillary separation channel, (8) injection cross point

μ is a parameter used to describe the velocity of a particle or a group of particles under an applied electric field, and is defined as

$$\mu = \frac{v}{E} = \frac{\varepsilon_m \zeta}{\eta} \tag{2}$$

where v is the velocity of the particle, ε_m is the absolute permittivity of the solution medium, ζ is the zeta potential of the particle and η is the liquid viscosity. The ultimate goal of separation is to generate a position gradient for each type of paricles, in other words to move different types of particles to different locations. In Eq. (2), the only parameter that characterizes different types of particles is the zeta potential, since ε_m and η are constant once a solution medium is chosen. Therefore, separation based on EP force is dependent on different particles having different zeta potential. As a result, separation along the moving direction of the particles can be achieved.

Capillary electrophoresis (CE) is a widely used separation technique based on EP. Due to its ease of miniaturization and operation, CE is commonly used in Lab-on-Chip devices to perform separation tasks. Figure 1 shows a typical CE configuration in Lab-on-Chip devices. It consists of: (1) a buffer reservoir used to hold buffer solution; (2) a sample reservoir used to hold sample solution; (3) a sample waste reservoir used to collect unnecessary sample solution; (4) an end waste reservoir used to collect solution flowing through the separation capillary channel; (5) a buffer injection channel used to direct the buffer solution to the injection cross point; (6) a sample injection channel used to direct sample solution to the injection cross point; (7) a thin and relatively long separation capillary channel used to direct solution for separation; and (8) an injection cross point for mixing the sample solution and the buffer solution. The inner diameter of the capillary channel in Lab-on-Chip devices usually ranges from 25 μm to 100 μm while the length ranges from

L

10 mm to 100 mm depending on the applications. Buffer and sample injection can be achieved by several methods. One method is to apply a high voltage between the buffer reservoir (1) and the end waste reservoir (4) for buffer injection, and between the sample reservoir (2) and the sample waste reservoir (3) for sample injection, to generate an electroosmotic flow (EOF) that causes the bulk flow motion of the liquid solution to the injection cross point (8). Another method is to create a pressure gradient either between the buffer reservoir (1) and the end waste reservoir (4) for buffer injection, or between the sample reservoir (2) and the sample waste reservoir (3) for sample injection, to direct the solution to the injection cross point (8). After buffer and sample injection is completed, a high voltage is then applied between the buffer reservoir (1) and the end waste reservoir (4) for CE separation. The effective separation length is from the injection cross point (8) to the end waste reservoir (4). The migration speed of particles in CE is determined by their sizes and charges. Generally speaking, small, highly charged particles will migrate more quickly than large, less highly charged particles.

Dielectrophoresis (DEP)

Dielectrophoresis (DEP) is a phenomenon different from electrophoresis (EP). In fact, any non-polar material experiences a certain degree of polarization when exposed to an electric field. Depending on the material properties of the particle, electric dipoles are generated on opposing ends of the particle. The DEP force is due to the interaction between the dipole induced by an applied electric field and the spatial gradient of that electric field. The general expression of the DEP force exerted on a particle in an electric field is

$$\boldsymbol{F}_{\text{dep}} = \boldsymbol{p} \cdot \nabla \boldsymbol{E} \tag{3}$$

where $\boldsymbol{p}$ is the dipole moment of the particle and $\boldsymbol{E}$ is the electric field intensity. It has to be noted that in order for the DEP force to be nonzero, the gradient of the electric field ($\nabla \boldsymbol{E}$) has to be nonzero, which explains why the DEP force can be seen only when particles are in non-uniform electric fields. For a uniform sphere placed into an electric field, the induced dipole moment is given by

$$\begin{aligned} \boldsymbol{p} &= 4\pi \varepsilon_{\text{m}} R^3 \left(\frac{\varepsilon_{\text{p}}^* - \varepsilon_{\text{m}}^*}{\varepsilon_{\text{p}}^* + 2\varepsilon_{\text{m}}^*} \right) \cdot \boldsymbol{E} \\ &= 4\pi \varepsilon_{\text{m}} R^3 \cdot f_{\text{CM}}(\omega) \cdot \boldsymbol{E} \end{aligned} \tag{4}$$

where R is the radius of the particle and ε_{p} and ε_{m} denote the permittivities of the particle and the medium, respectively. The asterisk denotes the complex conjugate of the dielectric constant which is expressed by $\varepsilon^* = \varepsilon - \mathrm{i}\,(\sigma/\omega)$, where ε is the permittivity, σ is the electric conductivity, i is the imaginary number and ω is the angular frequency of the applied electric field. $f_{\text{CM}}(\omega)$ is known as the Clausius–Mossotti (CM) factor which describes frequency dependent characteristics of the particle relative to the medium. In a linearly polarized sinusoidal field, the time-average DEP force is usually used and is given by [3]

$$\langle \boldsymbol{F}_{\text{dep}} \rangle = \pi \varepsilon_{\text{m}} R^3 \,\text{Re}\left[f_{\text{CM}}(\omega) \right] \cdot \nabla \left| \boldsymbol{E} \right|^2 \tag{5}$$

where $\langle \ \rangle$ denotes the time average. Due to the spatial non-uniformity of the electric field, the particle experiences a force with orientation determined by the relative polarization of the particle with respect to the medium. If the polarization of the particle is greater than that of the suspending medium, $\text{Re}\left[f_{\text{CM}}(\omega)\right]$ will be positive and the dipole will align with the field and the particle will be drawn to the region of stronger electric field. This is known as positive DEP, or pDEP. However, if the polarization of the suspending medium is greater than that of the particle, $\text{Re}\left[f_{\text{CM}}(\omega)\right]$ will be negative and the dipole of the particle will align against the field and the particle will be attracted to the region of lower electric field strength, known as negative DEP, or nDEP. A translational force on particles can be generated in a field with spatially varying phase by assigning voltages with the same frequency but different phases to multi electrodes. The resulting DEP force is termed traveling-wave DEP (TWD) and is given by [3]

$$\langle \boldsymbol{F}_{\text{tw dep}} \rangle = 2\pi \varepsilon_{\text{m}} R^3 \,\text{Im}\left[f_{\text{CM}}(\omega) \right] \cdot \nabla \times \left(\text{Im}\left[\boldsymbol{E}\right] \times \text{Re}\left[\boldsymbol{E}\right] \right) \tag{6}$$

DEP-based separation can be achieved by the sign of $\text{Re}\left[f_{\text{CM}}(\omega)\right]$. For particles with different electrical properties, a frequency and solution conductivity can be chosen such that $\text{Re}\left[f_{\text{CM}}(\omega)\right]$ is negative for one group of particles (nDEP) and $\text{Re}\left[f_{\text{CM}}(\omega)\right]$ is positive for another group (pDEP). Therefore, the group subject to the pDEP force will be attracted to the electrodes and the one subject to the nDEP force will be repelled from the electrodes, resulting in separation. One can also make use of the magnitude of $\text{Re}\left[f_{\text{CM}}(\omega)\right]$ and $\text{Im}\left[f_{\text{CM}}(\omega)\right]$ to achieve DEP-based separation for particles with subtle difference. Subject to the nDEP force, particles with different electrical properties will be lifted up to specific corresponding heights. The height is determined by the nDEP force and the gravity of the particle. Thus, different types of particles will appear in different heights. TWD is also useful and can be used as a separation scheme. Particles subject to TWD force

tend to move in one direction continuously. The velocity of the particles is a balance of the TWD force and the fluid frictional force. Since different particles experience different frictional forces, separation along the moving direction can be achieved.

Detection Techniques

Ultraviolet (UV)-Visible Absorbance Detection

Most organic molecules and biological cells are partially or completely opaque under ultraviolet (UV) or visible light. UV-visible absorbance detectors make use of this by responding to substances that absorb light with wavelengths in the range of 200 to 400 nm for UV light absorbance and 400 to 800 nm for visible light absorbance. UV-visible light is directed to pass through the sample and fall on a photo-electric array. The output from the photo-electric array then enters an amplifier and finally translates to a recorder or an image acquisition system. The relationship between the intensity of the UV-visible light after interacting with a sample, P_t, and the analyte concentration, c, is given by Beer's law, which states that

$$P_t = P_0 \mathrm{e}^{-klc} \quad \text{or} \quad A = \ln(P_0/P_t) = klc \tag{7}$$

where P_0 is the intensity of the UV-visible light before entering the sample, k is the molar extinction coefficient of the analyte for the specific wavelength of the UV-visible light, l is the optical path length of the sample and A is absorbance. From Eq. (7) it is easy to see that the absorbance is linearly dependent on the concentration of the sample. This is quite convenient in terms of analyzing extracted data from measurements.

There are two possible modes for UV-visible absorbance detection. One is to detect a single type of substance at a specific UV-visible wavelength if all the other substances do not absorb the light at all. The other mode is to detect several substances at one time by measuring the spectrum over a wide range of UV-visible wavelengths. A UV-visible absorbance detection system usually contains a light source with high output power, a set of lenses that are properly aligned to focus light onto a small area with a high power density, several pieces of fibers used for concentration and transmission of light, a band-pass filter that can select an appropriate wavelength to detect a single type of substance or a monochromator that can sequentially detect several wavelengths within a wide range, and a light-sensitive detection device such as a charge-coupled device (CCD) camera that can receive and amplify the signal to achieve detection with high accuracy.

Fluorescence Detection

Fluorescence detection is quite useful in detecting particular components of complex biological samples such as living cells. Very precise and selective detection can be achieved by measuring the visible or nonvisible light emitted from fluorescent dyes or fluorophores attached to the specific target cells or molecules of interest. The first step in fluorescence detection is to attach fluorescent dyes or fluorophores to specific target cells or molecules of interest if necessary since most particles do not have fluorescent properties. Typical examples of fluorophores include ethidium bromide, Fluorescein-isothiocyanate (FITC) and Texas Red. The second step is to use a high-energy light source with an excitation wavelength of λ_1 to illuminate the sample. Both laser and light emitting diode (LED) can be used as the excitation light source. Upon absorbing light energy, a fluorophore can reach an excited energy state S_e of higher energy than the ground energy state S_0. The excited energy state exists only for a finite period of time called the excited-state lifetime, typically $1-10$ ns. During this time, the fluorophore is unstable and undergoes conformational changes. It dissipates a part of the energy and returns from a relaxed energy state S_r to the ground energy state S_0. During this process, visible or nonvisible light is emitted with a wavelength of λ_2. Due to energy dissipation during the excited-state lifetime, the energy of the emission light is lower than that of the excitation light, and therefore of longer emission wavelength than the excitation light. Typical values of the excitation and emission wavelengths of fluorophores are 545 and 605 nm for ethidium bromide, 490 and 520 nm for FITC, and 596 and 620 nm for Texas Red.

A fluorescence detection system is quite similar to a UV-visible absorbance detection system, except that a laser light source or a LED with high output power is used, a set of band-pass filters must be present to select appropriate wavelengths for the excitation and emission light to achieve precise measurements, and fluorescent tags must be attached to the target particles if necessary.

Electrochemical (EC) Detection

In fact, most compounds are not naturally fluorescent and must be pre-bound with a fluorophore before being detected through fluorescence. Electrochemical (EC) detection is a universal label-free technique that is cost-effective and easy for integration with other functionalities in Lab-on-Chip devices. EC detection can be further divided into three categories:

- conductimetry (conductivity detection);
- amperometry (amperometric detection); and
- potentiometry (potentiometric detection).
